Mindfulness meditation aids in lowering blood pressure, improves immune system and brain function, and minimizes pain sensitivity [186]. It can improve mood and reduce distress and distractive thoughts and behaviors [187].

26.11.3 Movement and Exercise

The human body was created to be in motion. In ancient times, movement was essential for survival, but the conveniences of modern life have drastically reduced that dependence. Our lymph system, which is essentially our immune system, is dependent on our physical movement to stimulate flow. The value of motion is important to our very well-being. The joy of moving our body, from a simple stretch or deep breath to a trail race, should be something that you enjoy as opposed to a dreaded task.

This becomes more complicated when experiencing treatment-induced fatigue or related to the cancer itself. At that point, the goal is to incorporate even the simplest movements. The benefits of physical activity have been connected to every aspect of our health, from our brain to our bone density. Exercise has been shown to reduce stress, improve sleep, prevent cognitive decline, alleviate anxiety, boost memory and ability to learn new things, enable neurogenesis (the creation of new brain cells), improve productivity and creativity, increase strength and flexibility, increase bone density, reduce the risk of cardiovascular disease, metabolic syndrome, and type 2 diabetes, reduce the risk of cancer, and increase longevity [188].

During treatment, proceed with care. The NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines®) for Cancer-Related Fatigue advise starting slowly and progressing incrementally [189]. Depending on fitness and comfort level, some people may want to start with a 10-minute walk around the block; others may find they can exercise for 20 minutes (or longer) initially, but the goal should be at least 30 minutes of aerobic exercise 5 days a week or more if tolerated. Caution is advised to find the level that fits with the circumstances.

The guidelines give practical suggestions for planning exercise such as if the patient doesn't have the energy to exercise a full half hour, break it up; try three 10-minute walks during the day; make exercise enjoyable; recruit a walking partner or listen to music with headphones while on a recumbent bike or treadmill; dress comfortably and drink plenty of water; consider yoga and tai chi which, while not aerobic, integrate movement and meditation and enhance wellness; and look for programs designed for cancer patients. Some health clubs and hospitals offer exercise classes that address the challenges and needs of people with cancer; avoid swimming pools as they can expose the patient to bacteria that may cause infections and the chlorine may irritate skin; and don't encourage exercise if the patient is not feeling well or running a fever [189].

26.11.4 Massage or Touch Therapy

Touch therapy is one of the oldest therapies known to man. From the lightest touch to deep tissue massage, the benefits range from relief of muscular pain to the opening of the energy meridians of the body to facilitate healing. Back massage given during chemotherapy significantly reduces anxiety and acute fatigue [190]. Massage therapy can be supportive in relieving lymphedema due to surgery or treatment. Gentle massage is used to help move lymph out of the swollen area and into areas with working lymph vessels [191].

Postsurgical scar formation can benefit from massage therapy in several ways. A valuable resource can be found to describe forms of massage therapy [192].

- Manual lymph drainage optimizes lymphatic circulation and drainage around the injured area.
- Myofascial release helps ease constriction of the affected tissue.
- Deep transverse friction can prevent adhesion formation and rupture unwanted adhesions.
- Lubrication of the scar helps soften and increase its pliability.
- Stretching aids in increasing range of motion.
- Heat application helps the pliability and flexibility of the scar.

26.11.5 Posttreatment: Creating an Empowerment Plan

Cancer treatment is a tug of war between fear and empowerment. Much of our power is handed over to physicians and the system during the duration of therapy, and when that time comes to a close, there is a big void in a patient's life. Oftentimes, fear and uncertainty fill this void, and several outcomes are a result of this phase. Some patients will return to their old ways with a misguided sense of the threat being over, some will remain stagnant in survivor groups reliving the trauma in a sense, some will throw caution to the wind and adopt habits that make them potentially more at risk for recurrence, and some will want to know how to lock the door in all ways possible to their cancer returning. This is a tremendous opportunity to positively impact and empower each and every one of these people and to arm them with holistic strategies to optimize their future. Giving patients strategies to keep themselves healthy, to rebuild their bodies, and to nourish and detoxify themselves can powerfully shift both their physical and mental well-being. Creating a plan for living should be the last step before releasing patients from treatment. Here are some ideas that the author incorporates as a foundation for an empowerment plan and can be modified depending on the particular patient and their mind-set and prognosis: Achieve and maintain optimal weight and body mass, detoxify, restore and optimize micronutrient levels in the body through food and supplements, and employ mental well-being strategies to manage fear, stress, worry, and body image and function.

Nutrition ultimately is about nourishing the body and the soul, and cancer treatment and posttreatment periods are incredibly powerful times to positively impact a patient's life. Take full advantage of that potential on every level to affect

Box 26.5 Sample IFMNT Nutrition Care Process

- *Stage 4 adenocarcinoma of the lung – non-smoker*
  - *Assessment Data:* 63 yo female, BMI 23.5, osteoporosis, mild central adiposity, hx constipation, cough, mast cell allergy, with high-stress lifestyle for many years. Abnormal immunological findings in serum/+viral load/nutritional insufficiencies: vitamin A, zinc, vitamin D with genomic homozygous VDR, high Cu:Zn Ratio 2.1 (goal 0.9–1.0), anemia, macrocytic RBC, low IgA, low NK cell count and activity. Presented to ER with shortness of breath and X-ray revealed large masses in lung and liver, 4 liters fluid removed from pleural cavity. Diagnosis: Stage 4 adenocarcinoma of the lung cancer. Further testing ROS1+ (rare genetic mutation statistically does not respond to immunotherapy).
  - *Nutrition Diagnosis:* Multiple nutritional insufficiencies/deficiencies with compromised immune system secondary to poor diet history and confirmed through laboratory testing.
  - *Interventions:* Refer to integrative doctor for assessment. IV Rx: Antiviral plan with oral artemisinin, Lauricidin, Vit D3, zinc, copper−/iron-free multivitamin/mineral with bioactive forms of B vitamins, vitamin C, quercetin, and sulforaphane (broccoli sprout) with ketogenic diet. Educated in application of ketogenic diet with monitoring and logging to maintain nutritional ketosis with intermittent fasting and use of exogenous ketones. Follow up regarding nutrition plan and ketogenic diet weekly × 4 weeks and then monthly.
  - *Monitoring and Evaluation:* Weekly monitoring of diet history, lab findings, and urine ketone log. Goal to maintain average of 1.5–3.0 ketones, healthy body mass, and no muscle cramps. IVs: Weekly high-dose vitamin C, artesunate, and immune support nutrients.
  - Follow-Up 1 Year: "I feel amazing, better than I have in a long time." Cancer markers normal, CT/PET no evidence of disease.

the shift that is so desperately needed in this realm. Push the currently established boundaries until integrative care is the norm. The science is there; it needs only an army to carry out the mission. Be part of that army! (▶ Box 26.5)

26.12 Conclusion

This summary shares a case study that illustrates the potential of functional integrative care:

A patient called to ask how to submit imaging results of her cancer prior to an appointment. All of her focus was on her tumor, its size, and location. We explained to the patient that the primary driver of our course of action together would be the *whole* person and not specifically the imaging results. Integrated functional nutrition therapy will take into account the location of the cancer as it relates to the history of the patient and its possible emotional aspect but most importantly will create a set of tools that will support the metabolism, immune system, and mindfulness of the patient.

This illustration best summarizes the idea that we must focus on the terrain before the germ, the person before the cancer. It also brings to light the fear and disempowerment experienced by patients and the potential to radically improve the level of their care through education and the implementation of an integrative plan.

The majority of cancers arise from lifestyle issues and environment, which impact immune function, create inflammation, and/or initiate epigenetic triggers that allow cancer to develop. It is critical to explore every avenue available that can best optimize the response of the patient throughout treatment by bolstering their whole person and creating evidence-based synergies where available with conventional therapies.

Each person will present with a unique history, experience, mind-set, and disease progression that will help to define which options may support their best outcome. Each supportive strategy will provide results, but each patient may respond better to a stronger focus on different options.

Strategies discussed above should be employed in such a manner that they will optimize and complement any conventional treatment the patient is undergoing. Tremendous clinical data supporting the effectiveness of each of the abovementioned therapies has been presented, dictating their value in both stand-alone and integrative applications. The creation of a patient-centered team empowered with holistic, restorative, functional integrated modalities will define the future of cancer treatment.

27.1 Introduction

The term microenvironment related to disease states has many possible meanings. Typically, conventional designations about biological microenvironments distinguish a smaller part of the larger organism that is related to, yet distinct from, the larger macro environment. In this context, we will be referring to the milieu involving a neoplastic site, an inflammatory site such as a joint or organ system, or even the blood. In the diseased state, various pathologies can alter localized physiological processes, creating unique encapsulated microenvironments. These microenvironments nurture disease progression locally and have the potential to affect other organ systems in the larger context of the organism. This chapter will introduce several disease state microenvironments and the factors leading to the formation of these environments. Nutritional considerations will be addressed that may lead to the initiation or progression of these disease states, as well as the nutritional interventions that may be appropriate for their reversal. The microenvironments of tumors, autoimmune-affected organ systems, and arthritic conditions will be discussed. This chapter will also include a discussion of the blood as a physiological microenvironment that can be reflective of pathological changes elsewhere in the body through the examination of live red and white blood cell morphology and pathology.

27.2 The Microenvironment in Malignancies

Microenvironment alteration is an area of great interest in cancer disease progression. Microenvironmental changes occur in a variety of malignancies and in specific stages of disease progression [1]. Malignancies insidiously alter their own environments through a variety of processes to increase the potential for proliferation and metastasis [2, 3]. In doing so, malignancies contribute to relentless progression and cause secondary pathologies in local environments [4]. The alteration of malignant microenvironments relates not only to aberrantly mutated cells but also to other cellular tissues in the vicinity that have been negatively affected by the inflammatory changes. There is collateral damage to the normal cells in the local microenvironment. These include blood vessels and vascular cell precursors, stromal cells, and cellular components of the immune system, which form a heterogeneous matrix [5]. The tumor manipulates this matrix to avoid rejection by the immune system and increase its metastatic potential [6]. In addition, the largely anaerobic microenvironment of tumors increases the potential for localized infection [7]. Research has revealed a variety of pathways related to the interactions between tumor cells and their localized environment, creating these pathological and physiological changes, and has identified ways in which diet can affect this progression [8]. In addition, specific nutritional compounds, including phytochemicals and their derivatives, can alter the various aspects of the tumor microenvironment, including angiogenesis, metastatic potential, and the tumor load [9].

27.3 Components of Tumor Microenvironments

The tumor microenvironment (TME) in cancer is defined as the various places a tumor can exist, including blood vessels, lymphocytes, immune cells, fibroblasts and signaling molecules, and the extracellular matrix [10, 11]. Tumors develop a milieu in which they can modulate pathological processes contributing to their progression and metastasis, as well as the induction of peripheral immune intolerance [12]. This is done largely through the process of cell signaling and gives cancer cells the ability to express different morphology, metabolic features, motility, gene expression, proliferation, metastatic and angiogenic potential, and immune adaptivity. These processes stem from the phenomenon of tumor heterogeneity [13, 14].

Although cancer cell antigens initially trigger a CD8+ T-cell response, there is good evidence that possible immunoediting and TME immune suppression can lead to a failure of a systemic immune response aimed at controlling the prevalence and growth of a tumor [15].

27.4 Cellular Components

The tumor connective tissue or stroma in carcinomas typically sits beneath the epithelial cells that it is derived from and contains the extracellular matrix, including fibroblasts and various immune cells. The cancer stroma is prone to inflammatory response when challenged by intrusion of other normal immune components, such as tumor-infiltrating lymphocytes. This inflammation can encourage angiogenesis, increase cell cycling, and discourage apoptosis and taken together may enhance tumor growth [16].

Normal cellular fibroblasts typically produce collagen and other fibrotic components of connective tissue. However, in malignancies, cancer cells can pirate the function of normal fibroblasts, directing their function toward carcinogenesis [17]. These carcinogenesis-associated fibroblasts (CAFs) perform a variety of different cancer-inducing functions, including the secretion of such proangiogenic factors as platelet-derived growth factor (PDGF), basic fibroblast growth factors (bFGFs), and vascular endothelial growth factor (VEGF). CAFs can also shuttle lactate to cancer cells as they are capable of aerobic glycolysis [18]. CAFs are also associated with extracellular matrix (ECM) remodeling, a process by which collagen fibers in the matrix are malformed and release matrix metalloproteinases, enzymes involved in the degradation of the extracellular matrix [19]. This ECM remodeling allows for cancer cells to escape the local environment by destabilizing the proteins in the TME. CAFs inhibit T-cell penetration into the tumor microenvironment by increasing the density of the stromal matrix in the microenvironment.

Chemokine (C-X-C motif) ligand 2 (CXCL2) is a small cytokine belonging to the CXC chemokine family that is also called macrophage inflammatory protein 2-alpha (MIP2-alpha), growth-regulated protein beta (Gro-beta), and Gro oncogene-2 [12]. Biosynthesis of CXC motif cytokines (CXCL12) targets the most promising actionable treatments for anticancer therapy [20]. CAFs such as pericytes also increase the potential for metastasis through angiogenesis promotion and in shielding tumors from anti-VEGF therapies [21].

In the TME, other cellular components responsible for inflammatory immune response are upregulated. One group of cells that has a very strong correlation between the inflammatory response and cancer are tumor-associated macrophages (TAMs). TAMs are one of the myeloid-derived suppressor (MDSC) cells, a variety of tumor-infiltrating immune cells, all of which have well-established roles in the progression of cancer. These cells have various attributes. They can repress T-cell response in general, and they tend to gravitate toward the necrotic areas of a tumor where they mask it from the immune system through the secretion of interleukin 10 [3]. Activated TAMs can support tumor growth by secreting various factors such as epidural growth factor (EGF) [22]. TAMs also secrete a variety of angiogenesis-promoting factors such as VEGF [23], PDGF, and transforming growth factor beta (TGFβ) [24]. TAMs also slowly upregulate nuclear factor kappa beta (NFκβ) expression, which leads to enduring inflammation [25]. Overall, many studies show that infiltrating TAMs are indicative of a poor prognosis in malignancies, especially breast cancer and certain lymphomas [26, 27].

27.5 Molecular Components

Dysregulation of molecular pathways is characteristic of cancer in general, but it is also increased in the established cancer microenvironment due to chemical imbalances occurring secondary to overstimulation of cells by inflammatory chemokines, cytokines, and other substances [28]. Several pathways that respond to nutritional interventions are involved in this disrupted and divergent cell-signaling process. One such substance is the tumor protein p53, which is a crucial component of tumor suppression in multicellular organisms. p53 has various cellular functions, such as activation of DNA repair, restriction of cell cycling in cases where DNA is damaged, and initiation of apoptosis if DNA damage is irreparable [29]. In normal tissues, p53 levels are difficult to detect, being present in actively proliferating cells but not in resting cells [30]. In most human cancers, p53 is found in increased amounts and generally found to be mutated with deranged function [31]. Of all the genes associated with cancer suppression, p53 is the most commonly mutated. A 2002 study showed various lifestyle and dietary components associated with p53 mutations [32]. A high glycemic load, consumption of fast food, trans-fat consumption, and consumption of red meats were associated with increased p53 mutation as opposed to control groups [32]. Other studies have linked alcohol consumption with the increased likelihood of p53 mutations in breast cancer [33].

p53 can bind with T-cell antigens, forming complexes that inactivate immune molecules, and mutated p53 can activate tumor development through several different pathways [31]. Overall, the cellular role of p53 is quite broad and includes involvement in energy metabolism, cell senescence, immune response, cellular motility and migration potential, cell signaling and communication, cell cycling regulation, and apoptosis. In addition to its intracellular effects, there is growing evidence that in its normal state, p53 can suppress angiogenesis by increasing collagen-derived antiangiogenic molecules in the extracellular matrix by transcription suppression of VEGF and through the stimulation of hypoxia-inducible factor 1 alpha (Hif1ά) degradation [34].

NFκβ is another intracellular transcription factor that binds specific DNA sequences involved in several intracellular processes, including regulating cellular growth and development, subsequent apoptosis, and immune and inflammatory responses. Dysregulation of NFκβ has been linked to a variety of diseases including cancer, viral infections, septic shock, and inflammatory and immune diseases [35]. NFκβ is an important regulator of these processes as it is rapidly acting – no additional proteins need to be synthesized for it to become active. NFκβ typically resides in the cellular cytoplasm, but when activated, it moves to the cell nucleus to initiate the expression of genes with specific binding sites. This can then lead to cellular proliferation, an inflammatory or immune response, or an antiapoptotic response [36].

Typical initiators of NFκβ activity include reactive oxygen species (ROS), tumor necrosis factor alpha (TNFα), interleukin 1 beta (IL-1β), bacterial by-products, certain drugs, and ionizing radiation [34]. As a potent upregulator of inflammation, NFκβ has a direct effect on the TME. NFκβ is a known inducer of such inflammatory tumor-promoting cytokines as interleukin 6 (IL-6), as well as progenitors for such inflammatory cytokines as cyclooxygenase 2 (COX-2). It also leads to low-level prolonged smoldering inflammation that is characteristic of the TME [37]. NFκβ is also associated with another DNA transcription factor known as signal transducer and activator of transcription 3 (STAT3). STAT3 and NFκβ engage in a variety of crosstalk, mediating the release of inflammatory cytokines in the TME. STAT3-mediated acetylation causes NFκβ to remain active in the cell nucleus longer and prolongs inflammatory response, which results in increased activity of TME inflammatory cytokines [38].

27.6 Nutritional Influences on the Tumor Microenvironment

27.6.1 Influences on the Extracellular Matrix

Many nutritional compounds can have an impact on the various aspects of the destabilized TME. One compound that helps to stabilize the extracellular matrix is epigallocatechin

gallate (EGCG), derived from green tea. In vitro studies have shown that EGCG can inhibit both matrix metalloproteinases (MMP) 2 and 9 [39]. Vitamin D levels were inversely associated with circulating MMP-2 and MMP-9 in several studies and therefore may be of benefit as well [40]. Resveratrol may also be useful in downregulating both MMP-2 and MMP-9, as shown in studies on chondrosarcoma and fibrosarcoma cells [41]. Curcumin, one of the pigment compounds of turmeric, has been shown to inhibit and regulate MMPs in a variety of diseases [42], as well as acting with proanthocyanidins to downregulate collagenase, which also degrades the ECM in the TME [43]. The anti-inflammatory effects of omega-3 fatty acids also seem to decrease circulating MMPs in studies in MS patients [44]. The botanical yarrow achilleifolia has also been shown to downregulate MMP-2 and MMP-9 in the inflammatory response [45].

27.6.2 Angiogenesis

The inhibition of the angiogenic cascade or signaling switch is also a potential target of many nutritional compounds. As previously discussed, TAMS promote a variety of angiogenesis-promoting factors such as VEGF, PDGF, bFGF, TGFβ, and EGR. Nutritional inhibitors of VEGF include EGCG [46], resveratrol, curcumin, and proanthocyanidins. Other natural compounds isolated from botanicals having a direct effect on VEGF include artemisinin (extracted from Artemisia annua), baicalin (extracted from Scutellaria baicalensis), silymarin (extracted from milk thistle), and honokiol (extracted from magnolia bark) [47]. Dietary flavonoids and Vitamin E have also shown to be effective modulators of VEGF [48]. PDGF expression can be affected by ellagic acid, a polyphenol found in fruit and nuts. Ellagic acid also simultaneously suppresses VEGF expression [49]. EGCG influences PDGF receptors, modifying their propensity to be stimulated by PDGF and can consequently inhibit PDGF effects through cell signaling [50]. bFGF can be affected by stabilizing the ECM overall, which reduces its availability through motility inhibition. TNFα stimulates production of bFGF, so agents that inhibit TNFα can also decrease bFGF. Nettle leaf extract has been shown in studies to be a potent TNFα inhibitor [51]. TGFβ is typically a tumor inhibitor initially, but in the hypoxic TME, tumor cells become resistant to it and proliferate due to its presence. Inhibitors of TGFβ include curcumin, emodi (a phytochemical found in rhubarb and Japanese knotweed) [52], and resveratrol [53]. TAMs also increase EGF, which itself promotes tumor growth. Retinol has been shown in studies to decrease secretion of EGF in endothelial cells [54].

As previously discussed, CAFs increase lactic acid shuttling and contribute to the hypoxic environment in the TME, which can promote angiogenic signaling of VEGF via protein kinase C (PKC). This produces a high-insulin environment, stimulating hypoxic cells to produce more lactic acid, which contributes to cell signaling. Improving insulin metabolism and decreasing insulin resistance by decreasing dietary omega-6 linoleic and arachidonic fatty acids and increasing omega-3 fatty acids may decrease activation of PKC and improve this aspect of angiogenesis activation [55, 56].

Both p53 and Nfκβ have been extensively researched as players in the progression of carcinogenesis and angiogenesis. Consequently, many nutritional substances have been identified as modulators of these two upregulators of the TME. p53 functionality is closely related to redox status since the p53 protein contains numerous cysteine particles that are sensitive to antioxidants, so increased levels of antioxidants can be important in the prevention of p53 dysregulation. Zinc deficiency also seems to be associated with increased oxidative damage to DNA and p53 upregulation and mutations [57]. Other natural dietary compounds that influence p53 mutations include vitamin E, retinoic acid, quercetin, and folate, which all may inhibit the expression of mutated p53 [56].

27.7 Inflammatory Influences

As previously mentioned, the transcription factor NFκβ initiates a variety of cascades in the TME, notably those leading to inflammation. There are many nutritional supplements that can inhibit the NFκβ activation process. Dietary components with anti-inflammatory and antioxidant properties that inhibit NFκβ include curcumin, quercetin, EGCG, and 6-gingerol, extracted from ginger. Zinc, in addition to its effects on p53 mutations, influences NFκβ levels and associated VEGF expression relative to its depletion [58] and thus may play a role in regulating NFκβ and modulating copper levels resulting from an acute-phase reaction and low zinc status [59].

Normalization of the stromal density in a TME may be facilitated by the inhibition of CXCL12. Diindolylmethane, a brassican compound isolated from cruciferous vegetables, was shown to downregulate CXCL12 in breast cancer patients [60].

27.8 The Microenvironment in Chronic Autoimmune Disease and Similarities to Cancer

The environments of cancer and autoimmune disease share common characteristics. Specifically, both show hallmarks of an upregulated immune response, leading to inflammation and subsequent tissue damage (see ▶ Chap. 19). The divergent point of the two disorders relates to how the pathology in the microenvironment progresses. In malignancy, the tumor microenvironment induces immunosuppression where tumor cells are unrecognized by the immune system. There is mixed immune response in malignancy. The tumor cells have an increased anti-inflammatory response but are invisible to specific antibodies, while the surrounding microenvironment is pro-inflammatory. Tumors in a sense are wounds that do not heal, as the tumor reorients the immune system's

healing response and uses it to drive its own progression and self-promotion.

In contrast, the microenvironment in autoimmune disease shows an activated inflammatory response that escalates in response to a lack of self-tolerance. The focus of the inflammatory response is the host tissue itself. There is expression of antibodies that are misrecognized, leading to further attack by the immune system. This self-perpetuating cycle results in permanent tissue damage over a long period. Typically in the microenvironment of autoimmune disease, the immune infiltrate is comprised primarily of either Th1 cells, and their inflammatory cytokines such as interleukin 2 and 17, or Th2 cells, and their anti-inflammatory cytokines such as interleukin 4 and 10. One interesting characteristic of autoimmune diseases is the diminished presence or impairment of CD4+ and CD25+ T regulatory cells, which have come to be thought of as an essential component of immune modulation and homeostasis [61].

Another commonality between the microenvironments of cancer and autoimmune disease is the propensity toward a hypoxic state. In autoimmune disease, the hypoxic environment is established largely due to immune cell infiltration, which increases the demand for oxygen over the available supply. In some autoimmune disorders, such as multiple sclerosis, the increased migration of lymphocytes and macrophages also increases the secretion of proangiogenic factors such as VEGF and MMPs. Although autoimmunity and cancer represent opposing ways in which the immune system can become dysfunctional, there is considerable overlap in terms of the potential targets for nutritional intervention.

Because of the propensity for inflammation, many of the cancer microenvironment anti-inflammatory strategies that downregulate proangiogenic factors, such as VEGF, could be considered appropriate. There are some different factors to consider, however. While there is good understanding of the role of macrophages and other immune cells in the cancer microenvironment, certain assumptions about the roles of specific immune cells in the microenvironment of autoimmune disease have led to research with conflicting conclusions. For example, there is an assumption that m1 macrophages would be present in Th1-type autoimmune diseases such as rheumatoid arthritis, Hashimoto's thyroiditis, and multiple sclerosis, but the research data is somewhat controversial [62, 63]. Conversely, the role of autoantibodies in autoimmune disease is well understood, but there is little understanding of their significance in cancer progression. Disease states such as hepatocellular carcinoma induced by hepatitis C or liver cirrhosis are proving to be helpful in delineating the role of the immune system in cancer progression [64].

27.9 Nutritional Influences on the Autoimmune Microenvironment

Hypoxia and proangiogenic factors are two components that cancer and autoimmune disease share. Consequently, suppressing factors that contribute to a hypoxic environment, such as VEGF and Hif1a, can be important in terms of destabilizing the autoimmune microenvironment (AIM). Dietary modulators of VEGF have been previously discussed in the section on cancer and include anti-inflammatory plant compounds that may also affect cytokine expression in autoimmune disease, such as curcumin, EGCG, proanthocyanidins, and resveratrol [46, 47]. Modulation of cytokine activity, both pro-inflammatory and anti-inflammatory, and transcription factors, such as NFκβ, are of interest in terms of the autoimmune microenvironment (AIM). In some autoimmune diseases, macrophages release TNFα, stimulating the migration of NFκβ into the cell nucleus, which in turn will upregulate inflammation and code for hyperproliferative cytokines such as interleukin 1, 6, and 8 [65]. Nutritional compounds that regulate TNFα and NFκβ include curcumin, quercetin, B6, and EGCG [66–69].

One well-known factor in autoimmune disease is the connection to pro-inflammatory "Western" diets high in fat, sugar, processed food, protein, and salt and the effect on CD4+ T cells in autoimmune disease [70]. Obesity tends to impact immunity through Treg cells and can promote a predominantly Th17 environment with upregulated IL6, which continues to signal immune response [70]. Consequently, the management of obesity and abnormal insulin response can be crucial in managing autoimmune disorders, especially of the inflammatory kind [71]. Vitamin D also seems to have a special role in the initiation and progression of autoimmune diseases. Vitamin D has been shown to increase the release of anti-inflammatory IL4 from immune cells and stimulate the production of Treg cells, which prevent the immune system from initiating autoimmune response by inducing self-tolerance [71].

27.10 The Microenvironment of Arthritic Conditions

Arthritic conditions, both inflammatory and noninflammatory, have an obvious inherent potential for microenvironmental changes and pathology. The microenvironment of the synovial capsule is an important target. It was previously assumed that the tendency for inflammation in arthritic conditions was isolated to those associated with autoimmune dysregulation, such as rheumatoid arthritis and psoriatic arthritis. However, research has shown that even in osteoarthritis, inflammation is a subclinical event that can lead to degradation of the joint [72]. One study examined the activation and infiltration of CD5+ cells in both rheumatoid and osteoarthritis and found them to be comparable [72]. Chondrocytes in an inflammatory synovial environment seem to be less susceptible to selective cell death and apoptosis and increase the inflammatory environment by secreting additional inflammatory cytokines such as MCP-1 and MIF [73]. Once tissue in the superficial zone of articular cartilage is damaged by inflammation, the mesenchymal stem cells present in it

lose the ability to regenerate, and tissue damage becomes permanent. Inflammatory cytokines such as IL2, which upregulate Nfκβ, lead to low-level persistent inflammation [74]. Again, we see the prevalence of an inflammatory cascade in a disease microenvironment becomes self-sustaining and difficult to reverse. Even in supposed noninflammatory arthritic conditions, changes in the synovial microenvironment affect the regeneration of the joint capsule. One study showed that changes in the synovial ME in osteoarthritis changed the RNA sequencing in joint chondrocytes, resulting in downstream changes in the joint cartilage formation [75]. Another interesting aspect of arthritic conditions and microenvironmental concerns is the correlation between the gut microenvironment in inflammatory bowel disease and the development of enteropathic arthropathies. One etiological theory proposed is that lymphocytes or macrophages from the gut may migrate to the synovium and bind to the synovial tissue vessels, dependent on the development of adhesion molecules such as vascular adhesion protein 1 (VAP1). This in turn leads to the development of inflammatory arthritis in the affected joint [76].

Another proposed mechanism relates to mesenchymal cells present in both the gut and joint being predisposed to stimulation with simultaneous overexpression of TNF leading to TNF-mediated inflammation [77]. The development of loss of tolerance of normal bacterial flora in inflammatory bowel disease (IBD) seems to be the initiator of this cascade of events leading to IBD-centered arthropathies [78]. Also, activation of toll-like receptors on immune cells by certain bacteria in the intestinal environment, such as overabundant *Prevotella copri* in RA, can lead to the upregulation of inflammatory cytokines in the joint, such as Nfκβ and IL1r [79].

27.11 Nutritional Influences on the Microenvironment in Arthritic Conditions

Dietary factors that help mediate low-level inflammation are important in inflammatory response but also in mediating tissue damage in the joint capsule. Consequently, nutritional supplements that downregulate inflammatory cytokines, TNF, and Nfκβ – such as curcumin, quercetin, polyunsaturated fatty acids (PUFA) like fish oil, and EGCG – are important. PUFAs, such as those contained in krill oil, reduce cytokine infiltration into the joint capsule [80]. Collagen, in addition to being an important constituent of the joint capsule and being necessary for its regeneration, also seems to assist in regulating T-cell function so they do not become activated and attack the joint cartilage [81]. Vascular remodeling has been shown to be an important factor in the potential infiltration of macrophages and T cells into the joint capsule, so the downregulation of proangiogenic factors through the use of proanthocyanidins and curcumin could be useful [82].

Because of the role of the gut microbiome in inflammation in arthritic conditions, optimizing the gut and decreasing the load of pathogenic bacteria could possibly have a significant effect, especially in RA. Increased levels of *Prevotella copri* have been observed in the gut microbiota of patients with RA, and it has been postulated that lowering the levels of *Prevotella* and optimizing the diversity of the microbiota in RA patients could be of clinical significance [83].

27.12 The Blood as a Potential Reflective Microenvironment

One microsystem of the body that is relatively easy to explore is that of the blood. The blood microenvironment can be observed through a microscope, most effectively in dark-field and phase-contrast viewing. Due to the fluid nature of blood, one can experience the living dynamics of the blood environment by observing it soon after obtaining a sample, without having to stain the blood or through time elapse, which could cause the sample to degrade. Dark-field illumination, which condenses light by blocking light that passes through the specimen and allowing only for oblique rays from the circumference of a specially designed condenser, allows for the viewing of objects that are unstained and absorb little or no light, such as bacteria and cell wall structures. Dark-field microscopy is less effective in determining intracellular dynamics [84–86]. Phase-contrast illumination allows light to be passed through the sample at a variety of angles, offering an almost three-dimensional aspect to sample viewing. In this way, the cellular structure and viability of red blood cells and white blood cells can be evaluated, and extrapolations can be made as to the nature of the blood microenvironment, the plasma.

The test itself is controversial, and there is limited evidence for the validity of the interpretations of dark-field and phase-contrast live blood examinations. But it is important that practitioners are educated about the practice, in case patients ask about it or bring in results from a test.

Practitioners of live blood cell analysis assert that the evaluation can be seen as more qualitative rather than quantitative. Since the blood is observed immediately after the sample is obtained, the dynamics of both the cells themselves and the plasma are visible. For example, in conventional hematology, it is possible to quantify the numbers of various types of white blood cells such as neutrophils, macrophages, and basophils, but it is difficult to determine the viability of these cells. Observing them live in the blood can lead to postulations about the actual nature of potential immune response by assessing their viability. For example, although there may be many white cells present in a sample, they may

exhibit poor phagocytic activity when observed in a live microscopic evaluation.

There are crucial considerations for sample preparation so that the possibility of artifacts remains minimal. Most often, comparing two samples from a patient as well as various views from a sample can reveal any inconsistencies arising from the sample preparation (e.g., abnormalities in slides or slide covers, air bubbles, or exogenous microorganisms). This section will briefly review some of the potential findings in live blood and the potential reflective clues they may have related to nutritional status. In terms of clinical relevance, findings in the live blood should generally not be considered diagnostic per se, but they may be useful in prioritizing other diagnostic testing or comparing to other diagnostic findings when considering a potential diagnosis.

Live blood cell analysis is most useful in enhancing existing findings arising from a conventional complete blood count (CBC) or, in some cases, findings in the metabolic panel (CMP). This relates to observing the morphology and activity of the blood cells within the microenvironment of the plasma. Cell wall structure can be observed, and phase-contrast viewing allows for some intracellular observations to be made. One example relates to relative cell size. Variabilities in cell size are easily visible in the live blood, and since anisocytosis is almost always associated with the various mechanisms leading to anemias, it can validate inferences about iron status or B vitamin levels, specifically B12 and folate [87]. In addition, a great variation in the sizes of RBCs can be interpreted as oxidative stress due to excessive homocysteine or, in cases of elevated oxidant catalysts such as mercury or excess iron, within the RBCs themselves [88]. In this case, the majority of cells tend toward macrocytosis. Another observation discernible in the live blood relates to cell membrane structure and viability. Many different abnormalities in the cell wall structure are visible under the microscope and include poikilocytosis, schistocytosis, and acanthocytosis. The blood cells appear with surface corrugations or spiculations. Two inferences can be made: potential oxidative stress causing the cell membrane to rupture and poor formation of the cellular membrane due to suboptimal essential fatty acid status subsequent to insufficient intake or metabolism.

White blood cell morphology is easily determined in either phase-contrast or dark-field viewing and can often enhance an understanding of the quantitative measurement available with a blood draw. For example, a CBC may show adequate neutrophils but may be hyper-segmented under microscopic viewing and therefore suggest B12 deficiency [89]. Reduced motility of various leukocytes may result from immunodeficiency disease processes [90]. Another example is related to the status of basophil activity. In conventional analysis, basophils may appear to quantitatively be within range, but microscopic evaluation may show excessive degranulation of the basophils, which would lead to an assumption of increased histamine activity [91].

Viewing the live blood under either phase-contrast or dark-field illumination can also show abnormalities in the dynamics of the red blood cells. One such phenomenon is the observation of rouleaux or stacking of the red blood cells. From a conventional perspective, rouleaux may be caused by acute-phase protein elevations in the blood, leading to a change in the overall pH of the blood microenvironment. Many times, it can be associated with increased fibrinogen or globulin levels, and often it is seen accompanied by spicules in the blood, also indicative of elevated fibrinogen [92]. In any case, the shift in valence of the serum pH can alter the potential of red blood cells to easily move through the peripheral vasculature, causing problems with circulation [93]. Often, improving protein digestion or the administration of proteolytic enzymes can reverse this condition in a short period of time.

Outside of conventional hematological findings that can be observed in the live blood, there are often observed findings that have a variety of potential interpretations. These observations are more often than not viewed as artifacts by conventional science. From the standpoint of certain schools of alternative medicine, these findings show the propensity of the blood microenvironment to be more conducive to various pathological processes [87, 94]. Several microbiologists in the past, including Gunther Enderlein and Gaston Naessens, have embraced this theory and extrapolated on the potential meaning of these findings in the live blood microenvironment [95, 96]. One example is the formation of pteroharps, or platelets spreading like wings of butterflies, in the blood. Platelets are observed to have spread out on the slide in a formation of a shadowy background. This does not occur in all samples and is variably interpreted to mean either a change in the blood valence due to an abnormal blood pH, similar to the rouleaux formation in the red blood cells, or it is interpreted to be a manifestation of an L-form bacteria without a cell wall. This finding is often associated with leaky gut syndrome and intestinal flora imbalances. Another typical finding in live blood is the presence of thecits, which are often thought to be corpuscles broken off other cells. An alternative interpretation is that these are a cell wall-deficient form of bacteria often correlated with intestinal dysbiosis.

27.13 Conclusion

The human body is complex and composed of a variety of structures and systems that are potential arenas for pathologies that can alter the local biological terrain and then have the potential to affect the organism. The understanding of disease microenvironments, therefore, is important not only in uncovering the process of systemic pathology but also in targeting nutritional interventions that can undermine the root of pathological processes before systemic disease occurs.

Case Study: Cervical Cancer

A 42-year-old female patient was diagnosed with stage IVb cervical cancer 1 month prior to initial integrative medicine consult. The patient was diagnosed after an abnormal PAP smear and biopsy with follow-up radiologic evaluation for staging. Multiple metastatic lesions were identified including the rectum and the supraclavicular lymph nodes. The patient otherwise was generally healthy, slightly obese, and only complained of chronic neck pain attributed to a previous motor vehicle accident. She elected to undergo conventional chemotherapy consisting of combined paclitaxel and platin-based therapy administered every 3 weeks for 6 cycles. The patient sought additional supportive integrative approaches throughout her therapy. Since antiangiogenic therapies such as bevacizumab were not used in the treatment of cervical cancer at this time, integrative treatment interventions focused on inhibition of angiogenesis in addition to standard anti-inflammatory and immune-modulating natural protocols. The patient was given an extract of curcumin, EGCG, and baicalin targeted to affect VEGF, PGGF, and p53 expression. In addition, she received high-dose resveratrol, which has been shown to inhibit STAT3 signaling. After the six cycles of treatment, the patient was sent for follow-up radiological exam and had negative CT/PET scan results. Conventional treatment was discontinued, but she remained on botanical and nutritional protocols for several years afterward. No adverse events were identified with this protocol. To date, 9 years after initial treatment, the patient remains disease-free. This case points to potential benefits possible when conventional cancer therapies are combined with dietary and medicinal plant interventions.

28.1 Introduction

Aristotle described pain as emotional, a passion of the soul, and the heart as the center of sensation. Later, Descartes asserted that pain was outside of the mind, a disturbance to the machine (body) that passed along nerve fibers through a pathway that led to the brain. The gate control theory introduced the brain as deeply involved in pain processing and perception [1]. In 1974, the International Association for the Study of Pain (IASP) essentially married the mind, body, and soul, weaving all theories into its current and finalized definition: "an unpleasant sensory and emotional experience associated with actual or potential tissue damage [2]." Although our understanding of pain is still in evolution, this integrative definition includes an emotional response, which, depending on the individual physiology, behavior and life experiences, will be perceived and then expressed differently for each person [3]. Even though pain and emotion travel similar pathways, this aspect of pain as personal experience is often ignored; it cannot convey what pain is or what it feels like to each individual [4]. Importantly, it does recognize that pain can be felt without tissue damage, as is the case with many chronic pain sufferers.

Thus, chronic pain is a complex multifactorial, biopsychosocial experience [5]. Chronic pain, as opposed to acute pain, exists for at least 3–6 months or beyond typical healing allowance [2]. It is a disease in and of itself, as in musculoskeletal pain or headaches, or it can be associated with other chronic conditions, such as diabetic or chemotherapy-induced neuropathy, obesity, rheumatoid arthritis (RA) or post-traumatic stress disorder (PTSD). As a central product of inflammation, pain intersects most chronic diseases today. According to the 2011 Institute of Medicine Report, there are more than 100 million people in the United States living with chronic pain, which is more than those affected by diabetes, heart disease, and cancer combined [6] (Fig. 28.1). It is the primary reason for visiting physicians and a leading cause of total disability, costing up to $635 million per year [7]. Affecting a total of 1.5 billion people worldwide, chronic pain is an increasing public health burden in most developed countries and afflicts people throughout the lifespan [8]. It is estimated that 25–46% of children and young adults experience chronic pain, most often in the form of headache or abdominal or musculoskeletal pain [9]. Of those surveyed, more than half of older adults, 53%, reported pain within the last month [10]. Pain in the elderly is often undertreated. It significantly affects quality of life and frequently crosses over into insomnia, depression and anxiety. Chronic pain not only becomes the central part of life for the sufferer, it impacts family, friends and the communities in which they live.

Most patients suffering with chronic pain are treated with pharmacology, local injection or surgery. Although these therapies play an important and necessary role, there is no epidemiological evidence that they have yet to alter the course or make a significant difference in patient outcomes, disability or cost [11, 12]. With its bio-individual manifestations, pain is ideally suited for an integrative and functional

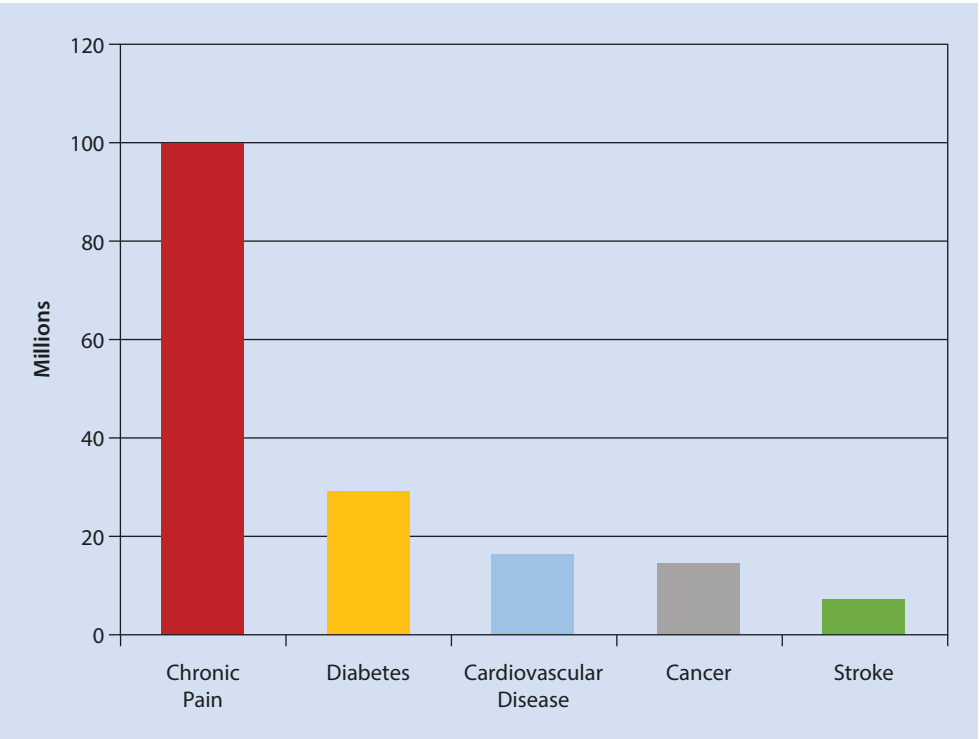

Fig. 28.1 Prevalence of Chronic Pain. (Courtesy of Jena Savadsky Griffith, RDN, IHC; Based on data from Pain [6], Diabetes [236], Heart Disease, Stroke [237], Cancer [238])

approach. The patient often needs multidisciplinary medical support and expertise in all aspects of life that are physical, emotional, and spiritual. A 2012 report on the practice of integrative medicine across America outlines significant strides being made in chronic pain, with nutrition at the therapeutic forefront [13]. In the first Multidisciplinary Pain Research workshop in Rome, 2016, researchers stated that patients with chronic pain should undergo nutritional assessment and counseling at the onset of treatment and that including nutrition in personalizing pain medicine is formidable and will improve any analgesic therapy, patient compliance and quality of life [14].

28.1.1 Mechanisms of Pain (See ◘ Fig. 28.2)

28.1.1.1 Nociceptive Pain

Nociceptive, or acute, pain results when noxious stimuli activate nociceptors in the peripheral nervous system (PNS) and serves an important protective function. This activation causes depolarization via first-, second- and third-order neurons in C fibers or A delta fibers that lead to the dorsal horn of the spinal cord and then up through the brainstem [5]. The thalamus then relays this nociceptive information to the higher cortical regions that include the amygdala, hypothalamus, periaqueductal grey, basal ganglia and regions of the cerebral cortex where the pain is processed, perceived and localized [15]. Pain is mediated via descending pathways by both excitatory (glutamate) and inhibitory (gamma-aminobutyric acid - GABA) neurotransmitters that either increase or decrease pain perception [5, 15]. Dysfunction can occur at all levels of ascending and descending pathways, resulting in chronic pain. The sequence of events in pain signaling involves four processes: transduction, transmission, modulation and perception [16].

28.1.1.2 Neuropathic Pain

Neuropathic pain is a complex multifactorial chronic pain state caused by a lesion, injury or dysfunction of either the peripheral or central nervous system (CNS). Accompanied by tissue damage or injured nerve fibers, these fibers misfire and send incorrect signals to various pain centers. These changes may not quickly resolve, as in diabetic neuropathy or postherpetic neuralgia. Thus, the impact of injury includes both damage to the fiber itself and the areas surrounding the injury. With neuropathic pain, neurons may continue to fire, leading to spontaneous pain and pain upon movement [5]. There may be inhibition impairment and alterations in central pain processing, which is key in chronic pain. Neuropathic pain can manifest in patients as shooting, burning, tingling or numbness.

28.1.1.3 Central Sensitization

It is now known that most patients with chronic pain have some degree of alteration in central nervous system processing called central sensitization (CS). CS is defined as a state in which the CNS is hyperactive or magnifies sensory input in multiple organ systems [5]. This hypersensitivity involves neuronal and microglial plasticity in response to activity, inflammation or neural injury [17]. The ensuing dysregulation produces allodynia (a greater-than-normal response to non-painful stimuli), hyperalgesia (heightened response to painful stimuli) and/or enables non-injured tissue to produce pain [18]. Localized pain can become generalized pain and manifest in joints or muscles. Pathophysiologically, signaling persists past the point of tissue healing and creates a sensory illusion where pain may be experienced with low or even absent sensory stimuli. These processes can either facilitate or inhibit pain transmission. This abnormal connectivity is driven by imbalances in concentrations of CNS neurotransmitters that control sensory processing, sleep, alertness, affect and memory [19]. Further, as a result of MR morphometry, it is now known that the cerebral cortex is reorganized and gray matter is decreased, creating a common "brain signature" in chronic pain sufferers [20].

Although an injury may be present with CS, it is not necessarily pathology of the tissue detected on a scan, but a functional pathology. Central sensitization is the underlying pathophysiology associated with fibromyalgia, irritable bowel syndrome (IBS), tension headaches, migraines, sleep disturbances, restless leg syndrome, chronic back and neck pain, osteoarthritis (OA), rheumatoid arthritis (RA), interstitial cystitis, and temporomandibular syndrome (TMJD). Importantly, CS is also implicated in anxiety, depression and PTSD [5, 21–23]. Whether or not chronic pain begins with a specific acute injury, as pain becomes chronic, multiple mechanisms overlap for many (◘ Fig. 28.3). That is, the pain appears to be caused by a complex mixture of nociceptive, neuropathic and psychological factors with central sensitization playing a dominant role [24].

28.1.1.4 Psychological Pain

Chronic pain often exists in the absence of any physiological cause or injury. Although patients should never be told that the pain is "in their head," a new paradigm concludes that CNS processing may be altered by emotional states and traumatic events, in childhood or adulthood, much like a physical injury, into what is called psychological pain [25]. A history of trauma and adverse early adulthood experiences co-exists with many pain syndromes [26, 27]. Pain is experienced as more severe than expected, and emotional processing seems out of proportion to physical pathology, if any exists. The nervous system is sensitized over weeks, months or years. More subtly, chronic pain may develop because of unresolved emotional issues. Although those experiencing trauma have good psychosocial adjustment, experiencing pressure or an unrelated stressful incident at a later time may recall the initial trauma.

28.1.1.5 Psychosocial Mediators

Most of the study and treatment of pain has been based on the linear concepts of physical medicine. Pain was simply nociception. In the 1960s, pain was recognized as a multidimensional experience with sensory (location, quality and

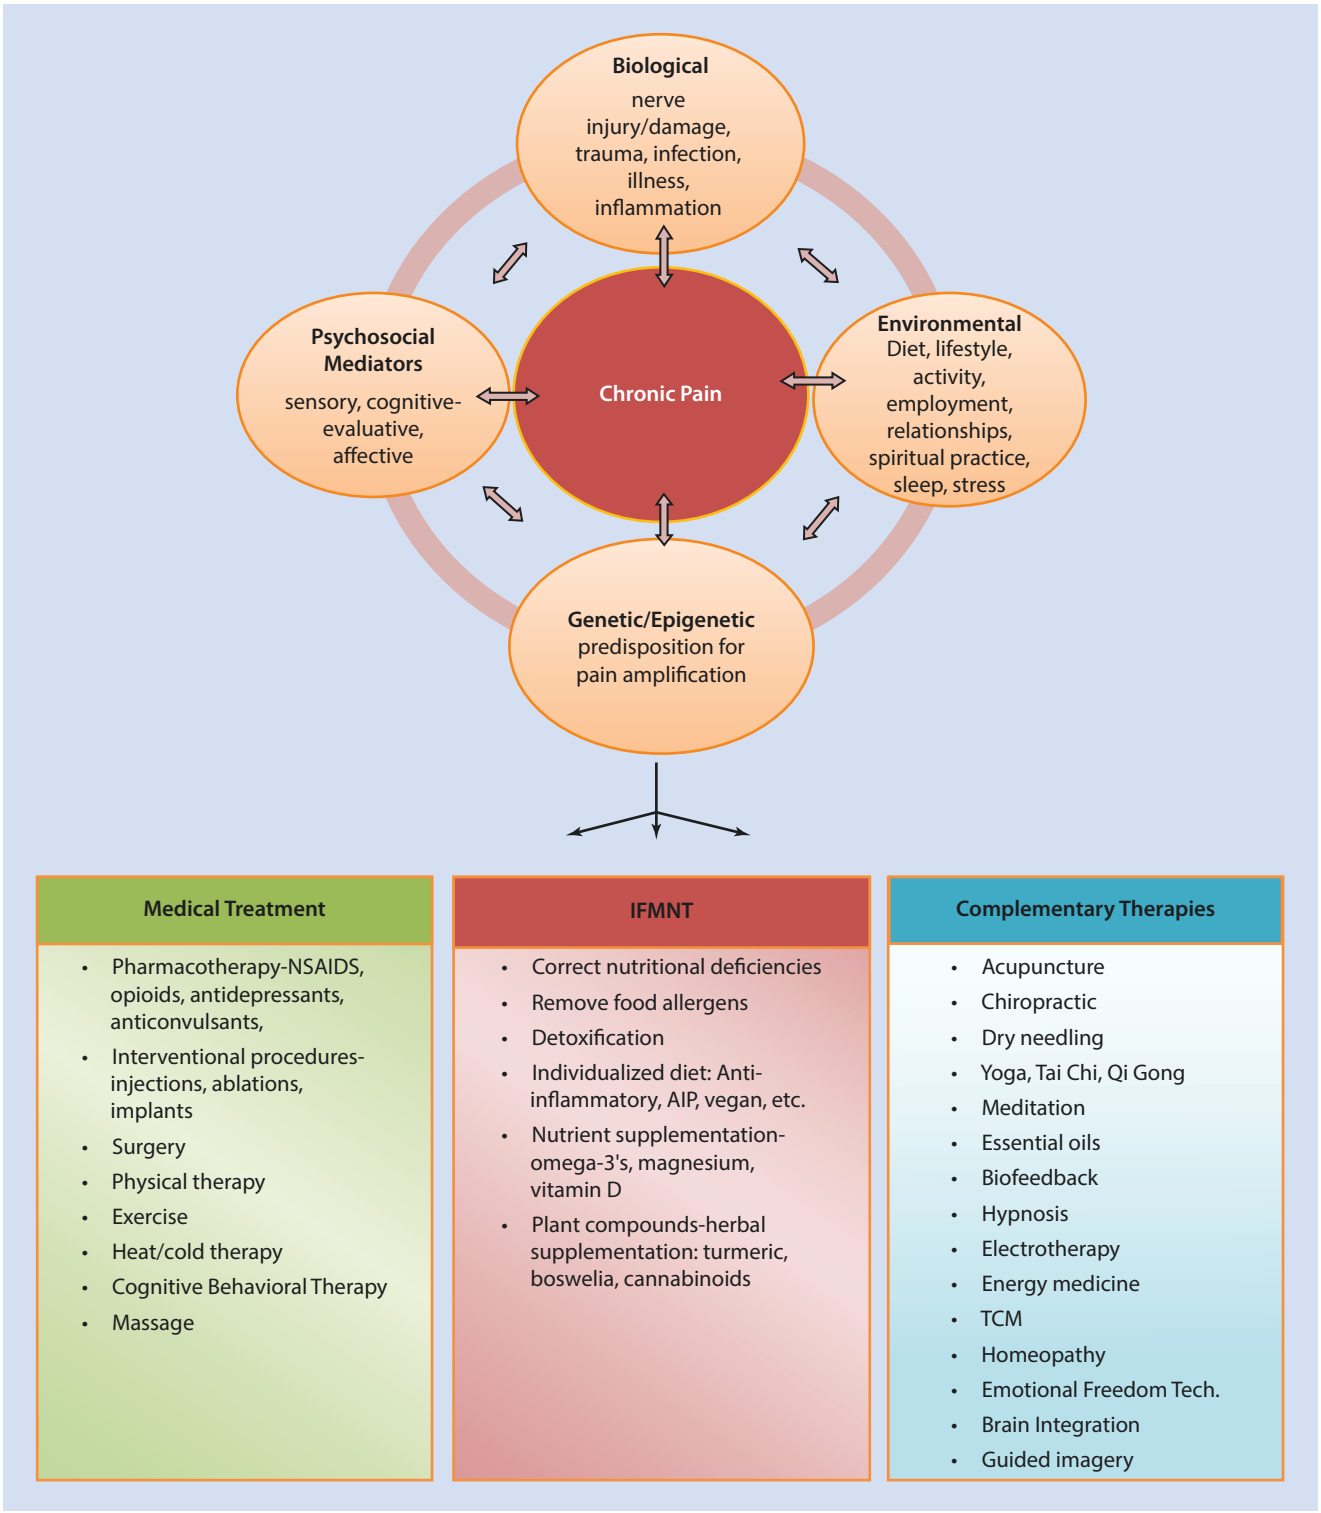

Fig. 28.2 Chronic Pain Pathophysiology and Management Algorithm. (Courtesy of Jena Savadsky Griffith, RDN, IHC)

intensity), affective (degree of unpleasantness) and cognitive-evaluative (attitude and beliefs about pain) components [28]. It integrated the common denominator of the individual and the embodiment of a person's history, energies and perceptions. Significantly, biopsychosocial factors provide a context for each person's pain experience. The degree of pain felt depends on disposition, mood, history of pain reactivity, attention, motivations, cognition, social influences, community, health and nutrition status and myriad other variables unique to that individual [12, 29].

28.1.1.6 Sleep, Depression and Chronic Pain

Pain can trigger a cascade of events and often has a cyclic relationship with anxiety, depression, sleep disturbance, PTSD, obesity, and inactivity. Connections with pain, depression and anxiety are expected as they share similar biological pathways and neurotransmitters with overlapping pathophysiology in the central nervous system [19, 30]. Those in chronic pain are four times more likely to have comorbid anxiety or depression than pain-free primary care patients [31], with studies assessing comorbidity from 30% to 60% [30]. Similarly, up to 75% of those with depression in primary care settings complain of chronic pain, including headache, stomach pain, neck and back pain and idiopathic pain [31].

Sleep complaints are present in 67–88% of chronic pain conditions [32]. Most studies confirm its reciprocal relationship, with pain causing sleep disturbances and insomnia causing increased pain sensitivity. Loss of sleep increases inflammation, alters metabolism, depresses immunity and does not allow the body time to rest and replenish energy stores. Released along with glutamate during pain signaling is neurotransmitter substance P. During deeper stages of sleep, substance P is naturally decreased; therefore, inadequate sleep amplifies pain as more substance P remains [33]. Nutrition and lifestyle intervention should address inflammatory aspects of diet, coffee intake (see hydration), potential insulin resistance, supplementation, use of NSAIDs, stabilization of the gut microbiome and exercise.

28.1.1.7 Cancer-Related Pain

Due to the breadth and depth of cancer-related pain as its own entity, the chronic pain conditions discussed in this chapter are non-cancer-related. Cancer is a leading cause of chronic pain and presents challenges to both patient and practitioner. The American Cancer Society's most recent figures estimate 30% of newly diagnosed cancer patients have pain, 30–50% of patients undergo active treatment experience pain, and 70–90% of patients with advanced disease experience pain [34, 35]. Pain in cancer patients may be related to the cancer itself (metastatic bone disease or local tissue damage), to procedures (post-surgery, injections) or it can be related to treatment (radiation, chemotherapy) [12, 35, 36]. In addition, patients may experience nociceptive, neuropathic pain or both. Pain is one of the most feared aspects of cancer for both patients and their families; however, there are many diet and lifestyle interventions that can relieve patients of anxiety and stress, increase nutritional status, and empower patients to play an active role in their own care.

28.1.1.8 Nutrition and Chronic Pain

Eating is a daily practice that can contribute to or detract from health. According to the Centers for Disease Control and Prevention, 70% of all deaths in the United States result from chronic preventable diseases that are attributed to diet and lifestyle [37]. The current standard diet may be the most serious threat to public health [38]. Deficiencies, toxicities and sensitivities within any one or multiple biochemical and signaling processes can contribute to chronic pain conditions. While research is just beginning to address diet and pain, the connections are undeniable and individual dietary roadmaps can be created. There is evidence that specific foods, nutrients, diets and herbs can provide pain relief while other foods and dietary patterns contribute to increased pain. Regardless of the chronic pain label, from diabetic neuropathy to migraines to fibromyalgia, addressing food and its ingestion, absorption, digestion and elimination is an empowering and worthwhile first line of defense when a patient presents with chronic pain. Nutrition and diet may be the most appropriate initial recommendation for pain sufferers to activate a healing response [12].

28

28.1.1.9 Obesity

Chronic pain and nutrition status are linked in direct and indirect ways. Nutrition is clearly implicated in diabetes, obesity-related musculoskeletal pain, or where a food trigger may be at play, such as in migraines or IBS. Obesity and pain coexist and have negative reciprocal effects. As an epidemic with 150 million people, the treatment of obesity and chronic pain should be considered as synergistic [14]. As BMI increases, so does pain. That includes less obvious conditions as neuropathic pain and headaches [39]. In a survey of one million Americans, chronic pain rates were 68–254% higher in obese individuals compared to those who were non-obese [40]. Women who are overweight or obese have a 60–70% greater risk of developing fibromyalgia [41]. Extra weight can compress and cause body malalignment that leads to pain in the back, neck, knee, foot and hip [42]. Alternately, each pound of weight loss resulted in a four-pound reduction in stress on the knee per step, in a study of obese adults with OA [43]. Further, in the Framingham study, an 11-pound weight loss was associated with a 50% reduction in the risk of symptomatic knee arthritis [44]. Although most trials have been done with OA and knee pain, weight loss reduced pain and increased function in those with fibromyalgia and low back pain as well [45, 46]. Importantly, obesity and metabolic imbalance can be a consequence of chronic pain. Its continuance often leads to a decline in physical activity, trouble sleeping and use of food as coping mechanism [47, 48]. Chronic pain patients may have reduced ability to experience pleasure from food and thereby increase consumption, especially regarding "sugary and fatty foods [49]." Addressing and modifying the diet in the clinical setting is key in the management of pain chronification and its further progression to metabolic dysfunction.

28.1.1.10 Inflammation

Greater than a function of overload, however, obesity is more often related to pain as a product of systemic inflammation. Increased pain in non-weight bearing regions include the spine, neck and upper extremities, as well as conditions including fibromyalgia, migraine and headaches [42, 50–52]. Markers of inflammation, including C-reactive protein (CRP), tumor necrosis factor alpha (TNFα) and various cytokines, are elevated in progression of OA and low back pain, particularly in the obese population [39, 52–54]. For almost every type of chronic pain, whether it is biochemical, structural or stress-induced, systemic, local tissue or neural inflammation is an underlying or contributing factor [55–62]. By definition, pain is one of the four manifestations of inflammation [63]. All pain states—nociceptive, neuropathic, and mixed pain related—are associated with inflammation. Inflammatory mediators act to exacerbate or inhibit pain. An increase in proinflammatory cytokines is linked to the maintenance and induction of neuropathic pain, and these cytokines and free radicals produced at the site of injury may be involved with nociceptor sensitization and maintenance of nerve-injury-induced pain [64]. In the absence of injury, nerve inflammation causes neuropathic-like pain and induces spontaneous activity away from the generation site [65].

Designed to protect, inflammation is the body's immune response to pathogens, injury, or contaminants. As medicine looks less at symptoms of disease and more toward systems, inflammation gets more attention as a root cause and has become a common pathway for many of the chronic conditions that exist today, including persistent pain. A specific food can trigger an inflammatory response. Repeated consumption of inflammatory foods or dietary pattern can keep the body and immune system in a hyperactive inflammatory state. The current Western diet of highly processed, high-calorie foods, lower nutrient value, less fiber and suboptimal antioxidant power presents a heavy inflammatory load on all systems of the body and is central to the pathogenesis of chronic disease [38, 62]. The ideal balance of pro-inflammatory omega-6 essential fatty acids (EFAs) to anti-inflammatory omega-3 EFAs is 3:1; however, our standard American diet (SAD) supplies 20:1 and, for some, up to as much as 50:1 [66]. This often leaves a person profoundly burdened, malnourished, deficient and vulnerable to pain and pathogens. A ratio of 2–3:1 of omega-6 to omega-3 suppressed inflammation in patients with rheumatoid arthritis [67]. In response to chronic pain, an anti-inflammatory diet is a logical step. (see ► Chap. 23 and below ► Sect. 28.1.1.16)

28.1.1.11 Gut Microbiome

A normal inflammatory pain response requires a healthy gut microbiome. Although in its infancy, research continues to confirm Hippocrates' long-held edict that health begins and ends in the gut. Home to 100 million microbial cells, the gut microbiome not only facilitates nutrient absorption but has come to be known as the intrinsic regulator of the immune system, where 70–80% of it resides [68–70]. In a 2015 study, patients with RA had similarly altered gut and oral microbiomes that normalized after treatment [71]. A study of 42 fibromyalgia patients found that 100% of them had small intestinal bacterial overgrowth (SIBO—bacterial translocation from the large to the small intestine) [72]. Additionally, IBS was present in 30–70% of fibromyalgia patients [73]. This points to the disruption of a healthy microbiome and dysbiosis as an underlying feature for many with chronic pain and other inflammatory conditions.

With IBS, it is easier to make a direct food–gut connection as the pain resides in the abdomen. Affecting almost 15% of the population, it is the primary reason for visits to a gastroenterologist and second most common reason for work absence [74]. Etiology of IBS is, like chronic pain, as diverse as the people afflicted. While altered gut bacteria and infection are often causes, most attribute their condition to food sensitivities which are found in 50–84% of IBS patients [75]. The most common trigger foods are corn, wheat, coffee, eggs, tea, citrus and dairy foods. Followed by food sensitivity and lactose tolerance testing, and stool analysis, patients were put on an elimination diet for 1 year. In addition to many other symptomatic improvements, pain was reduced by 90%

[76]. It is common, however, to overlook the gut-brain connection that exists in IBS and chronic pain. As a regulator of the digestive process, the enteric nervous system (ENS) has its own pain receptors, nerves and neurotransmitters often identical to those in the CNS. Further, as the ENS has bidirectional communication with the brain, anxiety or stress can alter gut bacteria or altered bacteria can result in stress or anxiety. This confirms the central sensitization pathophysiological framework of life experience + psychological response + physiology that underlies the basis of chronic pain. Analysis of the gut microbiome has identified patterns of altered gut flora in patients with chronic pain conditions that also include complex regional pain syndrome, chronic fatigue syndrome, restless leg syndrome and comorbid conditions of anxiety, depression and obesity [77–79].

Diet can detract from or enrich the diversity of the microbiome. In general, a varied, fibrous whole-foods-rich diet that includes fruits, vegetables, nuts, quality protein, whole grains (if non-reactive), healthy fats that include omega-3 fatty acids, fermented foods and sufficient hydration, and is tailored to the individual goes far in restoring and maintaining health. Additional nutritional tools that can therapeutically increase gut health are prebiotics and probiotics [79, 80]. Detractors may be refined sugars, processed foods and hydrogenated vegetable oils/transgut microbiome fats, additives, preservatives, artificial sweeteners and high fructose corn syrup, in addition to multitude of other lifestyle factors that include alcohol, smoking, NSAIDs, antibiotics, acid blockers, other pharmaceuticals, chronic stress, cesarean sections and widespread use of antiseptics and sanitizers [80–85].

Thus, disruption of the gut microbiome does not only cause local distress but can affect other biological systems. Chronic pain patients may also present without traditional symptoms of gastrointestinal (GI) distress, leading clinicians to potentially miss an integral piece. For example, it is estimated that 57% of those with neurological dysfunction of unknown cause have gluten sensitivity [86]. In addition, 20 fibromyalgia patients, 17 of which had IBS and 8 with migraines, all testing negative for celiac disease, went on a gluten-free diet for at least 6 months. All 20 participants reported dramatic improvement in widespread chronic pain, with 15 indicating they were pain-free [87].

28.1.1.12 Food Sensitivities

Food sensitivities also play a direct role in migraine headaches, the second most common pain condition and one of the most prevalent pain disorders in the world. Overlapping many other pain conditions, migraines have genetic, hormonal, immune, environmental and potentially mitochondrial influences and are usually activated in response to a trigger [88, 89]. Overlooked causes include dehydration [90], altered oral and gut microbiome [91], celiac disease [92], gluten sensitivity, hypothyroid [93] or hyperinsulinemia [94]. As the most well-known trigger, food's association with migraines has been studied for over a century. Much research follows similar patterns to the 1930 study which resulted in 53% of migraine patients resolving headaches after avoidance of all allergenic foods with partial improvement shown in an additional 38%. Further, most research indicates a wide range of food as causation [95, 96]. Children with severe, frequent migraines were put on an elimination diet that consisted of one meat (lamb or chicken), one carbohydrate (rice or potato), one fruit (banana or apple), one vegetable, water, and vitamin supplements for 3–4 weeks. Children who did not improve were given a second elimination diet. On both diets, 88.6% recovered completely. Fifty-five foods provoked migraines. The most common were milk, egg, chocolate, orange and wheat. Other causes of migraines may be amines, nitrates, histamine, monosodium glutamate and artificial sweeteners [96, 97].

Trigger foods can only be identified if eliminated and then reintroduced. Although time consuming, individualized approaches where patients keep meticulous food journals (with symptoms) is an invaluable tool that helps patients understand the effect of food on their pain. Nutritional deficiencies linked with migraines and other forms of chronic pain include vitamin D, magnesium, vitamins B2, B6, B12, folic acid, COQ10 and alpha lipoic acid. (see Nutrients).

28.1.1.13 Oral Function

Affecting 7% of the population, oral facial pain (OFP) has a direct and reciprocal effect on nutritional status with risk for malnutrition. Due to decrease in function and chewing ability, common dietary advice suggests altered consistencies. However, simply recommending a soft diet may further contribute to deficiencies and malnutrition [98]. Offering customized dietary guidance based on an individual's challenges that may include protein (powders), antioxidant (fruit and vegetables), omega-3 and fiber rich (nuts, flax seeds) smoothies will potentially ensure maintenance of nutritional status, if not improvement in the pain condition.

28.1.1.14 Nutrition Assessment

As the first step, a complete nutritional assessment and interview of the chronic pain sufferer is crucial and improves outcomes and patient satisfaction [99]. All systems need to be reviewed and should include a comprehensive diet history, current intake, nutrition-focused physical findings and functional labs. An integrative assessment includes current and past medical and social health history, current work, stressors, role of exercise, sleep quality, relationships, current familial support and spiritual practice. It is a "how are you?" as opposed to "where is your pain?" Many chronic pain patients arrive angry, depressed, hopeless and have experienced losses in work and life that had previously given them meaning and purpose. Because of chronic pain's pervasive effect on the psychological and social aspects of life, listening, understanding and giving attention to the pain patient's story is the goal and builds trust [100]. Due to the multifactorial nature of pain, a thorough, thoughtful and compassionate patient-centered assessment cannot be understated. Patient participation, investment and co-creation of goals is an integral part of the relationship and is also necessary for a positive

outcome. Asking open-ended questions and motivational interviewing is an optimal approach [101]. As caring for the chronic pain patient can be challenging, the health of the clinician must also be a priority. Introducing a more healthful diet is easier and more acceptable if the clinician can speak to its benefits from personal experience. There are myriad assessment tools that measure pain intensity, its effect on function, mood and specific types of sensation. As mentioned, there are many secondary factors and pain comorbidities including mental health, which encourages an interdisciplinary team approach. Although reduction of pain is clearly a goal, the overall objective is to increase wellbeing and function.

28.1.1.15 Functional Labs to Assess Nutritional Status

Deciding what testing is needed for a patient is an art, a skill and different for each individual. Tests cannot reveal everything, and they should not be solely relied upon, but together with interviews and questionnaires, they can help uncover integral pieces of the puzzle to create a treatment plan to optimize health. As many chronic illnesses begin in the gut, GI tests are often used. Below is a suggested list representative of baseline laboratory testing that is tailored to the individual patient:

- Organic acids test
- Comprehensive stool testing
- Immunologic: Food allergy/sensitivity/intolerance testing
- Glucose tolerance tests
- Candida antibody tests
- SIBO tests
- Methylation testing
- Hormone testing
- Vitamin D status
- Nutrient status testing
- Amino acid testing

28.1.1.16 Therapeutic Diets

As most pain patients view their situation as hopeless, diet can be a powerful and potentially transformative intervention [102]. Most research involving food and a certain disease state focuses on one isolated nutrient. The power of food, however, comes from its synergistic effect: a naturally coordinated and complex array of phytochemicals and nutrients combined, not only with other foods of high biological value, but how it interacts with the biology, genetics and biography of each individual. A shift in the patient's dietary pattern brings the most lasting change. Although much of the research linking dietary patterns and chronic pain has focused on different forms of arthritis [103], as outlined below, many diets have been successful in improving quality of life and ameliorating pain, at times, to resolution. Further, as the etiology of pain is steeped in bio-individuality, the dietary intervention should follow suit, and be tailored to the individual, including personal preferences, traditions and culture. The intervention may be as individual as the biology and biography of the patient in which it resides.

The *Elimination Diet* is universally accepted as the standard for identifying and eliminating potential food intolerances and is a frequent beginning diet. Although there are many versions, suspect foods are eliminated from the diet for a certain period, usually 3–12 weeks, followed by a reintroduction and food challenge phase [104, 105]. After the set period of elimination, foods are brought in one at a time, every 4 days, eating the food often. Accounting for 90% of all food reactions, the top eight allergens are milk, eggs, peanuts, nuts, wheat/gluten, soy, fish and shellfish [106]. Foods that are eaten most often that patients "cannot live without" are usually the most problematic. Many start out eliminating refined sugar, dairy, wheat and processed foods. Removing these foods potentially translates to less activation of innate immune pathways, less inflammation and less pain perception.

Celiac disease testing is recommended for pain patients due to the many non GI manifestations of the disease, but gluten-free diets have been used successfully without having a celiac diagnosis. Migraines, fibromyalgia, different forms of arthritis, IBS, chronic musculoskeletal pain and various idiopathic and identified neuropathies have been substantially improved on *gluten-free* diets [86, 87, 107]. There are ongoing trials to study gluten's effects on low back pain [108].

If the root cause of pain is chronic inflammation, *the anti-inflammatory diet* (AID) is a reasonable option. Considered to be the hallmark of integrative pain management, the AID is followed by many without chronic pain or illness, as it complements a healthy lifestyle. There are several versions, but the concepts are similar and strictness can be adjusted. The AID emphasizes high amounts of fruits and vegetables, whole grains, legumes, soy, fish, herbs and spices. Each dietary component addresses potential inflammatory markers that influence pain. High intake of antioxidants replete with vitamins and minerals modulate inflammatory cytokines, C-reactive protein production and temper damaging oxidative stress. In particular, evidence exists that removal of free radicals—nitric oxide, superoxide, and peroxynitrite—can prevent and reverse inflammatory pain, neuropathic pain, morphine-induced hyperalgesia, and tolerance [14]. In the British Cohort study, low intake of fruits and vegetables contributed to chronic widespread pain [109]. Soy foods may be beneficial in neuropathic pain and osteoarthritis [109, 110]. Broccoli, grapes, fish oil, ginger, green tea and tomatoes were found to reduce inflammation and pain [111]. Inclusion of fish and fish oil supplementation maximizes the omega-3 anti-inflammatory prostaglandins, while mitigating the competing omega-6 arachidonic cascade that is highly influential in modulating pain. (see Fig. 28.4). A personalized anti-inflammatory diet can reduce the prevalence of many of the chronic conditions associated with pain including diabetes, obesity and autoimmune disease.

The *Mediterranean diet*, a mainstay in the nutrition world, is also recommended to pain patients and has been successful in those with RA [110–112]. Similar to the anti-

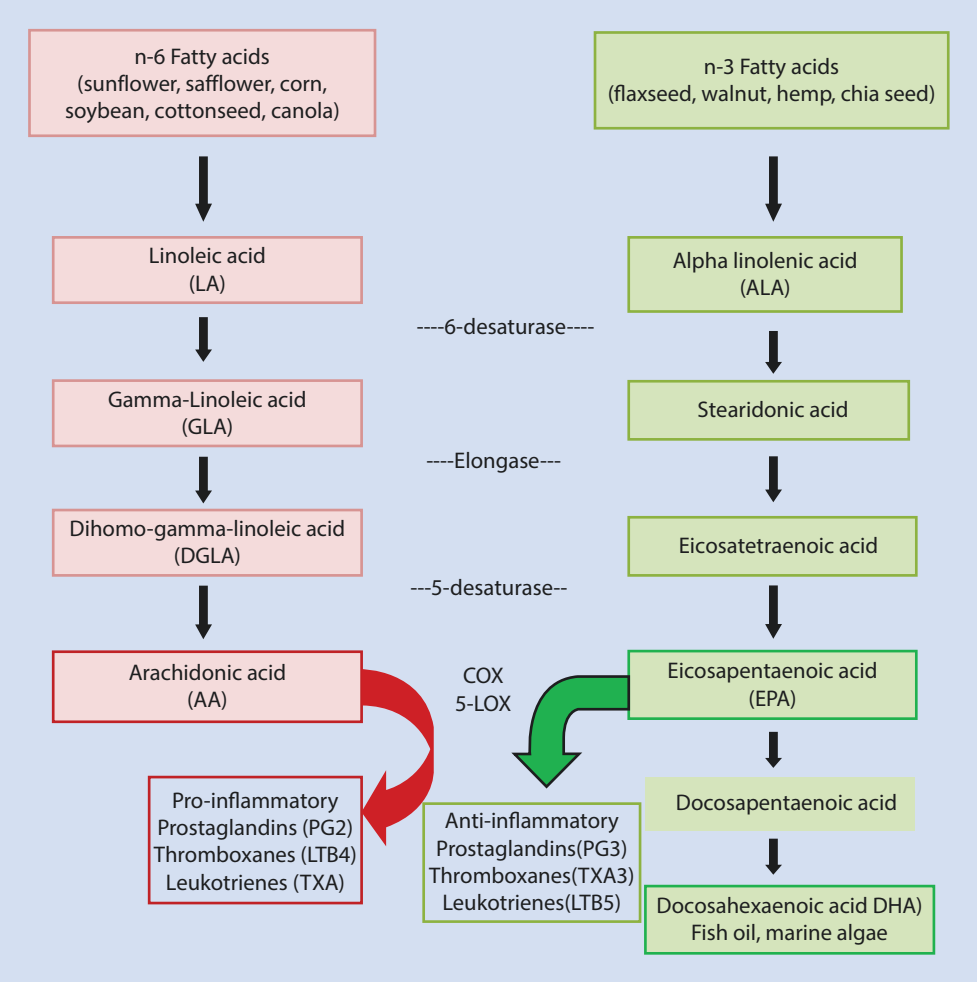

Fig. 28.4 Inflammatory Pathways of Essential Fatty Acids. (Courtesy of Jena Savadsky Griffith, RDN, IHC)

inflammatory diet, it is plant-heavy and features fruits, vegetables, whole grains, fish, less meat, legumes, nuts, olive oil, red wine and exercise. When more attention is given to a healthful eating plan, general health will improve, pain notwithstanding.

Based on the principle of the evolution discordance theory, genetic adaptation has not been able to adjust to our diet since the appearance of agriculture 10,000 years ago, and, more importantly, since the industrial revolution. Accordingly, food processing has altered these dietary indicators: (1) glycemic load, (2) fatty acid composition, (3) macronutrient composition, (4) micronutrient density, (5) acid-base balance, (6) sodium/potassium ratio, and (7) fiber content [38]. Considering we remain similar to Paleolithic ancestors, the principle of the *Paleo Autoimmune Protocol* (AIP) follows that their dietary pattern should still be relevant. Based on the work of Boyd Eaton, the paleo diet includes vegetables, fruits, nuts, roots, meat and organ meats and excludes dairy, grains, sugar, processed oils, alcohol and coffee [113]. Although open to interpretation, the AIP is generally an austere version of the diet, retaining only the most nutrient dense foods while excluding anything potentially inflammatory to even the smallest subset of people. In the age of information, research has yet to catch up with all who have successfully adopted AIP. While the scientific literature analyzing the efficacy of a paleo diet is small, it is unanimous [114]. In a 2017 study of 70 postmenopausal women who submitted to a paleo versus a prudent diet (low-fat, low-calorie, low-salt), both groups lost weight, but those on the paleo diet had greater reduction in inflammatory markers [115]. Type 2 diabetes patients following a paleo diet versus the diet suggested by the American Diabetes foundation (low fat dairy, whole grains, legumes) showed significantly greater glucose control and lipid profile [116]. Diagnosed with MS and confined to a wheelchair, Dr. Terry Wahls began researching brain and mitochondrial health, adopted a version of the AIP, added supplements, lifestyle changes and ended her chronic pain, fatigue and migraines. Her continued clinical trials repeating her process have been successful and have large implications for chronic pain conditions [117]. Critics of the diet suggest it has inadequate calcium supply and maintain that digestive abilities today are different than Paleolithic humans [118].

Vegan, *vegetarian* and *FODMAP* (fermentable oligo-, di-, monosaccharides and polyols) diets have also shown efficacy in chronic pain conditions [119, 120]. Fasting is practiced worldwide for cultural, religious and health

reasons. There is ample empirical and observational evidence that medically supervised therapeutic fasting from 7 to 21 days confers benefits for rheumatic diseases and chronic pain syndrome [121]. After a 7-day juice fast in an integrative medicine clinic, 952 patients with various chronic pain syndromes significantly decreased their pain and improved quality of life [122]. Observational data and experimental research also support caloric restriction, intermittent fasting and a ketogenic diet [123]. Fasting mechanisms include increased production of neurotrophic factors, reduced oxidative mitochondrial stress, autophagy and neuroendocrine activation [124].

The nightshade vegetables and *oxalate*-containing foods may also be implicated in chronic pain. From the *Solanaceae* family, the nightshades include more than 2000 species, but most notably, tomatoes, potatoes, eggplant, peppers of all kinds and tobacco. Mostly linked with arthritis, the nightshades contain specific alkaloids—solanine in potato and eggplant, tomatine in tomato, nicotine in tobacco and capsaicin in garden peppers—that inhibits neurotransmitter enzyme, cholinesterase. When these alkaloids accumulate in the body, with help from other cholinesterase inhibitors such as caffeine, the result may be a paralytic-like muscle spasm, aches, pains, tenderness, inflammation and stiff body movements. Two surveys of arthritis patients adhering strictly to the "no nightshade" diet reported 72–94% had complete or substantial relief from the diet [125].

Foods high in *oxalate* may also cause inflammation and pain. Oxalate is found primarily in plant foods, with highest amounts in spinach, rhubarb, almonds and yams. Ordinarily, oxalate is routinely metabolized, minimally absorbed and excreted. However, compromised gut health causes oxalates to bind with calcium and form crystals that can lodge not only in the kidneys, but within body tissues causing pain. Excess oxalate also leads to oxidative damage and depletion of glutathione [126, 127]. The connection of pain and high oxalates is the basis for the *Pain Project* where participants have gotten relief from fibromyalgia, vulvodynia, interstitial cystitis and pelvic floor dysfunction after following a low oxalate diet [128]. While restoring gut health is of primary concern, experimenting with the elimination of these foods may be a next step if other therapeutic diets are not yielding expected results.

28.1.1.17 Nutrients and Supplementation in Pain Management

Correcting deficiencies and alleviating inflammation are at the core of most evidence-based supplementation for chronic pain. Supplementation of high doses is often used, but importantly, use of supplements has significant advantages and is universally preferred as the side effects are drastically reduced versus pain pharmacotherapy. Changing little over the last 40 years, micronutrient recommended dietary allowances (RDAs) are population statistics, represent rough estimates and are, to some extent, arbitrary figures. Therefore, the optimum level may be on a continuum well above or even below the RDA [129] (See ◘ Table 28.1).

For their role in scavenging reactive oxidant species and suppressing inflammation, antioxidant power is the backbone of a healthy diet, for those with pain and without. Further, concentrated nutrients that complement a healthy antioxidant, fiber-rich diet can increase efficacy of dietary nutrition intervention and further mitigate risks of medications. Due to the nature of scientific research and the study of nutrients in isolation, several supplements have been found to dramatically decrease the intensity of pain and increase function. With any neuropathy, it is recommended that clinicians check for "nutritional neuropathies" or those due to deficiency of specific nutrients, including thiamine, vitamin B12, vitamin E, vitamin B6, niacin, and copper and following bariatric surgery [130].

Bio-individuality is foundational for supplementation. Sufficiency for one patient may be deficiency or toxicity for another. Patient involvement, testing, tracking, individual preferences, current state of microbiota, absorption, excretion, skin color, age, other medical conditions, and medications all factor in to finding the optimal diet and nutrients in order to move toward reducing pain and restoring function.

28.1.1.18 Omega-3 Essential Fatty Acids (See ◘ Fig. 28.4)

Due to their established role in inflammatory pathways, and therefore pain control, long chain omega-3 (n-3) polyunsaturated fatty acids (PUFAs) are popular in pain management and one of the most effective natural anti-inflammatory agents available. Higher levels of n-3s that include DHA, EPA, and vegetable-sourced ALA are associated with lower levels of inflammatory mediators, anti-nociception, and greater emotional/cognitive functioning. Competing omega-6 (n-6) PUFAs are associated with inflammation, nociception and greater psychological distress [131]. Additionally, when EPA and DHA are metabolized by cyclooxygenase and lipoxygenase, they are converted into powerful resolvins and protectins that cause inflammatory recovery and suppression. Although both are essential, ratios of n-6:n-3 have increased substantially over and above the recommended 3:1 to about 20:1 or higher, causing greater inflammation within cell membranes and a biochemical susceptibility to excitotoxicity, cell damage, central sensitivity and chronic pain [132]. Omega-3s alleviated chronic nonsurgical back and neck pain after taking 1200–2400 mg for 8 weeks, with 59% discontinuing their use of prescription NSAIDs [133]. Similar results were found for RA with 2.7 g/day for 3 months [134], and after a dietary intervention of high n- 3s and, importantly, a low intake of n- 6s, chronic headache sufferers reduced headache pain, altered antinociceptive lipid mediators, and improved quality of life [135]. Although the mechanism is hypothesized, animal studies have found n- 3s to be protective and alleviate neuropathic pain, post-traumatic brain injury, stroke, ALS, diabetes, lupus and other neuroinflammatory conditions [136]. Five

Table 28.1 Summary of dietary supplements used in the treatment of chronic pain

Nutrient/supplement/functional food	Pain states	Known action	Suggested dosage	Considerations
Omega-3	All	Anti-inflammatory	2.7 g/day EPA and DHA	Anticoagulant properties
Omega-6, borage/EPO		Anti-inflammatory, anti-thrombotic	500–1800 mg/day	
Cod liver oil (A,D,omega-3)	All	Immunity, inflammation, bone health	1 tsp/day	
Vitamin D	All	Immunity, inflammation, bone health	Level dependent 1000–2000 iu/day	Personalization, with A, K2, magnesium
Magnesium	All	Inflammatory mediator, muscle function, energy production, immunity	400 mg/day or more	Cofactors B6 and boron
Vitamin B1/thiamine	FM, alcoholic neuropathy	Mitochondrial function	600–1800 mg/day	
Vitamin B2/riboflavin	Headaches	Mitochondrial function	400 mg/day	
Vitamin B12	Back, neck, neuropathy, neuralgia	Neuroprotection, regeneration	1000 mcg/day	Cofactor folate
Bee pollen		Anti-inflammatory, antioxidant, rich nutrient profile including B complex	½–1 tsp.	Begin slowly to ascertain tolerance/allergy
Quercetin	RA, inflammatory pain, allergy headache, gout, spinal cord injury	Antioxidant, anti-inflammatory, analgesic, antihistamine	500–1000 mg/day	Often formulated with Bromelain, Contraindicated for kidney disease
Turmeric	Arthritis, JP, FM, IBS, DN, PMS, gout	Anti-oxidant, anti-inflammatory, analgesic, anti-arthritic	Average of 400–600 mg/3×/day	Anticoagulant properties
Ginger	RA, OA, migraine, JP, dysmenorrhea	Anti-inflammatory	200–500 mg/day	
Boswellia	RA, OA, dysmenorrhea	Anti-inflammatory, analgesic	300–500 mg/2–3×/day	
Willowbark	Headache, back, myalgia, RA, OA, dysmenorrhea, gout	Anti-inflammatory, analgesic	240 mg	Not for use with children, peptic ulcers or any condition where aspirin is contraindicated
Butterbur	Migraine/headache	Anti-inflammatory, antispasmodic	50–150 mg/day, age dependent	Extracted to remove hepatotoxic alkaloids
Feverfew	Migraines, RA, dysmenorrhea	Anti-inflammatory, inhibit platelet aggregation	6.25 mg 3×/day. (CO2 extracted)	Not with anticoagulants or during pregnancy

FM Fibromyalgia, *JP* Joint pain, *RA* Rheumatoid Arthritis, *OA* Osteoarthritis

patients with chronic pain resulting from burns, spinal stenosis, carpal tunnel syndrome, fibromyalgia, and cervical disc herniation were given 2400–7200 mg of EPA/DHA for at least 7 months, with all reporting significant pain reduction [137]. Fish oil also appears to attenuate the negative cellular and behavioral effects of opioids [138]. A lower dietary intake of omega-6 fatty acids, however, will necessitate a lower need for omega-3s. Quality sourcing of all essential fatty acids and understanding the potential for interaction with other anticoagulants (herbal and pharmaceutical) is important in clinical application.

Discovered in 2008, unsaturated fatty acid palmitoleic acid, or Omega-7, has also been found to have potential anti-inflammatory effects on metabolic diseases and muscle pain.

Potentially controlled by mTOR (mechanistic target of rapamycin) signaling, it is found in macadamia nuts, sea buckthorn oil, olive oil and in certain fish, such as salmon and anchovy [139].

28.1.1.19 Omega 6 Fatty Acids

While omega-3s understandably receive all of the anti-inflammatory notoriety, omega-6 fatty acids are in fact, essential and offer their own, often overshadowed, benefits for chronic pain and inflammation. Gamma linolenic acid (GLA) specifically, has proven anti-inflammatory benefits. Found in plentiful amounts in our food supply, linoleic acid (LA) from seed oils (sunflower, soy, corn) is the starting point for the synthesis of omega 6, mirroring the processes of omega 3, using the same or similar enzymes to form arachidonic acid:

LA → (GLA) → dihomo-gamma-linolenic acid (DGLA) → arachidonic acid (AA) (See ◘ Fig. 28.4).

DGLA is anti-inflammatory and anti-thrombotic and counteracts the inflammatory actions of AA. However, DGLA must be synthesized in the pathway from LA and GLA with all enzymes functioning, specifically, delta-6-desaturase, which naturally decreases with aging. If the conversion process is compromised, AA, in oversupply from the diet, flourishes, creating greater inflammation. Regarding chronic pain states, this reduced capacity to create DGLA has been associated with rheumatoid arthritis, diabetes and associated neuropathy, dermatitis/eczema, premenstrual syndrome, obesity, cancer and cardiovascular disease.

28.1.1.20 Vitamin D/Vitamin A

Extensive research concludes a worldwide deficiency of vitamin D, from 40% to 75% of the population, greater in the northern hemisphere and in those with pain. Known for its most direct role in osteomineral metabolism, vitamin D is more recently known for its contribution to immunity strength, cell growth, neuromuscular function and inhibition of inflammation [140, 141]. With vitamin D receptors in virtually every cell, it may be responsible for regulating more than 200 genes and has potential influence on multiple biologic systems of the body. It is also considered a neuroactive steroid that may modulate neuronal excitability. Some research shows indirect support for a role for vitamin D in nonspecific musculoskeletal pain, central sensitization (migraines and fibromyalgia), abdominal pain, knee pain, back pain and various pain comorbidities [142]. Although several studies have shown vitamin D supplementation to improve sleep, mood, pain levels and well-being, there is inconclusive evidence to implicate vitamin D deficiency in the etiology or maintenance of chronic pain or that supplementation alone will confer alleviation [142]. The most efficient source of vitamin D is the sun. Small amounts of vitamin D are found in several foods, including fatty fish, egg yolks, yogurt and mushrooms. The highest amount of food-sourced vitamin D is in cod liver oil at 450 iu/tsp and is often used, as it has a complementary amount of vitamin A. Pastured butter or ghee are additional sources of K [143]. If supplementation is used, vitamin D3 is the preferred form.

Testing should be done every 3 months. Vitamin D status is most often measured by storage 25(OH)D in the blood. The US lab reference is 30–74 ng/mL, while the Vitamin D Council recommends 40–80 ng/mL. However, based on a review of more than 1000 studies, the IOM recommends a more conservative range of 20–50 ng/mL, citing little to no benefit over 50 and increasing evidence that high levels cause harm. According to these definitions, the entire population may be deficient, and in fact, low OH (25) levels are found in both sick and healthy individuals. Therefore, a re-evaluation of this method of measurement is needed, as it does not consider the active form of vitamin D, the relationship between storage and active D, metabolic factors affecting its conversion (inflammation, infection, current mineral and nutritional status), genetics and other matters of bio-individuality.

In order for a nutrient, vitamin or mineral to become metabolically active, it often needs cofactors [143]. The metabolism of storage or pre-formed D, 25(OH)D (calcidiol) at every stage—in the skin, liver and kidney—into its active form 1,25(OH)2 (calcitriol) requires sufficient magnesium. In a state of hypomagnesemia, calcium is usually high. As Vitamin D absorbs intestinal calcium for use, with ample calcium, vitamin D may remain low. While magnesium has its own cofactors, attention should also be given to sodium and potassium to balance electrolytes. Further, vitamin A is D's biological antagonist. For vitamin D to be effective, sufficient, fat-soluble, vitamin A is needed; thus, vitamin A and vitamin D protect against the other's toxicity [144].

Recent studies also suggest that A and D also need vitamin K2, found in animal fats and fermented foods. Vitamin K2 ensures that calcium is appropriately transported to bones and teeth rather than to the soft tissues, contributing to disease. The many roles of vitamin D in the maintenance of health is a subject of continuing research. Whether low vitamin D is a physiological response or cause of disease has yet to be absolutely confirmed. In an integrative and functional setting, it is important to investigate the potential root cause before artificially raising vitamin D levels with supplementation.

28.1.1.21 Magnesium

Magnesium plays an essential role in hundreds of physiological processes and is critical to the electrical stability of cells. As it relates to pain, magnesium is instrumental in blocking the NMDA receptor, whose excessive stimulation is the primary mechanism of central sensitization. Low magnesium also enables excess substance P response, which triggers the entire inflammatory cascade [145]. Magnesium deficiency should be considered a public health crisis with some experts estimating current magnesium deficiency of the population as high as 80%. It quietly contributes to the process of inflammation and pain, therefore implicating all chronic disease and pain comorbidities including insulin resistance, obesity, depression, anxiety and insomnia. Magnesium is central in energy production, bone health, and muscle relaxation with deficiencies leading to cramping, spasms, myofascial tightness, and tightness in the smooth muscles of the GI tract.

Supplementation significantly alleviated pain in patients with migraines, fibromyalgia, neuropathic pain, chronic low back pain, IBS, diabetic neuropathy and postherpetic neuralgia [146–151]. Correcting magnesium deficiencies can potentially correct both the symptom and cause of chronic pain. With most magnesium stored in bone and soft tissue (99%) and the remaining under tight control, testing serum magnesium is inefficient and deficiency often goes unnoticed. A preferred test would be a Mag RBC test (magnesium red blood cell). Although not without its limitations, assessing RBC magnesium inside the cell as opposed to serum outside the cell will provide an earlier indicator of magnesium deficiency. An increase in refined foods, greater environmental and emotional stress, inflammation, infection, excess calcium, excess vitamin D, depleted soil mineralization, and drug interactions account for many of the contributing factors for deficiency. Cofactors include vitamin B6 and boron for absorption and proper utilization. Magnesium needs and levels fluctuate, depending on absorption, stress levels and myriad other factors with many deficiency symptoms included in a pain sufferer's profile: anxiety, insomnia, depression, fatigue, constipation, hypertension, muscle cramping, headaches, etc. As magnesium is a critical, water-soluble electrolyte needed daily, attention should also be given to the balance of sodium, chloride and potassium. Including mineral-rich sea salt and food sources of potassium (virtually all fruits and vegetables) is required to keep minerals regulated and/or from one mineral depleting the other. Dietary sources of magnesium include greens—one of the most missing foods in the modern diet—as well as nuts, seeds, and whole grains. Supplementation in the form of glycinate, malate, taurate, or threonate, 200–400 mg or higher, may be best for chronic pain sufferers; however, magnesium form may need to be personalized and started slowly. No less important is magnesium in oil form applied topically and Epsom salt baths.

28.1.1.22 B Vitamins

Essential for various metabolic processes, several B vitamin deficiencies are implicated in chronic pain. Vitamin B6 is a cofactor for the enzyme reaction that converts excitatory neurotransmitter glutamate into inhibitory neurotransmitter, GABA. Without sufficient B6, there is more glutamate and less GABA, which fuels excitotoxicity in the CNS [145]. Without sufficient B6, blood homocysteine levels increase, contributing to inflammation and potential toxic effects on CNS neurons. Elevated homocysteine is one potential mechanism for migraines [152]. Neuropathy due to B6 deficiency begins with numbness, paresthesias or burning pain in the feet which then ascends to affect the legs and eventually the hands. Although deficiencies are rare in the general population, chronic pain patients with inflammation and higher intake of NSAIDs will have disrupted B6 metabolism. Excess B6 can also cause neuropathy [130].

Fibromyalgia may have symptoms in common with thiamine deficiency; high doses of thiamine, 600–1800 mg/day, produced significant decreases in pain [153]. Alcohol intake should be assessed, as neuropathy can be the result of depleted thiamine. Riboflavin, vitamin B2, addresses the potential cause of migraines as aberrant mitochondrial metabolism. Daily use of 400 mg of B2 for 3 months resulted in a 50% reduction in headaches for the majority of patients [154].

Due to its integral role in neurological function and myelin integrity, vitamin B12 (methylcobalamin or hydroxycobalamin or adenosylcobalamin,) has been used for decades to treat pain. In other countries it has been labeled as an analgesic drug. Through supposed neuroprotective and regenerative actions, B12 administered orally and via injection has been successfully used to decrease pain in chronic low back pain, neck pain, diabetic or chemo-induced neuropathy and various forms of neuralgia [155]. Pain may be alleviated even with adequate levels of B12. Vitamin B12 supplementation of 1000 mcg, combined with a plant- based diet, improved pain in diabetic neuropathy patients compared to just supplementation alone [156].

A deficiency of B12 is linked to inadequate folate. Proper functioning of the folate cycle ensures formation of neurotransmitters, the pain signal messengers. As a critical cofactor for B12, inadequate folate can mask B12 deficiency; therefore, giving isolated folate without B12 is contraindicated. A sublingual dose of B12 at 1000 mcg is helpful. B12 may improve pain, insomnia and fatigue [157]. Assuming no genetic polymorphisms (MTHFR), taking a full range of B vitamins in combination may also be beneficial than one in isolation. Vitamins B1, B6 and B12 in combination with other medical therapy alleviated pain and increased mobility in those with back pain [158].

As the body does not store water-soluble B vitamins well, the need for them may be increased for the chronic pain population. Liver, poultry, shellfish and eggs have high amounts of B vitamins, especially B12. Plant sources include whole grains, potatoes, lentils and beans. Leafy greens are high in folate. An overlooked source of B-complex vitamins, including B12, is bee pollen, one of the richest sources of vitamins found in a single food in nature. If folate supplementation is used, L-methylfolate or folinic acid is preferred.

Other nutrients studied for their effect in the management of pain include coenzyme Q10, 5- HTP, glucosamine and chondroitin, MSM, alpha lipoic acid, melatonin and resveratrol.

28.1.1.23 Essential Nutrients

In a larger context, everything taken in, from food to oxygen to art, is essentially a nutrient, with its own specific energy. Experiences of life are absorbed in many ways that have physical, emotional and spiritual effects. Nutrients can be put on a continuum from inflammatory to nourishment, depending on individual, context and other known and unknown variables. Other overlooked and underestimated nutrients that increase pleasure, comfort, and joy while decreasing pain that are evidence-based and empirically substantiated include light, nature, music ("robustly relieves pain"), love, touch, community, dancing and laughter, hugging yourself and others, gratitude, and spiritual practice [159–167].

28

28.1.1.24 Hydration

Thirst is our own odometer, a signal from the hypothalamus that our blood volume is too high. However, for many, the sense of thirst becomes dulled. It is especially an issue within the vulnerable pain populations of the elderly and children. Among children and adolescents, water accounted for only 33% of fluid intake, with the remaining coming from high-calorie beverages [168]. As an underappreciated disease etiology, dehydration causes decreases in cognition and GI function, headaches, muscle and joint pain. Recently, even mild dehydration was found to increase pain sensitivity and pain perception [169]. Water provides lubrication for tissues, cartilage, discs and joints. Without water, there is slowed nutrient transportation, a buildup of metabolic waste and increased inflammation. Increased water intake reduced gout attacks by almost 50% [170]. There are several recommendations for water intake including the standard six to eight glasses or half the individual body weight in ounces, with needs fluctuating depending on activity, season, temperature, and energy intake.

In addition, many of the fluids commonly consumed today are diuretics—soft drinks, alcohol, tea and coffee. The most widely consumed legal drug in the world, coffee, is a CNS stimulant that is more of a cultural habit, than a hot beverage. Coffee as a recommendation for pain relief is controversial. Although the mechanism is unknown, caffeine is said to potentially reduce pain through its effect on adenosine receptors [171]. Conversely, caffeine triggers a stress response and causes various alterations in brain chemistry including neurotransmitter imbalances (serotonin, dopamine, GABA) that lead to irritability, mood issues, depression, headaches, insomnia and fatigue. It decreases melatonin [172] and can affect nutritional status by increasing insulin resistance, depleting vitamin B6 and inhibiting absorption of magnesium, B vitamins calcium, iron and vitamin D [173]. Although it is considered an antioxidant, there are individual sensitivities and varied genetic traits related to caffeine metabolism. Considering its range of parallel effects in the chronic pain population (sleep, anxiety, glucose control, dehydration), assessing function and pain without coffee/caffeine would be recommended.

28.1.2 Plant Compounds

28.1.2.1 Turmeric (*Curcuma longa*)

A long history of use in Ayurvedic medicine and extensive research over the past half century has confirmed that turmeric, with active ingredient *curcumin* (77%), has antioxidant, anti-plaque, anti-arthritic, anti-cancer and anti-inflammatory properties. In Sanskrit, turmeric is credited with 53 names, most likely due to its various mechanisms; however, research indicates that blocking the activation of NF-kB, the body's central inflammatory switch, along with other inflammatory mediators, may be its main pathway [63, 174]. Turmeric contains at least six different COX-2 inhibitors, the enzyme responsible for the inflammatory prostaglandin PG-E2, and may also deplete substance P. Studies indicate pain relief with turmeric in arthritis, diabetic neuropathy, gout, joint pain, IBS, PMS and fibromyalgia, in addition to positive influences on obesity, diabetes and depression [175, 176]. Curcumin was equal to and advantageous to ibuprofen in a 4 week study of OA of the knee [177]. The most comprehensive summary of turmeric benefits concluded that it outperforms many pharmaceuticals against chronic and debilitating diseases with virtually no adverse side effects [178]. Results have been found with as little as 200 mg/day or up to 8 g with an average dosage of 400–600 mg three times per day. In addition to capsule form, it can be added to food, taken as tea, and heated and made into a turmeric milk. Bioperine (black pepper) increases the bioavailability of curcumin by up to 2000% [179]. Turmeric's anticoagulant properties should be considered.

28.1.2.2 Ginger (*Zingiber officinale*)

Ginger is one of the most consumed dietary condiments and a member of the same plant family as turmeric (Zingiberaceae). It has been used alone and in combination with other herbs for thousands of years for its antioxidant anti-inflammatory properties. Ginger is effective in treating pain of RA, OA, migraine (in combination with feverfew), joint pain and dysmenorrhea. Historically used for OA and RA, ginger inhibits several inflammatory mediators, most notably enzymes 5-lipoxygenase and COX-2. Dosages range from 200 to 500 mg daily [180, 181].

28.1.2.3 Boswellia

Considered one of the most ancient and valued herbs in Ayurveda, gum resin is tapped from the boswellia tree then dried to extract the oil and solidify the resin. The resin has various terpenes and four major boswellic acids responsible for the inhibition of pro-inflammatory enzymes. The most potent is acetyl-11-keto-β-boswellic acid (AKBA) that specifically inhibits leukotrienes via 5-Lipoxygenase (5-LOX), a major inflammatory enzyme [182].

Boswellia has been used analgesically for RA, OA and dysmenorrhea. Pain from knee OA was reduced notably within 7 days, and there were significant improvements seen after 90 days of using boswellia standardized to contain 30% AKBA. Beyond its analgesic effects, patients had unexpected joint regeneration, assigning disease modification benefits [183]. Often taken with other herbs, a combination of boswellia and curcumin proved superior in effectiveness and tolerability compared to diclofenac for OA [63]. A later OA study proved similar results versus 200 mg celecoxib (celebrex) with a combination capsule of 700 mg curcumin and 300 mg boswellia extract. *Boswellia* products vary, but it is typically given as an extract standardized to contain 30–40% boswellic acids, 300–500 mg two or three times/day [63].

28.1.2.4 Willowbark

Dating back to the time of Hippocrates, patients were advised to chew on willow bark for pain and fever [184]. It is often called "nature's aspirin" because the active ingredient of willow bark is salicin, used to develop aspirin in the 1800s. Its analgesic and anti-inflammatory properties, however, come from salicin's combination with flavonoids and polyphenols within the bark. Although both are nonselective COX-1 and COX-2 inhibitors, its multicomponent synergy gives willow bark a broader mechanism of action than aspirin, without the GI damage. People have used the herb for headache, low back pain, myalgia, OA, RA, dysmenorrhea and gout. Patients with low back pain receiving 240 mg of willow bark had more significant relief than those receiving 120 mg or placebo [185]. Willow bark should not be used in children, in those with peptic ulcers or any other condition where aspirin is contraindicated [63].

28.1.2.5 Butterbur and Feverfew

Headaches are one of the most common types of chronic pain reported by Americans. After magnesium, both butterbur and feverfew, respectively, are commonly used in headache treatment and prevention, separately and in combination. Butterbur, *Petasites hybridus* root extract, is thought to inhibit inflammatory leukotriene production and have a potential antispasmodic effect on cerebral blood vessel walls [186]. Migraine frequency was reduced by 48% in those who took 75 mg of petasites BID [187]. Almost 80% of children and adolescents reported a reduction in migraine frequency of 50% by taking 50–150 mg/day, depending on age, for 4 months [188]. Butterbur has hepatotoxic alkaloids so the extract must be manufactured carefully to remove them.

Called medieval aspirin, the parthenolides within the leaves of feverfew are thought to be its active ingredient and mechanistic driver. These compounds may relieve migraines, RA and menstrual pain by inhibiting inflammation and platelet aggregation, which normalizes blood flow. Feverfew contains many medicinally active compounds including melatonin and an essential oil, chrysanthenyl acetate. Some evidence shows lack of efficacy which is thought to be due to varying plants and bioavailability, extracts used and dosage [186, 189]. Feverfew is not recommended during pregnancy or with anticoagulants. If taking for more than 1 week, stopping abruptly could produce rebound headaches and/or joint pain. Studies have used 100–325 mg up to four times daily for adults, standardized to contain 0.2–0.4% parthenolides. For feverfew supplements that are carbon dioxide extracted, 6.25 mg, 3 times daily, for up to 16 weeks was successfully used [189].

28.1.2.6 Cannabinoids

Despite political, legal and social issues surrounding its use and history, the addition of cannabinoids to the clinician's toolbox offers another approach and is evidential in chronic pain. Further, surveys report that due to lack of education and resources about cannabinoids, clinicians often do not bring up the topic [190]. Cannabis or medical marijuana is one of the most pharmacologically active plants known, with more than 400 chemical compounds, 85 of which are cannabinoids. The main cannabinoids by volume and notoriety are delta-9-tetrahydrocannabinol (THC), its primary psychoactive compound and cannabidiol (CBD), the non-psychoactive counterpoint [191]. Among its many properties, THC is a potent antioxidant, neuroprotective, anti-inflammatory and painkiller. Influencing many pathways, THC inhibits glutamate release, a central mechanism in most chronic pain conditions. CBD dampens THC's psychoactivity and elevates the plant's potency with its own complex anti-inflammatory and analgesic regulating effects. Possessing 20 times the antioxidant power of vitamin C and E, CBD notably inhibits TNFα. The study of cannabinoids led to the discovery of the endocannabinoid system, a group of endogenous cannabinoid receptors, CB1 and CB2, throughout the CNS and PNS that regulate homeostasis and have a significant role in the regulation of pain. Much like the bicarbonate buffer system regulates blood pH, the endocannabinoid system reacts to the environment and mediates response to mood, sleep, hormone regulation, pain and immunity [191, 192]. Notably, dietary omega-3 fatty acids reverse the dysregulation of the endocannabinoid system, improve insulin sensitivity and control body fat [66].

Current pain conditions may be a potential endocannabinoid deficiency. Although current research is hindered by its schedule one status by the US Drug Enforcement Administration, studies confirm that cannabis alleviates chronic pain conditions, neuropathic pain, headache, and untreatable pain, often with relief from stress/anxiety and insomnia, with minimal, if any side effects [193, 194]. Adverse effects are more often reported with synthetic versions [195]. Further, in 2014, the American Academy of Neurology provided a level A effectiveness to oral cannabis extract for spasticity related symptoms and pain [196]. Cannabinoids are delivered via smoking, vaporizers, sprays, tinctures and edibles. Medical marijuana is currently legal in 33 states and Washington, D.C., with only a few states approving treatment specifically for chronic, severe or intractable pain [197].

Interest in medicinal potential of CBD has catalyzed a rebirth of hemp in the USA and CBD hemp oil. Often confused, hemp and cannabis come from the same species, *Cannabis sativa*; however, hemp contains only trace amounts of THC. In order to be legal, it must have a THC content below 0.03%. There are varying hemp laws by state and much is imported [192, 198]. Securing its non-psychotropic status, it is considered a less controversial alternative while still maintaining the plant's benefits. Animal studies show CBD-induced suppression of chronic pain without tolerance. Researchers suggest these non-psychoactive components of cannabis may represent a novel class of therapeutic agents for the treatment of chronic pain [199]. Usual methods of delivery for CBD hemp oil include tincture and capsule form. Standards range; therefore attention must be given to a product's cultivation, harvest, extraction, exact constituents, testing, and manufacturing.

28.1.2.7 Medical Treatment and Nutritional Implications

A thorough physical, functional and psychological examination with detailed pain, medical and psychosocial history is vitally important to guide diagnosis and treatment. Additional testing is usually done to categorize the pain, determine its etiology and consider emotional and environmental factors. There is not one diagnostic test for chronic pain and, although helpful in certain cases, imaging does not always reveal a specific pathology or problem. Despite pain as one of the most universal symptoms in medicine, the assessment of a pain patient is challenging and takes time not often available. As pain is a subjective experience unable to be viewed by others, the evaluation of pain characteristics relies on self-reporting. Its complexity has further led to varying pain measurement scales and questionnaires that attempt to capture the patient, the pain and contributing and relieving factors. There are one-dimensional tools that that measure pain intensity, as in the Verbal Rating Scale (VRS), Numerical Rating Scale, Visual Analogue Scale (VAS) and Faces Pain Scale, which is helpful with children. More complex tools, such as the McGill Pain Questionnaire, distinguish nociceptive from neuropathic pain and attempt to decipher the pain dimension: sensory, affective and/or evaluative. Additional tools exist to assess function, substance abuse, opioid risk, emotional distress, potential for catastrophizing and pain-related fear and depression [200–203].

As complete analgesia is rarely achievable, the goal of medical treatment is to improve pain, and more importantly to optimize physical function and coping. One in three patients will get greater than 50% pain relief, which is regarded as an excellent result in chronic pain [200]. Pain medications fall into three general categories:

1. *Non-opioids*: aspirin, non-steroidal anti-inflammatories (NSAIDs), and acetaminophen (paracetamol).
2. *Opioids*: morphine, codeine, hydrocodone, oxycodone, methadone, fentanyl, etc. Although not true opioids biochemically, Tramadol and tapentadol are included as they work on the same receptors.
3. *Non-opioid or adjuvant analgesics*: Medications that may alleviate pain, although primary use is for another indication: antidepressants, anticonvulsants and antiarrhythmics, corticosteroids, muscle relaxants, local anesthetics, topical medications, adrenergic agonists, sympatholytics, and neuroleptics.

The use of NSAIDs remains a first line of defense for most classic physicians for mild to moderate joint, spine-related pain and headaches. Besides their well-known inhibition of prostaglandin synthesis via both COX-1 and COX-2 enzymes, their mechanism of action in producing analgesia is multifactorial, exhibiting both central and peripheral effects [63]. By blocking COX-1, which also normally acts to protect the gastrointestinal mucosa, nonselective NSAIDs and aspirin can cause significant GI and other tissue damage including gastritis, abdominal pain, ulceration, edema, hemorrhage, renal impairment, hypertension and death. This was the stimulus for the creation of such selective COX-2 NSAIDs as celecoxib (celebrex). However, more recently, all NSAIDs and in particular, COX-2, were found to increase risks for heart attack and stroke [204]. After 14 days, Ibuprofen was found to reduce testosterone production in males with implications for fertility, muscle mass and strength, fat distribution and mental health. Recommendations are to prescribe lowest possible doses for shortest duration. To mitigate GI damage from NSAIDs, many patients are given proton pump inhibitors (PPIs). Usually given for gastrointestinal reflux (GERD), PPIs are among the top ten most widely used drugs in the world with many patients remaining on them for long periods of time, without evidence-based indication [205]. However, these medications do not offer protection to the lower small intestine, but exacerbate NSAID-induced small intestinal lesions and increase the presence of pathogenic bacteria in the gut microbiome. The initial microbiotic insult from NSAID use decreases beneficial *lactobacilli* and impairs intestinal pH, permeability, mucosal production and immunity [206]. Following PPI treatment, there is an additional loss of beneficial and protective bacteria *Bifidobacterium* and *Lactobacillus*. Further, PPIs are associated with a deficiency of vitamin B12, iron, vitamin C, calcium, and magnesium [14, 204–207].

Due to the gastrotoxicity of NSAIDs, and PPIs when applicable, acetaminophen is recommended by the American College of Rheumatology for mild-to-moderate pain as first line therapy for OA of the knee and hip and lower back pain [208]. For its safety profile over NSAIDs, acetaminophen is also recommended for the elderly population [209]. Although too mild for most for most chronic pain patients and lacking in anti-inflammatory properties, it may have a sparing effect when taken with NSAIDs and opioids. Care should be taken regarding the potential hepatotoxicity of acetaminophen and its interaction with high doses of vitamin C [210].

Opiates are the mainstay of pain management for severe chronic pain. While opiates stem specifically from the alkaloids of the poppy plant (heroin, morphine, codeine), opioids are synthetic drugs that produce opiate-like effects and include oxycodone, Percocet, Demerol and methadone. Clinically, the term "opioid" now encompasses all natural and synthetic versions that act upon opioid receptors in the CNS, PNS, and immune system. The opioid system consists of three G-protein coupled receptors, Mu, Delta and Kappa, usually activated by endogenous opioid peptides like endorphins. Individual drugs interact with each receptor, accounting for the differences in analgesia and various side effects; however, the majority of activity occurs on the Mu receptor. Opioids are often called Mu agonists. The net effect of Mu receptor activation is inhibition of pain signal transmission to the brain and a decrease in the perception and experience of pain [11, 211].

Opioid receptors are also involved in other functions of the body, including modulation of reinforcement and reward mechanisms, which can sometimes drive the addictive pattern of use. Results of activation also include the most common side effects of constipation, respiratory depression, itching, sedation and nausea. With rates ranging from 15% to 90%, mitigating opioid-induced constipation is an important aspect of the management of a patient's quality of life. Increasing fiber, fluids, and activity is recommended, with fiber intake occurring several hours before or after taking the drug so as not to interfere with bioavailability [11].

Other side effects can be altered mood and cognitive function, dry mouth, urinary retention, sexual dysfunction, sleep disturbances, dizziness, hypotension and myoclonus (muscle twitching) [11]. Due to adverse side effects, approximately 20% discontinue therapy [212]. Often unrecognized, long-term opioid use also causes hormone suppression. Opioids action on receptor sites can lead to inhibitory or stimulatory effects on hormone release. Testosterone appears to be most often affected, leading to decreased libido and erectile dysfunction in men, oligomenorrhea or amenorrhea in women, and bone loss or infertility in both sexes [213].

Frequently misunderstood, tolerance and dependence are normal physiological responses to opioids. A more recently recognized opioid toxicity is induced hyperalgesia (OIH), where increasing the dose of the opioid exacerbates the pain [214].

While accepted for cancer-related pain, the use of opioids for chronic pain has been controversial due to concerns about side effects, long-term efficacy, functional outcomes, and the potential for drug abuse and addiction. These concerns have often led to the undertreatment of pain patients. Heeding criticism, physicians began prescribing more pain medications in the 1990s with the support from many professional pain societies. In response to the growing prevalence of chronic pain and its disabling effects, opioid prescriptions have increased to the point that they are the most commonly prescribed class of medications in the USA, with pharmacies dispensing 245 million prescriptions in 2014. The rate of death from opioid overdose has quadrupled in the past 15 years and nonfatal overdoses needing hospital care increased six times [215, 216]. While many opioids are diverted and improperly used, at the core of what is now called an opioid crisis is an increasing cohort of those in chronic pain, overreliance on a known analgesic, and limited alternatives for prescribing physicians [11, 217].

When pain cannot be controlled with medications and central sensitization cannot be prevented, there are various interventional pain procedures that can be used. These include nerve blocks, injections, ablative procedures, implants and neuromodulation.

28.1.2.8 Genetics

Genetics also has a role in the biopsychosocial matrix of an individual's perception and response to pain. Heritability can be explored across pain disease states or by the pain signaling process, adding another layer of complexity to its study. By examining pain behavior in female twins, genetic factors could account for 22–55% of the variance in chronic pain [218]. Although in early stages of research, various genes encoding for receptors are now known to play a role in pain sensitivity, reporting and susceptibility. Overall, the genetic contribution to chronic pain suggests small variations in a large number of single nucleotide polymorphisms (SNPs) that may represent different functional pathways [219, 220]. One of the most extensively studied "pain genes" is catechol-O-methyltransferase (COMT), an enzyme involved in the inactivation of dopamine, epinephrine, and norepinephrine (catecholamines) neurotransmission [221]. Sustained elevation of catecholamines, released from the adrenal glands in response to stress or severe pain, is associated with chronic pain conditions. Several single nucleotide polymorphisms (SNPs) of the gene that encodes COMT have been found to lower its activity, thereby increasing pain sensitivity. SNPs in the Mu opioid receptor gene, OPRM1, may contribute to individual differences in pain sensitivity. Further, mutations in OPRM1 and COMT combined may modulate opioid efficacy [222].

There are several genes that affect neurotransmitters. SNPs of the GCH1 gene (encoding GTP cyclohydrolase) has been shown to have a protective effect on lower back pain after surgery, less sensitivity to heat, ischemic and pressure pain and reduced incidence of low back pain. Polymorphisms of the serotonin transporter gene (*SLC6A4*), beta 2 adrenergic receptor ADRB2, and serotonin receptor 2A HTR2A are all associated with an increased risk for chronic widespread pain. Alterations in pain-related genes associated with ion channel function may also contribute to chronic pain susceptibility as found in sciatica, OA, phantom limb pain and discogenic disease. Called the neuropathic pain susceptibility gene, CACNG2, a protein involved in the transport of glutamatergic AMPA receptors, significantly affects susceptibility following nerve injury [221].

Although not related directly to pain signaling, genetic mutations in enzymes involved in the folate methylation pathway may be a factor in the pain population. Two common SNPs, C677T and A1298C have been identified in the MTHFR gene that codes for the methylenetetrahydrofolate reductase enzyme, also MTHFR. Mutations in this gene cause decreased activity of the enzyme, thereby disrupting methylation and blocking key detoxification pathways [220].

28.1.2.9 Epigenetics

In an experimental study of healthy adults, pain intensity ratings ranged from 0 to 100 (bottom and top of the scale) for an identical cold-water stimulus [222]. As experienced by each individual differently, the concepts of environment and bio-individuality are embedded within the definition of pain. Environmental toxins, medications, diet, and psychological stresses can alter epigenetic processes such as DNA methylation, histone acetylation, and RNA interference [223]. Epigenetic mechanisms modify DNA expression depending on information received from the environment. Early life experiences can positively or negatively leave their biological

mark on the genome. Negative childhood experiences have been linked to mental health, drug addiction and obesity, all mediating factors in chronic pain and treatment [224]. There are also learned coping strategies and behaviors, learned reactions to pain and attention received as the result of pain at all ages. Familial patterns, lifestyle and diet are more of an epigenetic factor than genetic, and have a profound influence on susceptibility to disease. After nerve injury, more than 1000 genes may be activated or turned on with significant evidence pointing to epigenetic control from, at minimum, inflammation, immune response and opioid receptor function. What turns the acute pain into chronic is the biological terrain and environment it occurs within [225].

As an active mediator of inflammation, immunity and the microbiome, nutrition has significant epigenetic power. Nutrients can influence gene expression by directly inhibiting enzymes that catalyze DNA methylation or histone modifications or by altering the availability of substrates necessary for those enzyme reactions. Many of the components of an anti-inflammatory diet have positive epigenetic effects. Sulforaphanes like broccoli, Brussels sprouts and cabbage are known to increase histone acetylation. Butyrate, or butyric acid, is a short chain fatty acid found most prominently in butter, but also created by fermentation of dietary fiber in the intestines. It is a favored source of fuel for the colon, contributes to a healthy gut microbiome and increases histone acetylation [226]. Methyl donor nutrients include folate, vitamin B12, methionine, choline and betaine. Foods rich in folate include leafy green vegetables and citrus fruits. Sources of vitamin B12 are fish, meat and eggs. Choline is oxidized to form betaine, found in high concentration in beef liver, eggs and toasted wheat germ. The anti-inflammatory actions of vitamin D may be accredited to DNA methylation and histone modifications. Plant compounds curcumin and resveratrol, with known analgesic effects, have been found to positively alter epigenetic mechanisms [227].

28.1.2.10 Lifestyle

As discussed, psychological, social and environmental factors including activity, obesity, support, sleep and stress are foundational in the chronification of pain. Elevated BMI, past and current smoking and higher unemployment rate were associated with chronic pain in the 1958 British Cohort study. The study further concluded that chronic pain is a cause of unhealthy diet and lifestyles rather than a consequence [109]. Increased risk for chronic low back pain is also linked to weight gain and increased alcohol intake [228]. The musculoskeletal overload and systemic inflammation of obesity are significant contributors to the prevalence and severity of chronic pain. Exercise confers far-reaching, well-known beneficial effects including weight loss, lower inflammation and free radical reduction. Further, in the pain population, movement increases mental health, normalizes dysfunctional brain connectivity found in central sensitization, increases GABA production and reduces pain perception [229]. Fear of movement (FOM) has been increasingly recognized as a significant explanation for chronic pain development and is the basis for its recent characterization as a lifestyle disease. A cycle of fear, avoidance and catastrophizing leads to inactivity and physical deconditioning. In addition, study of the mesolimbic reward system reports that voluntary—as opposed to forced—exercise shows even greater analgesic effects [230].

Although the majority of low back pain (90%) resolves on its own in 3 months, it is often difficult to treat due to the psychosocial nature of its cause and is the most prevalent chronic pain condition [231]. With medical treatment often focusing on pain control instead of restoring function, modifiable lifestyle factors appear to make a difference and are studied often with this condition. Tai chi is an effective intervention regarding movement and posture in OA, low back pain, and fibromyalgia [232]. In a review of low back pain sufferers, yoga was found to have positive and significant effects on function and pain. Co-creating gradual exercise or movement intervention that is tailored to the interests, needs, abilities and fears of an individual will better prevent attrition and increase function, quality of life and recovery.

Contributing to its elusive treatment, low back pain is also linked to anxiety, depression, job dissatisfaction, poor body image and somatization. Lack of support, in relationships, family or work environments can lead to a perception of greater individual burden that can manifest physically. In addition to the physical demands of work, perceived lack of support from supervisors and lack of encouraging culture in the work unit are associated with an increased risk of intense low back pain and low back pain-related sick leaves [233].

Stress is linked to pain in multiple causative and consequential ways. In most chronic pain conditions, there is an ongoing reactivation of the stress response from pain or other stressors, that exhausts cortisol and the HPA axis, contributing to and/or causing pain and inflammation. Adding insult to the initial injury or event, the depletion of cortisol increases inflammation and creates vulnerability to pathogens, greater psychological stress and pain. Mind-body approaches that include progressive muscle relaxation, meditation, laughter, mindfulness-based approaches, hypnosis, guided imagery, yoga, biofeedback, and cognitive behavioral therapy have all shown efficacy in chronic pain [234].

The typical chronic pain patient has a heavy toxic burden that may include medications, decreased absorption, disturbed sleep and increased stress that compound and/or create conditions that take an acute injury and turn it into chronic pain. There are clear opportunities for clinicians to facilitate changes in lifestyle that have the potential to improve function, decrease inflammatory burden and create conditions for patients to flourish. As neuronal plasticity can cause central sensitization and chronic pain, diet and lifestyle changes can potentially decrease inflammation, desensitize the nervous system and reduce chronic pain.

28.1.2.11 Language of Pain

As mentioned, in the premiere definition of pain, it is described as a "negative experience." Further, all descriptive language for pain is in the context of weaponry and damage

[235]. Pain is viewed as something that must be killed, as it is a disability, a disorder and now a disease. If pain can only be negative, it can produce only negative effects and nothing positive may come out of it; the language, therefore, creates an inherent obstacle to recovery from pain conditions. As an integrative and functional medicine approach shifted its focus from treating disease to restoring health and wellness, for pain outcomes to change, the metaphors may need to change as well. If pain could be viewed as an invitation, a message to go deeper into its root cause, it may help patients look at pain not as something that must be destroyed, but as a potential doorway to physical, emotional and spiritual health.

29.1 Introduction

The brain, nerves, neurotransmitters, and genes are constantly impacted by numerous micro- and macronutrients. Gene activity may be turned off or on by a vitamin or mineral; nerves and cell membranes are built of essential fatty acids; amino acids are the building blocks of neurotransmitters. Brain structure is 80% lipid, and current evidence and theory indicate, in contrast to the traditional view, that ketones also play vital roles as metabolic and signaling mediators, even when glucose is abundant [1]. It is known that brain, blood, and cell content reflects the nutrient intake from the diet or supplements. There are communication pathways from brain to gut and gut to brain [2]. How could mental processes *not* be affected by nutritional status? [3] The question asked by nutritionists, molecular biologists, psychiatrists, geneticists, and other scientists is: "How?" Exactly how do nutrients affect these processes, individually or acting together?

The answers are not all in. Some studies focus on mood, which does not necessarily translate into clinical outcomes; epidemiological and tissue studies, meanwhile, struggle to disentangle the respective roles of nutrients in the body or brain [4]. Despite these challenges, we understand the connection between nutrition and mental health more now than in the past. The Nutrition Care Process, more than ever, needs to include assessment of nutritional factors that are influencing mental status.

In 2006 a poll of 1000 Americans indicated that more Americans feared loss of their mental capacity (62%) than feared loss of their physical capacity (29%) [5]. In 2014, there were an estimated 9.8 million adults aged 18 or older in the United States with serious mental illness (SMI)—4.2% of all US adults [6]. There were an estimated 43.6 million adults in the United States with any mental illness (AMI) in the past year—18.1% of all US adults [7]. The Surgeon General's Report of 1999 states that mental illness is the second leading cause of disability and premature mortality, comparable to heart disease and cancer [8–10].

29.1.1 Spectrums of Psychiatric Disorders

With respect to mental status and functioning, the human condition is wide-ranging and variable through time for each individual. If functioning varies in certain ways, or to such a degree that it disproportionately affects function and relationships, it may be diagnosed and treated to improve the quality of life of the individual. The ranges and degrees of differentiation of conditions may be expressed in a spectrum or continuum.

Mood disorders are a group of conditions that vary in severity and direction of the emotional states (Fig. 29.1). Each disorder has certain criteria for diagnosis. This spectrum differs from the Spectrum for Psychotic Disorders and the Autism Spectrum.

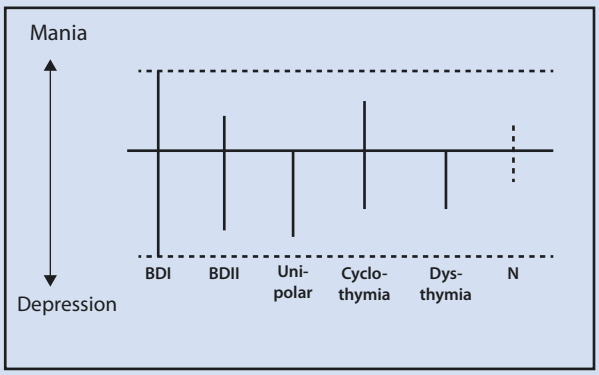

Fig. 29.1 Mood disorder spectrum. (Adapted with permission from Nemeroff [11]). *BDI* Bipolar Disorder I and II, *N* Normal

In the past, the Autism Spectrum encompassed the diagnoses of autism, Asperger Syndrome, Pervasive Developmental Disorder Not Otherwise Specified, and Childhood Disintegrative Disorder. The DSM-5 combined these into one category: "Autism Spectrum Disorder." Features of these disorders include social deficits and communication difficulties, stereotyped or repetitive behaviors and interests, sensory issues, and in some cases, cognitive delays [12]. (See also ▶ Chap. 30 for Intellectual and Developmental Disorders).

The spectrum of psychotic disorders includes schizophrenia, schizoaffective disorder, delusional disorder, schizotypal personality disorder, schizophreniform disorder, and brief psychotic disorder, as well as psychosis associated with substance use or medical conditions [13].

This chapter will provide in-depth discussion of the effect of nutrients on mental status and the major psychiatric diagnoses of depression, bipolar disorder, and schizophrenia.

29.1.2 Serious Mental Illness and Genetics

Schizophrenia, bipolar disorder, and severe depression have been shown to be genetically linked. A recent study determined that one of two genes code for the cellular mechanism for regulating the flow of calcium into neurons. Variation in one of these genes, CACNA1C, is known to impact brain activity involved in emotion, thinking, attention, and memory—functions disrupted in mental illnesses [14].

An earlier study found a gene common to all three; it appears to influence which symptoms occur [15]. This genetic abnormality results in removal of eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), arachadonic acid (AA), and gamma linolenic acid (GLA) from phospholipid structure. An intake ratio of 3 EPA:1 DHA is advantageous for treatment. This decreases the overactivity of one of the phospholipase enzymes that breaks down phospholipids' structures.

Table 29.1 Selected genes, interventions, and mental health

Gene	Effect	Potential nutrition intervention	Link to mental health
ACE	Produces an enzyme to help regulate the body's response to sodium intake. People with certain variants are at greater risk for high blood pressure when eating lots of salt. 7 in 10 people are at risk	Assess and advise re recommended sodium intake Assess fluid intake and interaction between excessive fluid intake and Na intake	Individuals on lithium need to maintain consistent Na intake. Polydipsia, water intoxication, and/or hyponatremia has been noted in psychiatric populations
GLUT2	Helps regulate glucose, or sugar. People with certain variants prefer sweet foods and drinks. 1 in 5 people is at risk	Assess and advise re keeping % of kcal from low-nutrient sources. Assure adequate intake of Cr, Mg, and B-1, needed for CHO metabolism	Psychotropic drugs may increase craving for sweets
CYP1A2	Gene variants result in slow or fast metabolism of caffeine. Heavy coffee drinkers who are slow caffeine metabolizers retain more of the stimulant in the body	Assess and advise re caffeine intake. High residual caffeine increases risk of having a heart disease, developing diabetes, and hypertension, already increased in individuals with mental health disorders	Caffeine may increase stimulation of individuals in manic phase of bipolar disorder. Patients with eating disorder may use caffeine beverages to manage food intake
TPH2 Tryptophan hydroxylase (Patrick and Ames [16])	Regulates serotonin synthesis and release	Assess vit D level: Goal ≥30 ng/dl	Support serotonin synthesis and release/ activation
		EPA, DHA intake Supplement: 2 g EPA and 1 g DHA from fish oil	"
		Exercise	Promote tryptophan entry into the brain

In July 2015, Jonathan Flint found two genetic markers reproducibly linked to depression. One was unknown; one was located next to a gene linked to energy production in mitochondria (Table 29.1) [17].

29.1.3 Depression

Depression may present with a variety of non-specific symptoms during a nutritional assessment—change in weight or appetite, fatigue, indecisiveness, or impaired concentration, as well as gastrointestinal symptoms and abdominal pain. Partial and acute vitamin deprivation studies suggest that the earliest impairments occur in measures of mood rather than mental performance [18]. Some researchers report the presence of inflammation underlying depression. Polyunsaturated fatty acids (PUFAs), folic acid, and probiotics are three supplements that target inflammation [19]. Evidence suggests a dysregulation in serotonin neurotransmission is central to the pathophysiology and treatment of Major Depressive Disorder (MDD).

Adolescents with Selective Serotonin Reuptake Inhibitor-(SSRI)-resistant depression exhibited deficits in red blood cell DHA compared with healthy adolescent controls, and it was shown that supplementation with fish oil was effective and well-tolerated. Two dose levels were compared: dose one was 2.4 g/day (EPA 1.6 g + DHA 0.8 g; 4 capsules/day) and dose two was 16.2 g/day (EPA, 10.8 g + DHA 5.4 g; 2 tbsp/day). Baseline-to-endpoint EPA and DHA levels increased, and depression symptom severity scores decreased, in both low-dose and high-dose groups [20].

A study of nutritional status in a group of depressed individuals showed intakes of vitamins A, B1, B2, B6, folate, C, sodium, potassium, Mg, Ca, P, Fe, and Zn and fiber ($p < 0.05$) were lower in the depression group. Fasting blood glucose levels, serum vitamins B12, and folic acid ($p < 0.05$) in the depression group were lower than controls. Meanwhile, median levels of body weight, waist circumference, hip circumference, and waist-to-hip ratio ($p < 0.05$) were significantly higher in the depression group. Serum insulin and Homeostatic Model Assessment (HOMA) levels of the two groups were similar [21].

Following a systematic search of PubMed, CINAHL, Cochrane Library, and Web of Science for clinical trials using adjunctive nutrients for depression, researchers concluded current evidence supports adjunctive use of S-adenosylmethionine (SAMe), methylfolate, omega-3, and vitamin D with antidepressants to reduce depressive symptoms [22].

29.1.4 Bipolar Disorder

Bipolar disorder (BD) is 80% heritable [23]. Folate-sensitive fragile genetic sites were found to be more frequent in patients with BD than in controls [24]. Patients and relatives

had specific alterations in methylene tetrahydrofolate reductase (MTHFR) and were shown to have elevated homocysteine and be low in folate and vitamin B12 [25]. Normalizing these levels may decrease the symptoms of bipolar disorder.

Altered metabolic end-products suggest that individuals with BD have metabolic differences in the metabolism of PUFA when compared to control subjects. Patients with bipolar disorder have lower intake of Se, EPA, DHA, AA, and DPA as determined using fasted plasma samples & 7-day diet records [26]. A review of small trials reported that fish oil can enhance the effects of standard treatments for bipolar disorder and yield improvement in their bipolar depression symptoms [27].

Nierenberg et al. comment that data implicate mitochondrial dysfunction as an important component of the pathophysiology of bipolar disorder. Biological processes that may be dysregulated in BD are monoamine activity, immune and inflammatory processes, and oxidative stress [28]. Several tolerable and readily available mitochondrial modulators (MM) may be potential treatments, including N-acetyl-cysteine (NAC), acetyl-L-carnitine (ALCAR), (SAMe), coenzyme Q(10) (CoQ10), alpha-lipoic acid (ALA), creatine monohydrate (CM), and melatonin. Targets of treatment include mitochondrial dysfunction, oxidative stress, altered brain energy metabolism, and the dysregulation of multiple mitochondrial genes in patients with bipolar disorder. They conclude that clinical trials of individual MMs as well as combinations are warranted [29].

Lithium salts have been in use for the treatment of bipolar disorder for more than 50 years. There is a narrow therapeutic range between effectiveness and toxicity for lithium treatment. Target lithium blood levels are generally 0.8–1.1 mmol/L. Levels above 1.5 meq/L may result in marked tremor, nausea, diarrhea, or blurred vision. Levels above 2.0 meq/L have been associated with life-threatening side effects, such as neurotoxicity, delirium, and encephalopathy [30]. Reported cellular targets for Li (+) action involve Mg (2+)-activated enzymes, which are inhibited by Li(+) [31]. Sodium intake affects renal clearance by 30–50%. A consistent intake of Na supports a stable blood level of the drug [32].

Self-reported data from 348 patients in the United States diagnosed with bipolar disorder indicated the group had tried over 40 different supplements, and the long-term users took 19 different supplements. The most commonly taken supplements for both groups were fish oil, B vitamins, melatonin, and multivitamins [33].

29.1.5 Schizophrenia

In 2015 a proposal was made to drop the term "schizophrenia," with its connotation of hopeless chronic brain disease, and replace it with a term like "psychosis spectrum syndrome." Japan and South Korea have already abandoned this term [34]. Past classifications did not acknowledge the continuity between schizophrenia and other psychotic disorders, including schizoaffective disorder, delusional disorder, bipolar disorder with psychotic features, and depression with psychotic features. The DSM-5 terminology is "schizophrenia spectrum and other psychotic disorders" [35].

Folate concentrations have been inversely related to the Scale for Assessment of Negative Symptoms total score [36]. Negative symptoms associated with schizophrenia are social isolation, lack of initiative, socially awkward behavior, and discomfort when interacting with people. Positive symptoms are psychosis, hallucinations, delusions, secondary agitation, and thought disorder. Cognitive symptoms, which include memory, decision making, and problem solving, are a third type of impairment [37].

Studies show that phospholipids and essential fatty acids are depleted in red cell membranes of schizophrenic patients compared with control subjects, particularly arachidonic acid (AA) and DHA [38]. A healthy ratio decreases the overactivity of a phospholipase enzyme and normalizes the removal of EPA, DHA, AA, and GLA from phospholipid structure. Studies on the effect of diet and membrane changes on tardive dyskinesia have had mixed results.

Another 4-week, double-blind study of patients experiencing an acute episode of schizophrenia or schizoffective disorder found that baseline levels of PUFA affected the response to supplements of ethyl-EPA, vitamin E and/or vitamin C, given in divided doses. Symptoms became worse in individuals with a low baseline level of PUFA after taking a supplement of either ethyl-EPA (500 mg) OR vitamins (364 mg/day vitamin E or 1000 mg/day slow-release vitamin C). Use of the vitamin supplement increased the dose of medication needed for alleviating symptoms. Symptoms that worsened included positive symptoms of suspiciousness/persecution, delusions, hallucinations, paranoia, and hostility. Giving all three supplements neutralized this effect. These effects were not present in patients with a high baseline level of PUFA. Low serum α-tocopherol was the best predictor of low PUFA baseline levels. A possible explanation for this outcome is that, at high doses, vitamin E acts as a pro-oxidant in an environment of insufficient antioxidant capacity. At low baseline levels, and only when not combined with vitamins E & C, EPA increases RBC arachidonic acid, which increases positive symptoms (hallucinations, paranoia, delusions). *Knowledge of baseline PUFA needs to inform recommendations for supplements of vitamin C and E during acute episodes of schizophrenia* [39].

A comparison of diet histories of patients with schizophrenia and a matched group from the Health and Nutrition Examination Survey (NHANES) population led investigators to suggest that the higher proportion of obesity in the schizophrenic group was related to factors such as medication side effects and reduced physical activity rather than diet [40]. Another study of the intake of fatty acids and antioxidants suggested that membrane changes may be caused by abnormal membrane phospholipid metabolism rather than intake.

One explanation for the increased risk of obesity, metabolic syndrome, and diabetes is fat storage; computed tomog-

raphy showed that with equal total body fat and equal subcutaneous fat, there was three times the amount of visceral fat stored by schizophrenic patients. The results of patients who were taking antipsychotics were no different than those who were not.

29.2 Other Conditions: Conditions that May Be Accompanied by Changes in Mental Status

29.2.1 Brain-Derived Neurotropic Factor (BDNF)

Peripheral BDNF has been positively correlated with lifetime depression episodes, psychiatric hospitalizations, and suicide attempts. Brain-derived neurotropic factor (BDNF) has been proposed as a biomarker for bipolar disorder, individuals with BD having lower levels of BDNF than controls. The BDNF gene provides instructions for making a protein found in the brain and spinal cord. This protein promotes the survival of neurons during growth, maturation, differentiation, and plasticity. The BDNF protein is found in regions of the brain that control eating, drinking, and body weight; it likely contributes to the management of these functions. The negative correlation between BDNF and number of mood episodes was moderated by impaired glucose metabolism [41].

29.2.2 Celiac Disease

Neurologic and psychiatric complications seen in gluten-sensitive patients may be the primary presentation in patients suffering from this disease. Data suggests that up to 22% of patients with celiac disease (CD) develop neurologic or psychiatric dysfunction and as many as 57% of people with neurological dysfunction of unknown origin test positive for anti-gliadin antibodies [42].

29.2.3 Metabolic Syndrome

The rate of metabolic syndrome was found to be higher in individuals with bipolar disorder (33%) and schizophrenia (47%) compared to matched NHANES controls (17% and 11%, respectively) [43]. Risk of metabolic syndrome was also associated with higher depression scores and abdominal obesity [44]. Nutrition care includes monitoring for indications of the development of metabolic syndrome, and intervening to prevent long-term consequences of the syndrome [45, 46]. (See also ▶ Chap. 46.)

The combined effect of depression and metabolic symptoms was greater than the sum of the individual effects: An individual with both depression and metabolic risk factors is more than six times more likely to develop diabetes [47].

Weight-loss programs designed for those with mental illness have been successful [48]. The behavior change process is facilitated through the use of self-monitoring, goal setting, and problem solving. Studies suggest that behavioral treatment produces weight loss of 8–10% during the first 6 months of treatment [49].

29.2.4 Hyponatremia/Water Intoxication

Psychotropic medications often increase dry mouth and thirst, which may increase fluid intake. Water intoxication may lead to hyponatremia. Symptoms of water intoxication in the early stages include nausea and vomiting, headache, or changes in mental state such as confusion or disorientation. Low serum sodium (hyponatremia) < 136 mEq/L is an osmotic shift of water into brain cells causing edema in the brain, caused by an excess of water relative to sodium. Signs and symptoms of acute hyponatremia include headache, confusion, and stupor. More severe symptoms can also occur: muscle weakness, spasms, or cramps; seizures; unconsciousness; coma. To prevent hyponatremia, avoid drinking more than 1 L of fluid per hour [50].

29.2.5 Caffeine Intoxication

Assessment for caffeine intoxication needs to include a variety of potential sources: prescription and over-the-counter medications, coffee, tea, soft drinks, caffeine shots, or chocolate. Signs and symptoms may involve (1) the central nervous system (CNS): headache, lightheadedness, anxiety, agitation, tremulousness, perioral and extremity tingling, confusion, psychosis, or seizures; (2) the gastrointestinal (GI) system: nausea and vomiting, abdominal pain, diarrhea, bowel incontinence, or anorexia; or (3) the cardiovascular system: palpitations or racing heart rate, or chest pain [51].

Wang, Woo and Bahk [52] and others [53] have discussed the possibility that caffeine could induce de novo psychotic and manic symptoms as well as aggravate previous disorders. Single doses of caffeine up to 200 mg (about 3 mg/kg for a 70-kg adult) are not a safety concern [54, 55].

29.2.6 Food Insecurity

Food-insufficient adolescents were significantly more likely to have had dysthymia, thoughts of death, and a desire to die and to have attempted suicide. Data from the NHANES III survey found that 5% of 15- and 16-year-old adolescents reported they had attempted suicide, and 38.8% reported at least one suicidal symptom [56, 57]. "Of all the top ten causes of death in the United States, only suicide is on the rise," said Charles Nemeroff, MD, at the Congressional Neuroscience Caucus briefing on June 29, 2016 [10].

29.3 The Effect of Micro- and Macronutrients on Mental/Behavioral/Neurological Health

Assessment vitamin, mineral, essential fatty acid, or amino acid status is not common, and methods are not universally accepted. These assessments are also an expense insurance companies are not willing to support. However, it is clear that a deficiency of many nutrients will effect mental status and that the majority of Americans do not meet the 2015–2020 guidelines for a healthy diet [58]. Less than 25% of Americans eat the recommended amounts of fruits, vegetables, or dairy foods. Who knows how many Americans experience fatigue, irritability, difficulty concentrating, altered cognition, anxiety, low-grade inflammation, or other effects of poor nutritional status?

29.3.1 Lipids, Glucose, Amino Acids

29.3.1.1 Essential Fatty Acids

Substantial evidence implicates a dietary deficiency in long-chain omega-3 (LC*n*-3) fatty acids, EPA and DHA, in the pathophysiology of psychiatric disorders, including MDD, bipolar disorder, schizophrenia, and attention deficit hyperactivity disorder (ADHD). A deficiency may coincide with, and may precede, the initial onset. Case–control studies have consistently observed low erythrocyte eicosapentaenoic acid EPA and/or DHA levels in patients with these disorders [59]. Deficiency of essential fatty acids (EFA) has been linked to violence, hostility and aggression, and suicide [60].

It is wise to remember that research in these areas is complex and fairly recent. A 2015 Cochran Review of research on the use of fatty acids for depression reports the quality of the evidence for all outcomes as low to very low. The number of studies and number of participants were low, and the majority of studies were judged to be at high risk of bias and also suggested a likely bias toward a positive finding for n-3 PUFAs [61].

If n-3 fatty acids are replaced in the diet by n-6 fatty acids the ratios in cell and brain tissues also change. Changes in fatty acid content of cell membranes may increase vulnerability to depression.

Messamore and McNamara report results that indicate the majority (75%) of psychiatric patients exhibit whole-blood EPA + DHA levels at ≤4% of total fatty acid composition. Twenty-five percent of the general population has this level of total fatty acids. Corrective treatment with fish oil-based products has resulted in improvements in psychiatric symptoms without notable side effects. This provides a rationale for screening for and treating omega-3 fatty acid deficiency in patients with psychiatric illness [59, 62].

Even a short course (2 weeks) of a nutritional supplement containing EPA has reduced the rates of new-onset depression to 10% [63]. In addition, both EPA and DHA delayed the onset of depression, and both treatments were well tolerated, with no serious side effects.

Use of EFA as an adjunct has allowed reduced doses of other medications and has reduced the relapse rate in bipolar disorder [59].

Total normal brain and hippocampus volumes have been directly associated with levels of omega-3 fatty acids in a study of more than 1000 postmenopausal women [64].

After a review of evidence, essential fatty acids were accepted in 2006 by the American Psychiatric Association Committee on Research on Psychiatric Treatments, the Council on Research, and the Joint Reference Committee of the American Psychiatric Association (APA) as a treatment option for depression. They concluded that evidence of epidemiologic and tissue compositional studies support a protective effect of n-3 EFA intake for unipolar and bipolar depression. Bipolar disorder and major depression were more influenced by supplementation than mild-to-moderate depression. They also felt use of EPA and DHA appear to have negligible risk. They concluded that the evidence for n-3 fatty acid's protective effect for schizophrenia was less conclusive [65, 66]. The APA adopted the consensus recommendations of the American Heart Association for an EPA + DHA dose of total 1 g/day in patients with MDD.

Controlled intervention studies have in general found that daily doses in the range of 0.2–2 g/day of EPA + DHA may be effective for the treatment of mood symptoms. Emerging evidence also suggests that a larger ratio of EPA to DHA may be more effective for treating symptoms of depression. Edward Kane recommends a ratio of 4:1 LA:ALA (4 parts n-6 [linoleic acid, or LA] to 1 part n-3 [a-linolenic acid, or ALA] [67]. The US Food and Drug Administration (FDA) consider LC*n*-3 fatty acids doses up to 3 g/day to be generally regarded as safe.

Use of fish oil and krill oil products, when matched for dose and EPA + DHA content, yielded similar plasma and RBC levels of EPA + DHA, indicating comparable bioavailability irrespective of formulation [68].

Reference values for serum essential fatty acids and others may be found at Mayo Clinic Medical Laboratories in Rochester at ► http://www.mayomedicallaboratories.com/test-catalog/Clinical+and+ Interpretive/82426. The American Medical Association current procedural terminology (CPT) codes for blood fatty acid analysis by Gas Liquid Chromatography are (GLC) (82725, 82544, 82492), and those for GLC testing in general are (82541, 82542).

29.3.1.2 Cholesterol

Cholesterol-reducing diets often reduce the n-3 fatty acids in the diet and lower DHA, which is an essential part of the neuronal cell membranes. The brain synthesizes its own cholesterol, and there is little correlation between blood levels of cholesterol and neurotransmitter function [69, 70]. Exploratory correlations (but not planned statistical comparisons) of clinical variables revealed that mania severity and suicidality were positively correlated with UE:E EPA ratio (unesterified: esterified EPA), and that several plasma levels and ratios correlated with panic disorder and psychosis [71].

Although there is controversy about cholesterol becoming too low, total blood cholesterol levels below normal/desired levels have been linked to depression and suicide [72], especially in the young and the elderly. Multivariate Cox regressions predicting suicide, homicides, and accidents suggested that three predictor variables were significant: low total cholesterol, morbid depression, and anti-social personality disorder. The interaction between low cholesterol and morbid depression ($p < 0.005$) indicated individuals with both at baseline were ~7 times more likely to die from external mortality. Patients presenting with low cholesterol and morbid depression in clinical practice may warrant clinical attention and surveillance [73]. In older (80-year-old) males, total cholesterol levels of <160 mg/dL have been associated with depression [74]. Women with non-medicated LDL levels <100 were at increased risk of depression [75].

29.3.1.3 Amino Acids

Amino acids are precursors of neurotransmitters (Table 29.2). The nine essential amino acids are histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. A non-protein amino acid, homocysteine, can be produced from methionine or converted into cysteine. Hyperhomocysteinemia is a risk factor for brain atrophy, cognitive impairment, and dementia. Plasma concentrations of homocysteine can be lowered by dietary intake of B vitamins.

29.3.1.4 Carbohydrates: Glucose

Possible mental symptoms of hypoglycemia (<70 mg/dL) include: changes in behavior or personality, irritability or nervousness, argumentativeness, and trouble concentrating. Signs and symptoms of hyperglycemia include fatigue, headaches, constipation, diarrhea, and nerve damage. Fasting hyperglycemia is defined as blood glucose higher than 130 mg/dL after not eating or drinking for at least 8 hours. Postprandial hyperglycemia is defined as blood glucose over 180 mg/dL 2 hours after you eat [82].

29.3.2 Vitamins and Minerals

29.3.2.1 Vitamins

Vitamins affect energy metabolism in all cells, the synthesis of neurotransmitters, the activation or inhibition of genes, the repair of DNA, and the function and atrophy of the brain [83]. Below is information regarding the effects on mental status of selected essential vitamins.

Vitamin B1 (Thiamin)

Thiamin deficiency often presents as changes in mental status (alertness, attention, memory) and gait/mobility. Failure to suspect a vitamin deficiency can lead to permanent cognitive and physical disabilities that may necessitate lifelong care [84]. Wernicke's encephalopathy is an acute neuropsychiatric condition caused by an insufficient supply of thiamin to the brain. If undiagnosed or inadequately treated, it is likely to proceed to Korsakoff's Syndrome. Wernicke-Korsakoff encephalopathy (WKE) has historically been associated with alcoholism [85]; but it has more recently been recognized in patients who have anorexia nervosa, a history of bariatric surgery, cancer [86], or who consume a diet of "empty calories" which result in a high calorie/thiamin ratio [87].

Thiamin diphosphate acts as a rate-limiting co-factor for a number of thiamin-dependent enzymes involved in the degradation of branched chain amino acids. Deficiency can lead to exaggeration of emotional and stress reflexes, altered mitochondrial activity, impaired oxidative metabolism, and eventually selective neuronal death [88, 89]. Thiamin and its phosphate esters may regulate gene expression by influencing mRNA structure and in DNA repair [90]. Chronic alcoholism can impair the functions of gene mutations. Excessive alcohol intake keeps SCL19A2 and SCL19A3 turned off [91].

Vitamin B2 (Riboflavin)

An autosomal recessive disorder, Brown–Vialetto–Van Laere Syndrome 2 (BVVLS2) is a progressive neurodegenerative disease that is a consequence of severe riboflavin deficiency, related to disruption of riboflavin transporters. Treatment of a 20-month-old female with BVVLS2 was initiated with 10 mg/kg/day dose of riboflavin and titrated up to 70 mg/kg/day over 2 months. The child tolerated the riboflavin therapy well. Symptoms began improving in a week with widespread improvement in 2–3 months. No new symptoms were observed [92].

Vitamin B3 (Niacin)

A niacin deficiency, or decreased tryptophan (Trp) availability to the brain, has been linked to depression and anxiety through a decrease in serotonin. Pellagra, the niacin-deficiency disease, is known by the "four Ds": dermatitis, diarrhea, dementia, and death. Possible symptoms include depression, anxiety, vertigo, memory loss, paranoia, psychotic symptoms, and aggression [93].

Pellagra was present in 27% of patients who died during hospitalization for alcohol dependence. It has been suggested that niacin deficiency be included in the differential diagnosis of alcoholic withdrawal syndrome [94].

Vitamin B6 (Pyridoxine)

High total intakes of vitamins B6 and B12 are reported as protective against depressive symptoms over time. For every 10 mg increase in the intake of vitamin B6 and for every 10 μg increase in vitamin B12 the risk of developing symptoms of depression were decreased by 2% per year [95]. Low concentrations of vitamin B6, but not of folate or homocysteine, have been associated with lower mini-mental state examination (MMSE) scores and lower attention and executive function scores in a multivariate analysis [96].

Beyond its role as a necessary cofactor in the folate cycle, the role of vitamin B6 in amino acid metabolism makes it a rate-limiting cofactor in the synthesis of neurotransmitters such as dopamine, serotonin, γ-aminobutyric acid (GABA),

Table 29.2 Amino acids and neurotransmitters

Neurotransmitter	Related nutrients	Effect on the brain	Effect on mood	Tissue secreting	Other	Food sources of neurotransmitter precursors
Serotonin—A monoamine	Tryptophan, with B6, B12, and folic acid	Serotonin levels: 1. increase with dietary carbohydrate; 2. increase with omega-3 fatty acids; 3. decrease with high-protein diet	Increased serotonin levels: 1. improve mood; 2. increase pain tolerance and sleep; 3. decrease aggression and cravings	80–90% is secreted by the gastrointestinal tract; serotonin is synthesized by the brain and neurons and secreted into synapses between neurons	Other amino acids, especially branched-chain amino acids (leucine, isoleu-cine, and valine) compete with tryptophan to cross the blood/brain barrier; serotonin synthesis is sensitive to the availability of tryptophan from meals [76]	1. Foods high in tryptophan: meats, milk, yogurt, and eggs 2. Foods high in carbohydrates: grains, potatoes, fruit, and milk
Dopamine—A monoamine	Tyrosine and phenylalanine; along with B-12, folic acid, magnesium	Tyrosine blood levels rise with a high-protein diet; dopamine synthesis is insensitive to the availability of tyrosine from meals due to activity of tyrosine hydroxylase	1. Sufficient dopamine increases tolerance, mood, alertness, cognition, and problem solving 2. Dopamine depletion results in blunted pleasure response, clouded thinking, lowered motivation, and lowered vigilance in patients with schizophrenia [77]	Produced in the brain and released by the hypothalamus	Stress depletes tyrosine from the blood	1. Sources of L-phenylalanine: beef, poultry, pork, fish, dairy products, eggs, and soy products such as soybean flour and tofu and almond 2. The artificial sweetener aspartame is also high in phenylalanine 3. Sources of tyrosine include the following: oatmeal, soybeans, skim milk, beef, chicken, brown rice, and almonds

Norepi-neph-rine—A mono-amine	Tyrosine with B12, folic acid, magnesium	Norepinephrine increases with a high-protein diet	Low nor-epinephrine levels associated with irritability, depression, moodiness	Norepinephrine is synthesized and released by neurons in the brain and central nervous system and also by the sympathetic ganglia located near the spinal cord or in the abdomen and is released directly into the blood-stream by the adrenal glands	1. Too much results in fear, depression, compulsivity, mood swings, mania, and addiction 2. Too little results in depression and paranoia	Sources of tyrosine include the following: oatmeal, soybeans, skim milk, beef, chicken, brown rice, and almonds
Histamine	Histidine, one of the essential biogenic amines; responses, such as inflammation, gastric acid secretion, neurotransmission, and immune modulation	Histamine modulates neurotransmitters in the brain, stress-related release of hormones from the pituitary and central aminergic neurotransmitters [78] Diamine oxidase breaks down histamine to prevent buildup in plasma; deficiency may be genetic or acquired Alcohol attacks diamine oxidase and histamine builds up	Promotes/controls feeding behavior, wakefulness [79]	H_3 subtype, focused on as the therapeutic target for cognitive dysfunctions; expressed preferentially in neurons and modulates neu-rotransmitter release [80]. Produced by the granules in mast cells and basophils as part of a local immune response. Found in connective tissue; also synthesized in the brain; acts as a neurotransmitter. Stored and released in the entero-chromaffin-like (ECL) cells of the stomach	Serum: N = diamine oxidase activity ≥80 HDU/ml (HDU = high-dependency unit) Symptoms of excess histamine include migraine headaches, gastrointestinal disorders, chronic fatigue, and ADHD	Sources of histidine include the following: beef, pork, chicken, turkey, peanut butter, cheese, eggs, sesame seeds, and sunflower seeds Diamine oxidase is available on non-prescrip-tion basis Avoidance of alcohol advised

Adapted with permission from Leyse-Wallace [81]

noradrenaline, and the hormone melatonin. Even mild deficiency results in down-regulation of GABA and serotonin synthesis [93].

A 2012 report from the CDC demonstrated that 10.5% of the entire US population were biochemically deficient in vitamin B6 [97]. Groups most likely to be deficient in B6 are women of reproductive age, especially current and former users of oral contraceptives; male smokers; non-Hispanic African-American men; and men and women over age 65 [98].

Sensory neuropathy typically develops at doses of pyridoxine in excess of 1000 mg/day with pain and numbness of the extremities and in severe cases, difficulty walking. Since placebo-controlled studies have generally failed to show therapeutic benefits of high doses of pyridoxine, there is little reason to exceed the UL of 100 mg/day [99].

Vitamin B12

Mental signs of a B12 deficiency include agitation, apathy, emotional instability, psychosis, irritability, memory problems, mood swings, sleep disturbance, personality changes, suspiciousness/paranoia, and trouble concentrating. Psychiatric symptoms of B12 deficiency may present before hematologic findings [100]. Seventy to ninety percent of persons with a clinically relevant B12 deficiency have neurological disorders such as numbness and tingling in the hands and feet; in about 25% of cases these are the only clinical manifestations of the B12 deficiency [101]. Damage to the CNS may become irreversible. A review by the *Cochrane Group* confirmed orally administered cyanocobalamin with initial doses of 1000–2000 μg daily, then weekly, is just as effective as parenteral administration [101]. Oral supplements have been confirmed to be as effective as injections.

Vitamin B12 functions as a cofactor for methionine synthase and L-methylmalonyl-CoA mutase. Methionine synthase catalyzes the conversion of homocysteine to methionine. Methionine is required for the formation of SAMe, a universal methyl donor for almost 100 different substrates, including DNA, RNA, hormones, proteins, and lipids [102]. A deficiency in vitamin B12 causes an accumulation of homocysteine in the blood and may decrease the ability to metabolize neurotransmitters.

Elderly patients judged to have normal nutritional status using the Mini Nutritional Assessment (MNA) were found to be low in vitamin B12 [103]. B12 and folate have independently been shown to predict positive affect [104].

Vitamin C

Prior to the development of scurvy, vitamin C deficiency is accompanied by symptoms of mood disturbance, personality changes, and changes in scores on the Minnesota Multiphasic Personality Inventory (MMPI). Psychological symptoms occur earlier and with less severe depletion than physical signs and symptoms. Kinsman reports personality changes occurred at levels of whole blood of 1.21–1.17 mg/100 mL. Physical signs/symptoms occurred at 0.67–0.14 mg/100 mL ascorbic acid in whole blood [105]. In 2010, based on data from 2003 to 2004, 7% of the US population was determined to be biochemically deficient in ascorbic acid [106]. Tobacco smoking is frequent in mental health populations, which increases the need for vitamin C and also folic acid.

Short-term therapy for hospitalized patients with vitamin C raised plasma vitamin C levels, improved mood disturbance by 71%, and reduced psychological distress by 51% [107]. A number of reports describe observing signs of vitamin C deficiency in patients being treated for anorexia nervosa [108–111]. Low intakes of vitamin C, as well as other nutrients, are reported by people experiencing food insecurity [112].

Polymorphisms in the vitamin C transporter genes have been shown to compromise genes encoding sodium-dependent ascorbate transport proteins [113].

Folate

Low folate has been associated with changes in cognition affecting memory, attention, and language. Three weeks of a folate-deficient diet (5 μg/day) was reported to produce a decrease of serum levels from 7 ngs/mL to below 3 ngs/mL. In the 18th week, mental changes including insomnia, irritability, fatigue, and forgetfulness occurred, as well as anemia and red cell macrocytosis. Oral folate replacement of 250 μg caused remission of symptoms [114, 115].

There are contradictory opinions in the literature regarding interpretation of studies involving folic acid and depression [116, 117]. A group that received selective serotonin reuptake inhibitors and selective norepinephrine reuptake inhibitors (SSRI/SNRI), combined with 7.5–15 mg/day of L-methylfolate, was more effective than monotherapy with only an SSRI/SNRI [118].

Taking folic acid does not appear to improve the antidepressant effects of lithium in people with bipolar disorder. However, taking folate with the medication valproate improves the effects of valproate. There is conflicting evidence about the role of folic acid in age-related decline in memory and thinking skills. However, other research suggests no benefit [119].

A 16-week study showed that 2 mg of folic acid plus 400 μg of vitamin B12 improved negative symptoms of schizophrenia significantly. However, improvements were noted only when genotype was taken into account. Only patients homozygous for the 484T allele of FOLH1(rs202676) demonstrated significantly greater benefit with active treatment [120].

The tolerable upper intake of folic acid for healthy adults is 1000 mcg/day. Folate interacts with a large number of common and specialty drugs. Doses over 1000 mcg/day should be assessed for potential interactions. Excess folate may cause low blood pressure and may lower blood glucose. The Mayo Clinic website lists many herbs, supplements, and prescription and over-the-counter drugs that may interact with folic acid. For the entire list, see: ► http://www.mayoclinic.org/drugs-supplements/folate/safety/hrb-20059475.

Vitamin A

The retinoids are a family of compounds derived from vitamin A or pro-vitamin A carotenoids. They are necessary for the function of the brain and central nervous system, and new discoveries point to a central role ranging from neuroplasticity to neurogenesis. Retinoic acid is important for a regular pattern of sleep [121].

Isotretinoin is a vitamin A-derived medication that is associated with significant adverse effects including arthralgia myalgia, nosebleeds, headache, dyslipidemia, liver dysfunction, and depression. Case reports describe depression, suicidality, psychosis, violence, and aggression developing in conjunction with isotretinoin treatment (13-cis retinoic acid/Acutane) used in treating severe acne [122]. Evidence suggests probable clinical exacerbation of bipolar mood disorder and possible links to psychosis. Genetic polymorphisms in the retinoic acid receptor alpha (RARA), one of the main targets of isotretinoin, showed an association with the adverse effects of oral isotretinoin therapy [123].

Vitamin D

Low levels of vitamin D are found frequently in those with mental illness, especially schizophrenia [124–127]. One study showed that vitamin D status was associated with more negative symptoms in first-episode schizophrenia. Mixed results are reported in the relationship between vitamin D levels and depression. One study observed a trend toward a greater decrease in the Beck Depression Inventory in the vitamin D treatment group than in the placebo group [128]. One study showed that 58% of individuals who attempted suicide were deficient in vitamin D [129]. Another found initially low vitamin D levels were associated with clinically significant depressive symptoms across follow-up [130].

Vitamin D is now considered a potent neuroactive/neurosteroid hormone, critical to brain development and normal brain function, and valued for its anti-inflammatory property. A vitamin D ligand-receptor has been found throughout the body including the central nervous system [131].

A proposal by Patrick and Ames [16] in 2015 describes evidence that insufficient levels of vitamin D and essential fatty acids may explain an underlying mechanism contributing to psychiatric disorders and depression through a vitamin D receptor and the enzyme tryptophan hydroxylase (TPH2). Optimal intake of these nutrients may prevent and modulate the severity of brain dysfunction and alter behavior. Tryptophan depletion in the brain reduces serotonin levels, which results in favoring short-term over long term rewards, impulsiveness, antisocial aggressive behavior, feelings of anger, and incidence of self-injury. They comment that exercise is a helpful intervention because muscles preferentially absorb branch-chain amino acids, which compete with tryptophan for transporters across the blood-brain barrier. Exercise facilitates more tryptophan crossing the brain-blood barrier for serotonin synthesis.

Vitamin K

The vitamin K-dependent protein GAS6 is involved in chemotaxis, mitogenesis, cell growth, and re-myelination of nerves. Low levels of vitamin K have been associated with dementia and alterations in cognition, although much of the research on vitamin K and the nervous system has been on animals. One area of future research is the relative deficiency state of vitamin K induced by use of the drug Warfarin and its potential effect on cognition.

29.3.3 Minerals

Some minerals are essential for health and functioning. Some are generally toxic to humans. (See also ◘ Table 29.3) Some are essential, but may be toxic at extreme levels of intake. Either inadequate or toxic levels of minerals may affect mental functioning.

29.3.3.1 Nutrient Minerals

Copper

High concentrations of copper are found in the brain. Recent studies have found that copper helps brain cells communicate with each other by acting as a brake when it is time for neural signals to stop [133]. Some patients with Alzheimer's Disease had normal serum copper, but higher levels were found in cerebrospinal fluid [134]. In cases of copper deficiency, dopamine-hydroxylase (DBH) activity may decrease and result in elevated ratios of dopamine to norepinephrine. The balance between copper and zinc is important in maintaining neurotransmitter levels and function. Walsh has associated overload of copper and copper-zinc imbalance with schizophrenia, bipolar disorder, ADHD, and postpartum depression [135].

Wilson's disease is an autosomal recessive disorder resulting in copper accumulation in basal ganglia and neuronal loss. One third of patients present with psychiatric symptoms such as depression, labile mood, impulsiveness, disinhibition, self-injurious behavior, or psychosis.

Free plasma copper (in contrast to bound plasma copper) shows a significant inverse relationship with mini-mental state examination (MMSE) and attention-related neuropsychological test scores. About 95% of patients with the neurological presentation manifest the Kayser-Fleischer ring—a primary site of copper deposition in Wilson's disease.

A case of a male diagnosed with celiac disease and a hemoglobin of 4.9 g/dL, which was non-responsive to a gluten-free diet or supplements of iron, folic acid, and B12, was found to be low in copper. Two months of copper supplementation normalized his neutropenia [136].

Lithium

Lithium inhibits the release of thyroid hormone (TH), and lithium treatment has been associated with the development of goiter within weeks to months of initiating lithium ther-

Table 29.3 Potentially toxic doses of drug of minerals [132]

Mineral	Blood reference level	DRI: adults, M/F	Potentially toxic dose
Calcium	Serum Ca Hypocalcemia ≤8.0–8.5 mg/dL, Hypercalcemia: S/S > 11.5 mg/dL, Critical value: >12.0 mg/dL, A Medical emergency >15.0 mg/dL	1000–1300 mg/day	12,000 mg
Phosphorous	Serum phosphorous, hypophosphatemia 1.5–2.4 mg/dL moderately low; not usually associated with clinical signs and symptoms <1.5 mg/dL may result in muscle weakness, hemolysis of red cells, coma, bone deformity, and impaired bone growth <1.0 mg/dL are potentially life-threatening Values are lowest in the morning, peak first in the late afternoon, and peak again in the late evening	700 mg/day	12,000 mg
Magnesium	S/S Mg deficiency ≤1.0 mg/dL. Levels ≥9.0 mg/dL may be life-threatening	320–420 mg/day	6000 mg
Iron	Serum ferritin Males, 24–336 mcg/L Females, 11–307 mcg/L May be elevated inflammation, liver disease, chronic infection, autoimmune disorders, and malignancy May be elevated in iron storage disorders such as hemochromatosis, hemolytic anemia, and sideroblastic anemia and in those who have had multiple blood transfusions Native Africans, African Americans, and Asians may have higher mean concentrations of serum ferritin	8–18 mg/day	100 mg
Zinc	Normal urinary excretion of zinc—300 to 600 mcg/g creatinine/day Serum zinc—0.66 to 1.10 mcg/mL High urine/low serum zinc may be caused by hepatic cirrhosis, neoplastic disease, or increased catabolism High urine/normal or elevated serum zinc indicates a large dietary source, usually in the form of high-dose vitamins Low urine/low serum zinc may be caused by dietary deficiency or loss through exudation or gastrointestinal losses	8–11 mg/day	500 mg
Copper	16 years ± Urine 15–60 mcg/L Low urine copper levels: malnutrition, hypoproteinemias, malabsorption, and nephrotic syndrome Low serum copper associated with Wilson disease Excess use of denture cream containing zinc can cause hypocupremia Increased zinc consumption interferes with normal copper absorption	900 μg/day	100 mg
Fluoride	Plasma N = 0.0–4.0 mcmol/L Plasma fluoride >4 mcmol/L = excessive exposure Plasma fluoride >4 mcmol/L = adverse effects W/ fluoride-treated water-plasma fluoride 1–4 mmol/L W/O fluoride-treated water-plasma fluoride <1 mcmol/L	3–4 mg/day	4–20 mg
Iodine	Serum N = 40–92 ng/mL 80–250 ng/mL may indicate hyperthyroidism I ≥ 250 ng/mL may indicate iodine overload	120–150 μg/day	2 mg
Selenium	Serum N adult = 70–150 ng/mL (0.15 parts per million) Children require less circulating selenium than adults Se deficiency serum <40 ng/mL; associated with loss of glutathione peroxidase activity Usual treatment—Selenium supplementation to raise serum concentration > 70 ng/mL	55 μg/day	1 mg

apy. Goiter in patients receiving lithium therapy ranges from 20% of patients in iodine-replete areas to 87% in patients residing in iodine-deficient areas. Up to a third of patients on lithium therapy who develop goiter also may develop hypothyroidism, which usually remains subclinical, although it could conceivably affect weight status [137].

Magnesium

Possible causes of hypermagnesemia include laxative abuse, diuretics, lithium intoxication, and hypothyroidism; causes of hypomagnesemia, meanwhile, can include gastrointestinal diseases (Crohn's, ulcerative colitis, etc.), renal disease, vomiting, laxative abuse, and alcohol abuse [138].

Chronic magnesium deficiency may be related to numerous physical and mental disorders, including chronic fatigue, depression, irritability, disorientation, depression, and psychosis. Magnesium ions may block synaptic transmission by interfering with the release of acetylcholine. Consumption of alcohol, even in modest amounts, can double or even quadruple the excretion of magnesium. Some over-the-counter and prescription drugs, such as proton pump inhibitors, can lower body magnesium levels.

Mg is essential for the proper activity of DNA polymerase I, RNA polymerase, and DNA helicase. Its deficiency results in errors during DNA replication, transcription, and translation.

Supplements in the form of magnesium oxide, chloride, or lactate provide 60–84 mg magnesium per tablet. Sustained-release forms may reduce the potential diarrhea from magnesium supplementation.

Manganese

A U-shaped curve describes the need and effect of manganese in humans. Manganese (Mn) toxicity is a greater concern than deficiency. Manganese toxicity can result in a permanent neurological disorder such as tremors, difficulty walking, and facial muscle spasms. The toxicity syndrome, manganism, may be preceded by psychiatric symptoms, such as irritability, aggressiveness, and even hallucinations [139]. Iron deficiency has been known to increase manganese accumulation in the brain.

In the brain, the manganese-activated enzyme glutamine synthetase converts the amino acid glutamate to glutamine. Glutamate, an excitotoxic neurotransmitter, is a precursor to an inhibitory neurotransmitter, γ-aminobutyric acid (GABA). Expression of genes implicated in manganese, iron, and zinc homeostasis has been shown to increase with vitamin D3 treatment. It is possible that the control of systemic levels of zinc and manganese is regulated by vitamin D3 in the intestine [140]. With vitamin D treatment, the gene encoding the zinc and manganese transporter, ZnT10, had about a 15-fold increase in expression. Vitamin D3 also increases expression of the SLC30A10 gene. Mutations of SLC30A10 can cause manganese intoxication.

Selenium

Small amounts of selenium (Se) are essential; excess amounts of selenium are toxic. There is greater uptake of selenium in the brain than in other tissues. At times of deficiency, the brain retains selenium to a greater extent than other areas of the body.

The function of selenium in the brain is related to functions of selenium-dependent enzymes in the oxidative damage-protective system: polyunsaturated fatty acids (PUFA) are protected from peroxidation by selenium-dependent glutathione peroxidase (Se-GPX). Se-GPX activity occurs in myelin tissue.

Energy-adjusted intakes of selenium have been found to be a predictor of high scores for depression on the Beck Depression Inventory in Iran [141]. An analysis for 35 serum trace elements showed a different profile in schizophrenic patients and controls in China. Concentrations of selenium, zinc, and cesium were significantly lower in schizophrenia [142].

Serum selenium concentrations decline with age. Marginal or deficient selenium concentrations might be associated with age-related declines in brain function, possibly due to decreases in selenium's antioxidant activity [143].

Supplementation with a selenium-rich Brazil nut has shown potential in reducing cognitive decline in patients with mild cognitive impairment (MCI) patients, and could prove to be an effective nutritional approach early in the disease process to slow decline. Response to intake of Brazil nut intake by mRNA appears to be influenced by a number of SNPs and genotypes [144, 145]. Brazil nuts contain very high amounts of selenium (68–91 mcg per nut) and could possibly cause selenium toxicity if consumed regularly.

A strong garlic-like odor is usually present in acute, subtoxic, and chronic selenium poisoning, attributed to dimethylselenide. Neurologic symptoms of acute toxicity may include tremor, peripheral neuropathy, muscle spasms, restlessness, confusion, delirium, and coma. The most common sign of chronic selenium poisoning are nail changes: Nails become brittle, with white spots and longitudinal streaks. Other signs include nausea, vomiting, diarrhea, fatigue, and skin lesions. As selenosis progresses, decreased cognitive function, weakness, paralysis, and death occur [146]. The upper limit for a maximum safe daily dietary intake, based on the amounts of selenium that are associated with hair loss and nail brittleness, has been estimated at 400 μg for selenium from food and supplements combined [143].

Zinc

Zinc deficiency has been shown to induce depression-like and anxiety-like behaviors, and zinc supplementation has improved the efficacy of antidepressant drugs in depressed patients. Zinc deficiency may cause decreased appetite, change in the sense of taste, and weight loss. Data may indicate a role for zinc deficiency in the development of mood disorders, but also show that zinc may also be important in their treatment [147].

Zinc is found in in many body systems, participating in the activity of over 200 enzymes. Zinc functions in the incorporation of thymine into DNA, one of the four bases forming the structure of DNA. Zinc deficiency leads to both primary and secondary alterations in brain development and growth and is one of the causes of primary neural tube defect. Indirect effects of zinc deficiency occur in the lipid content of the developing brain.

Changes in brain zinc concentration are observed in Alzheimer's disease, Down syndrome, epilepsy, multiple sclerosis, retinal dystrophy, and schizophrenia. Recent investigations into molecular mechanisms suggest a role for zinc in the regulation of neurotransmitter systems, antioxidant mechanisms, neurotrophic factors, and neuronal precursor cells.

29.3.4 Potentially Toxic Minerals

29.3.4.1 Cadmium

In a review of heavy metals, Wu et al. explained Cadmium (Cd) toxicities are expressed through depletion of glutathione and bonding to sulfhydryl groups of proteins. Cadmium indirectly generates reactive oxygen species (ROS) by its ability to replace iron and copper. Lead becomes toxic to organisms through the depletion of antioxidants [148].

The most significant exposure to cadmium comes from cigarette smoke. Occupational exposure to cadmium has led to (a) slowing of visuomotor functioning on neurobehavioural testing; (b) increase in complaints of peripheral neuropathy; (c) altered equilibrium; and (d) lowered ability to concentrate, which were dose-dependent with cadmium exposure. Environmental exposure to cadmium has been shown marginally significant in relation to the development of Alzheimer's [149].

Sources of cadmium for non-smokers are terrestrial foods (98%), aquatic foods (1%), and water (1%). The content of terrestrial foods varies significantly related to the type of food crop grown, agricultural practices, and the atmospheric deposition of cadmium onto exposed plant parts.

With an absorption rate of 5% from ingestion, the average person is believed to retain about 0.5–1.0 μg of cadmium per day from food. The World Health Organization (WHO) established a provisional tolerable *weekly* intake (PTWI) for cadmium at 7 μg/kg of body weight. For a 150-pound (68 kg) person, this amounts to 477 μg/week, or 68 μg/day [150].

29.3.4.2 Mercury

Methyl mercury is more than 95% absorbed and can accumulate if rates of consumption exceed rates of excretion. It has a strong affinity for sulfhydryl groups in tissues and accumulates to a greater concentration in brain, muscle, and kidney. Methyl mercury easily crosses the blood-brain barrier, where it is biotransformed into inorganic mercury. The brain: blood concentration ratio after the initial distribution is between 10:1 and 5:1. Once in the central nervous system, methyl mercury can be demethylated to inorganic mercury. Inorganic mercury has a half-life of years in brain tissue [151, 152].

Since fish consumption is promoted for a healthy diet and excess fish intake may carry contaminants such as mercury, fish consumption should be part of diet histories and comprehensive health screenings to identify those at risk for mercury accumulation. The symptoms of excess methyl mercury include fatigue, headache, decreased memory, decreased concentration, muscle or joint pain, prickly sensations, and problems with fine motor coordination, speech, sleep, and walking. Although fish is the main source of mercury, additional routes of exposure to mercury are mercury vapor in certain occupations and some medications, herbs, remedies, and vaccines [153].

A general medical practice in Seattle reported out of 700 individuals who were screened, 123 needed laboratory evaluation. One hundred three (89%) of these had had mercury levels ≥5.0 μg/L; 63 (54%) had levels ≥10 μg/L; 19 (16%) had levels ≥20 μg/L, and four had levels >50 μg/L. After patients were advised to omit mercury sources or fish, follow-up found mercury levels declined rapidly in the first 3 weeks, followed by a slower reduction over time. All but two patients reduced their level to <5.0 μg/L by 41 weeks [154].

Mercury Reference Dose (RfD): no more than 0.1 μg Hg/kg body weight/day.
Acceptable levels:
Whole blood mercury level < 5.0 μg/L.
Hair level < 1.0 μg/g.

Consumer Reports lists these types of seafood as containing the lowest mercury content: shrimp, scallops, sardines, oysters, squid, tilapia, and wild and Alaskan salmon. The publication estimates that an adult could safely eat 36 ounces per week and children could eat 18 ounces per week of these fish [155].

29.4 Drugs: Nutrition and Mental Status

Weight gain is one effect of a number of psychotropic drugs. (see Table 29.4) This, in turn, is a frequent cause of patients discontinuing medication. Nutrition counseling incorporating diet and exercise principles has been successful with psychiatric patients, who have shown interest and motivation with multidisciplinary approaches [158].

- Drug: Nutrient Interactions include:
  - Protein pump inhibitors (Prilosec, Prevacid), H2 receptor antagonists (Tagamet, Pepcid, Zantac), and metformin reduce absorption of vitamin B12 and may induce a deficiency.
  - Antidepressant medications:
    - Taking vitamin B6 supplements may improve the effectiveness of some tricyclic antidepressants, such as nortriptyline (Pamelor), amitriptyline (Elavil), desipramine (Norpramin), and imipramine (Tofranil).
    - Monoamine oxidase inhibitors (MAOIs) may reduce blood levels of vitamin B6. Examples of

Table 29.4 Nutrition and psychotropic medications [156, 157]

Medication type	Generic Name (trade/brand name)	Side effects
Antidepressants: Selective serotonin reuptake inhibitors (SSRIs) are often prescribed for depression, obsessive compulsive disorder, social anxiety disorder, and occasionally eating disorders	Fluoxetine (Prozac) Sertraline (Zoloft) Paroxetine (Paxil) Fluvoxamine (Luvox) Citalopram (Celexa)	Weight gain Gastrointestinal symptoms Avoid tryptophan supplements St. John's wort
Antidepressants: Tricyclic	Amitriptyline (Elavil) Amoxapine (Asendin) Nortriptyline (Aventyl, Pamelor) Doxepin (Adapin, Sinequan) Imipramine (Janimine, Tofranil) Desipramine (Norpramin) Clomipramine (Anafranil) Protriptyline (Vivactil)	Carbohydrate cravings, slowing of metabolism, and appetite stimulation Weight gain may be dose-dependent and related to duration of therapy The greatest weight gain is from imipramine and amitriptyline. Minimal weight gain occurs with protriptyline and desipramine
Antipsychotic	Thioridazine (Mellaril) Novo-Ridazine Haloperidol (Haldol, Peridol) Molindone (Moban) Chlorpromazine (Thorazine)	Appetite changes, elevated cholesterol, glucose up or down, weight increase Take Mg, Ca, and iron supplement separately by 4 hours May increase riboflavin need
Atypical antipsychotics	Clozapine (Clozaril) Olanzapine (Zyprexa) Sertindole (Serlect) Risperidone (Risperdal) Quetiapine (Seroquel) Ziprasidone (Zeldox)	Greatest association with weight gain with clozapine and olanzapine
Antiseizure/anticonvulsants Phenytoin, Depakote anticonvulsants/ putative mood stabilizers May be prescribed for seizure disorders, bipolar disorder, and selected forms of depression	Divalproex (Depakote) Carbamazepine (Tegretol) Lamotrigine (Lamictal) Gabapentin (Neurontin) Topiramate (Topamax)	Initial weight gain, esp if patient at or below normal BMI May cause hyperinsulinemia; increased appetite May need Ca, Vit D, B-1, carnitine supplement; folate suppl frequently Rx; folic acid is an antagonist of phenytoin (dilantin), phenobarbitol, methotrexate, and other medications, appetite change
Lithium		Requires consistent fluid and sodium intake; moderate caffeine intake
Monoamine oxidase inhibitors Nonselective irreversible type Reversible (RIMA) types	Isocarboxazid (Marplan), Phenelzine (Nardil), Tranylcypromine (Parnate) Moclobemide (Manerix) and Toloxatone (Humoryl)	Limit foods w/ tyramine with nonselective MAOI: chocolate, aged and mature cheeses, smoked and aged/fermented meats, hot dogs, some processed lunch meats, fermented soy products, and draft beers

MAOIs include phenelzine (Nardil) and tranylcypromine (Parnate).

- Phenytoin (Dilantin used to treat seizures): Vitamin B6 makes phenytoin less effective [159].
- Riboflavin intake/status: Some drugs may lower riboflavin levels, but riboflavin may improve the effects of antidepressants: imipramine (Tofranil), desimpramine (Norpramin), amitriptyline (Elavil); nortriptyline (Pamelor), phenothiazines (Thorazine), phenytoin (Dilantin).

29.5 Summary Statement

Nutritional status and deficient or excess nutrients have meaningful effects on mental status, through enzymes, neurotransmitters, and metabolism; they interact with many drugs; and they influence genetic transcription. Thorough nutritional assessment and targeted interventions have the potential to improve the course of treatment and quality of life for individuals suffering from altered mental status.

Learning Objectives

- To support children with neurodevelopmental and neuro-immune disorders in reaching their optimal potential through lifestyle teaching, individualized diet, targeted supplements, and other modalities based on symptoms and biomedical testing.
- To understand the use of biomarkers and genetic individuality to support vulnerable areas of their biochemistry as evidenced by related dysfunctions in multiple systems to help these children thrive.

30.1 Introduction

The number of children with neurodevelopmental and neuro-immune issues is increasing at an alarming rate. Changes in obstetrics, farming, food production, health care, and the sheer number of chemicals, pesticides, and toxins in our daily life contribute to the rapid growth in neurologic, developmental, and autoimmune issues our children face. The importance of understanding these changes helps us support the healing of the gut, the immune system, and the neurologic system, including the brain, with therapeutic nutrition. Many factors need to be assessed to help these children to reach their optimal potential. The aim of this chapter is to highlight some of the current research relevant to helping children with neurodevelopmental disorders using autism spectrum disorder, ADHD, PANDAS, and seizure disorders as prototypes.

30.2 Children Are Not Little Adults

Understanding nutrition for growth and development, in addition to harnessing nutrition to mitigate toxic exposures prenatally and postnatally, is essential in caring for our children. Children are not "little adults." They differ from adults in their anatomy, physiology, musculoskeletal system, and organ systems as they are in the process of maturing. Children have a higher metabolic rate with an increased oxygen and caloric need. Newborns have a higher fluid-to-solid ratio: 75–80% water versus 60% in adults. Control of electrolyte status is less effective until 12–18 months of age, and children are more susceptible to malnutrition and electrolyte imbalance beyond 18 months. The daily water exchange rate is higher in children. Small children are more susceptible to head injury [1] due to thinner cranial vault bones and a large head-to-torso ratio and the length of time air-filled sinuses take to develop. At birth much of the skeleton is cartilage, while the flat bones of the skull, face, and jaw are composed of membranous bone for safe passage of the baby. Until puberty, bones are softer and more easily bent and fractured. The brain is immature at birth and completes about 60% of its development in the first 2 years of life. Because the brain is growing so rapidly during this time, adequate healthy fats, protein, energy, iron, zinc, copper, iodine, selenium, choline, folate, and vitamin A are important for development of the brain and the nervous system [2].

The developing immune system is influenced before birth by the fetal-maternal interface via the placenta and by the type of delivery. It turns out that there are more immune communications between mom and fetus than previously thought [3]. With a vaginal delivery, the infant is colonized by mom's vaginal and intestinal flora. However, during a C-section, this contact with vaginal microflora is absent and environmental flora plays a more important role in colonizing the infants' microbiome. The circumstances of the C-section also have an influence; a planned C-section, with no labor or rupture of membranes, has less microbial exposure, while an emergent C-section after a long labor with rupture of the membranes will introduce more maternal flora [4].

Atopic disease tends to be more common in children with C-section births than vaginal births, especially if there is a family history of allergy. The lack of exposure to maternal vaginal and intestinal flora is associated with alterations in the neonatal gut flora and cytokine responses which can lead to changes in the Th1/Th2 helper cells that favor atopy [5]. You may notice immune differences in siblings related to their type of delivery and exposures prenatally and postnatally. The composition of the early microbiota is an important factor in the health of the immune system [6]. The initial colonization of the infant gut is affected by genetics, prenatal exposures, antibiotics, type of delivery, and diet composition of breast milk or formula (Fig. 30.1).

Malamitsi-Puchner et al. found vaginal delivery promoted cytokines important to neonatal immune health. Exclusive breastfeeding, when possible, supports a healthy microbiota in infants by seeding and selecting for specific populations of bacteria. C-sections, antibiotics, and formula feeding may alter the development of the microbiome and have been linked to increased metabolic and immune issues [7].

30.3 Toxins and Toxicants

Children and fetuses are more vulnerable to toxins and toxicants. There is no known safe level of neurotoxins for an embryo and developing fetus. Due to trans-placental exposures and communication, the fetus is exposed to everything the mother takes in [8]. Of the 287 chemicals the Environmental Working Group detected in umbilical cord blood in 2004 [9]:

- 180 cause cancer in humans or animals.
- 217 are toxic to the brain and nervous system.
- 208 cause birth defects or abnormal development in animal tests.

After birth, infants and children experience greater exposure to chemicals pound-for-pound than do adults. They also have an immature and porous blood-brain barrier, which allows greater chemical/toxic exposures to reach their developing brain. In addition, their neurological, immunological, and detoxification organs are not yet mature. The liver, the main detoxifying organ, is more efficient by age 7, but it continues to mature until late adolescence and beyond. Children are

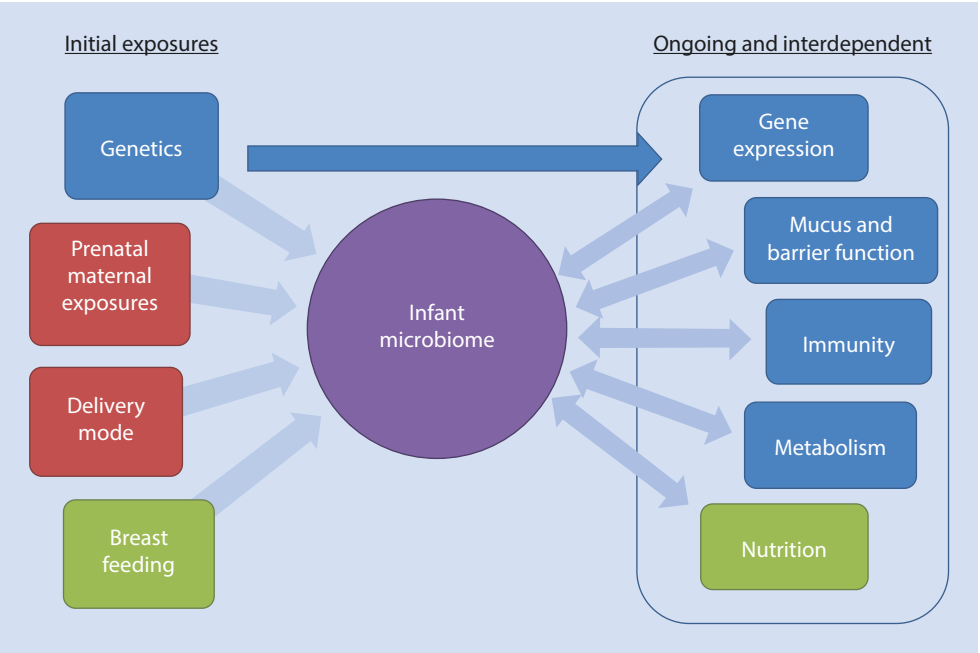

Fig. 30.1 Colonization of infant microbiome effected by initial and ongoing issues. (Reprinted from Houghteling and Walker [6]. With permission from Wolters Kluwer Health, Inc.)

exposed to more pesticides and toxins because they spend more time at ground level and through their exploratory and hand-to-mouth behaviors. Pregnant and breastfeeding mothers would be wise to avoid toxic exposures in food and the environment. The father's exposure history is also important to know. Has dad been exposed to work-related toxins, medications, alcohol, recreational drugs, or infectious agents?

There is an increasing epidemic of learning difficulties, as well as ASD and ADHD, because of the ever-increasing impact of environmental toxins on the development of children. Heavy metals can have a direct toxic effect reducing the ability to absorb essential nutrients. Mercury is considered the most toxic heavy metal. It affects the nervous system and alters brain function, leading to tremors, memory issues, irritability, and a host of other issues [10]. Mercury (Hg) blocks the absorption of iron, zinc, and selenium; however rat studies suggest adequate zinc can help decrease the toxicity of Hg exposure [11]. Zinc supports homeostasis, immune function, and apoptosis and reduces oxidative stress [12]. Aluminum displaces magnesium, calcium, and iron which can affect intercellular communication, cell growth, and secretory functions. Aluminum overload leads to inflammation and neurotoxicity [13]. Heavy metals and pesticides have a synergistic effect in humans and animals [14]. Likewise, an abundance of nutrient minerals can help to protect the body from absorbing as many toxic elements [15].

The enormous increase in electromagnetic frequency (EMF) waves, such as radio, television, cell phones, and Wi-Fi, is a vital concern for health. Radiofrequency radiation covers a wide range of frequencies from 900 MHz (megahertz) to greater than 15 GHz (gigahertz) for current 5G (5th-generation mobile networks). Children are disproportionately affected by cell phone radiation and EMF, and it is of greater concern for the developing fetus, infants, and children whose brains are thought to be more vulnerable because of smaller head size. The distance to the center of the brain is shorter because the skull and ears are thinner, allowing more radiation to reach critical structures. Their brains contain more fluid and therefore absorb more microwave radiation [16]. As body organs and systems are developing, there is increasing risk augmenting damage from previous EMF exposure in utero.

There is evidence that these frequencies have many effects down to the cellular level, adversely affecting mitochondria, causing oxidative damage from reactive oxygen species, and affecting cell membrane permeability [17]. Oxidative stress has been demonstrated in the brains and livers of developing rats exposed to EMF related to decreased glutathione peroxidase and antioxidant concentrations. Negative effects have been noted in rat testes and human reproduction. EMF exposure affects a wide range of human body systems with symptoms including headache, sleep issues, fatigue, skin problems, attention, and memory issues, as well as neuropsychiatric effects including depression and presumably autism [18]. The neuropsychiatric effects appear to be from activation of voltage-gated Ca2+ channels (VGCCs) in the outer membrane of cells in the brain, allowing excessive neurotransmitter and neuroendocrine release [19]. Excess calcium in the cells increases oxidative stress and ultimately affects mitochondrial function and DNA.

> Because the World Health Organization considers wireless radiation a possible human carcinogen, wireless radiation does not belong in schools with young children.

30.4 Family History and Genetics

The field of genetics is changing daily. Going beyond genetic determinism, epigenetics has shown us that factors such as diet, nutritional status, lifestyle, environmental toxicants and toxins, including air and water pollution, food processing, agricultural practices, and extremes of stress can affect an individual as well as future generations [20, 21]. Epigenetic marks can change for the better in response to a positive attitude, healthy diet and lifestyle, and limiting exposure to the increasing number of environmental toxins and toxicants.

"Epi" means "above." Epigenetics is "control above the genes." It denotes a change in gene expression (phenotype) caused by an external modification to DNA by the environment that turns genes on and off without a change to the DNA sequence (genotype). These changes are potentially reversible and preventable. The cell membrane picks up environmental signs that control the reading and expression of genes. The embryo stage of development lays down the genetic code, and from the fetal stage on, there is epigenetic modification.

Our genes work in concert with biochemical chain reactions. Nutrition and tailored supplementation are profound shapers of epigenetic changes and the subsequent effect on metabolic processes. A gene with a single nucleotide polymorphism (SNP) variation may mean the gene efficiency is altered; it could be working at a decreased or increased efficiency or may have lost regulatory controls. Related to how an enzyme functions, upregulation or downregulation can have far-reaching effects. Metabolic pathways require nutrient cofactors, which are vitamins and minerals required for enzyme function. If there is an adverse effect related to a SNP, supplementation may help mitigate the effect by stimulating the metabolic pathway affected. A deficiency in cofactors may limit the efficiency of a metabolic pathway. Supplying cofactors (vitamins and minerals) through supplementation may support gene function through epigenetic changes and/or metabolic pathways; SNPs may be indirectly supported by nutrients that modulate pathways through other mechanisms.

The tricky part is that the genes work in conjunction with one another, so the knowledge of a single SNP does not give a complete roadmap as effects vary for each person depending on their individual genetic makeup. For instance, if a methylation pathway is affected by a methylenetetrahydrofolate reductase (MTHFR) SNP, it may be under- or overmethylated and interact with other genes in this important pathway. (See ▶ Chap. 18 on Methylation.) Biomarkers, such as homocysteine levels or actual genetic testing if available, are useful to determine exposure, effect of exposure, disease progression, and susceptibility factors, as well as which SNPs may need support. Genetic SNPs need only be addressed if they need support, based on symptoms and biomarkers. Always treat the patient, not a lab test or SNPs. To understand the workings of the genes and their integration with biomarkers, it will take continued research and the help of artificial intelligence tools, since there are more than 20,000 genes, of which only a fraction are well-understood.

30.5 Lifestyle Factors

The basics of health are the same for all children:

- Remove foods containing additives and food triggers from the diet: processed foods, artificial colors, flavors, preservatives, GMO foods, pesticides, nitrites, artificial sweeteners, corn syrup, high fructose corn syrup, trans fats, MSG (monosodium glutamate), etc.
- Remove sources of environmental toxicants from the home: pesticides, chemical cleaners, air fresheners, fabric softeners, plastics, outgassing furniture and carpets, as well as any sources of mold. Don't forget EMF pollution and the effects of "smart meters." [22] Interestingly, many parents find their children sleep better when Wi-Fi is turned off at night. Avoid electronics in the bedroom.
- Pure water is essential. Additives to municipal systems can also be absorbed through bathing. Use multi-stage or whole-house filters to remove species such as asbestos, fluoride, arsenic, and other well-known biotoxins including drug residues. Because water is a source of minerals in its natural state, insure adequate minerals in pure spring water or the diet.
- Basic healthy, whole-foods diet: fats, protein, carbohydrates, fruits, and vegetables.
- Basic dietary supplements as needed: fatty acids, enzymes, probiotics, and appropriate multivitamin/mineral.
- Determine any special diet or dietary needs, including any food sensitivities or allergies.
- Increase nutrient-dense foods: eggs; meat from well-raised, pastured chickens and animals; organic liver [23]; sweet potatoes; leafy greens; beans; legumes; nuts; seeds; some grains; seaweed; blackstrap molasses; organic bone or vegetable broth; balanced smoothies or fresh juices; and fermented foods as tolerated [24].
- Repair the gut: leaky gut, yeast overgrowth, parasites, dysbiosis, and balance intestinal flora (see ▶ Chaps. 23 and 24).
- Targeted supplements: as indicated for immune support, reducing inflammation, healing the gut, and genetic support.
- Support detox pathways: optimize elimination through healthy bowel function and liver function and consider mild chelators and binders.

Sleep is crucial for children [25]. Babies sleep 20 hours a day to support the metabolic demands of their rapidly growing brain. Most toddlers and preschoolers need 11–14 hours of sleep. Insufficient sleep can add stress to an already challenged nervous system and can affect the neuroendocrine system by elevating stress hormones. In fact, a study of adolescents has found that sleep deprivation can mimic ADHD, including hyperactivity, impulsivity, poor attention, and other behavior problems [26]. Parents can visibly recognize the behavioral effects of sleep deprivation in young children, which have been evidenced in studies as affecting cognitive function as well as behavior [27].

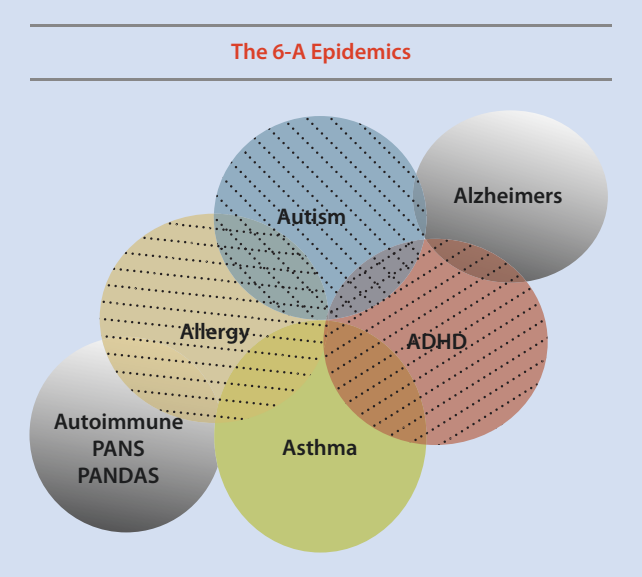

Fig. 30.2 Epidemics of developmental disabilities related to oxidative stress and inflammation

The 6-A Epidemics are rising at an alarming rate and have oxidative stress mechanisms and inflammation in common. They are influenced by environmental toxins, heavy metals, chemicals, infection, and damaged food. According to the Centers for Disease Control and Prevention report in 2008, one in six children in the United States has a developmental disability. At the same time, Alzheimer's disease is also increasing at an alarming rate. It is the sixth leading cause of death in the United States, having increased 55% between 1999 and 2014. What in our environment, lifestyle, and diet are causing these dramatic increases in neurologic diseases in children and adults? (Fig. 30.2).

30.6 Autism Spectrum Disorders (ASD)

Autism spectrum disorder (ASD) is one of the most confounding neurodevelopmental disorders in children. The CDC data from November 2015 shows that 1 in 45 children is now diagnosed with autism. 2.2% of children between ages 3 and 17 are currently affected by ASD. In the 1980s, the rate was 1 in 10,000. Prior to 1960, most cases of autism showed signs at birth. However regressive autism now represents 80% of the cases where children appear to be developing normally and begin losing developmental skills, most often between 15 and 24 months [28]. The incidence is four to five times higher in males, and families with one child with ASD have a 2–18% chance of having a second affected child. Although diagnosis and awareness have improved, teachers, grandparents, and pediatricians will tell you these children are truly different and each child is unique in their individual presentation. ASD is a heterogeneous condition with many variations in presentation. Genetic factors are involved, as well as environmental and other epigenetics factors, but genes do not create epidemics, though they may increase sensitivity to developing ASD. It has been aptly said that genetic vulnerability loads the gun and environmental toxins pull the trigger. This is an epidemic with high levels of special needs, devastating families and taxing school systems.

Early signs that parents notice are the absence of big smiles or warm joyful expressions by 6 months. No sharing of sounds, smiles, and facial expressions by 9 months. No babbling, pointing, or waving by 12 months. No words by 16 months. No two-word sentences by 24 months. Frequently early development appears on track and parents later notice a regression such as blank stares or loss of eye contact or words which can occur over weeks or months. Persistent regression is never normal in childhood development.

DSM-V criteria for autistic disorder describes a behavioral disorder with:

- Impaired social interaction
- Impaired social communication
- Restricted repertoire of activities and interests

Assessment of severity is based on social communication impairments and restricted repetitive patterns of behavior. This disorder affects the essence of a child's ability to communicate, rephrase, and use language, as well as their sense of self. Recovery rates are estimated to be 3–25% with traditional treatment. The earlier interventions are begun, the better the outcome, preferably before the age of 3. Changes are slower after the age of 8. However, with proper biomedical care, continued improvements are possible into adulthood, though they are more modest. Some children will be able to lose the diagnosis of autism and be mainstreamed in school.

Autism, once thought to be a behavioral disorder, is a **biological/neurological** disorder involving systemic inflammation and changes in the brain [29]. Oxidative stress, mitochondrial dysfunction, and immune dysregulation/inflammation have been recognized using peripheral biomarkers from blood and urine tests. Recent studies also report these abnormalities in brain tissue in individuals with ASD.

Associated conditions include:

- Seizures (30% +)
- Cognitive deficits or intellectual disabilities
- Savant skills
- Sensory dysfunction and/or impaired sensory-motor integration
- Motor dysfunction, including motor planning, delayed motor milestones, toe walking, etc.

Autism is not one disease but is different in each child. Many different systems can be affected. Kenneth A. Bock, MD [30], suggests there are subgroups of autism. One or more areas may be affected. Looking at symptoms and biomarkers can lead to effective interventions:

- Gastrointestinal: 50–70% have indigestion, constipation, loose stools, or abdominal pain
- Allergies/sensitivities (50% +)
- Immune deficiency/autoimmune/dysregulation
- Infections: viral, bacterial, fungal, and parasitic
- Metabolic: enzyme, mitochondrial dysfunction

- Nutritional imbalances
- Hormonal imbalances
- Toxic injury

Our food supply is compromised by the overuse of herbicides and pesticides [31]. The toxicity of commonly used glyphosate, originally patented as an antibiotic is compounded by the adjuvants in the herbicide that enhance bioaccumulation. This affects plants grown for human consumption as well as meat, eggs, dairy and farmed fish and our entire food chain, as animals and farmed fish are fed GMO feed. Many environmental factors come into play and affect homeostasis in multiple body systems. This creates physiological stresses that can include increased oxidative stress, heightened inflammatory responses, gut dysfunction, neurologic damage, and immune dysregulation.

The interaction of genes and environmental toxins and toxicants in the prenatal, perinatal, and postnatal period are contributing to the rise in ASD. Maternal immune activation can alter brain development and has also been linked to ASD [32, 33]. Neuro-inflammation is involved in autistic behavior. Findings suggest microglia activation or dysfunction can affect neurodevelopment [34]. Increased levels of inflammatory cytokines in patients with ASD have been reported, as well as the presence of serum antibodies against the central nervous system and maternal IgG reactive to fetal brain tissue [35].

30.7 History

A thorough history and timeline are essential. Was pregnancy easily achieved or was intervention needed? Were the parents excited about the pregnancy? Was the mother in a supportive relationship? What was her stress level? Were there drug or alcohol issues with either parent? What was the geographic location? Were there environmental exposures? Were mom or dad exposed to toxins at home or on the job? Were transgenerational epigenetic factors present, such as parental exposure to diethylstilbestrol, war related issues, etc?

Were both parents in good health? Any illnesses or autoimmune conditions? Was mom adrenally depleted or diagnosed with low thyroid? Thyroid hormones are critical to fetal development. Fetal thyroid function does not begin until 14 weeks of gestation. Iodine deficiency can lead to mental retardation. Inadequate thyroid hormone disrupts neuronal migration into the cortical layers of the brain in the fetus. Children with ASD can have defects of neurogenesis and neuronal migration. Maternal hypothyroidism can increase the risk of placental abruption, preterm labor, and postpartum hemorrhage. Evidence suggests that low maternal T4 levels can affect cortical development of the fetus [36]. Screening for congenital hypothyroidism between days 2 and 4 is critical as specimens prior to 48 hours may be falsely elevated.

What medications, vaccines, Rhogam (a necessary medication but potential risk factor as it can contain a mercury preservative), epidurals, Pitocin, etc., did mom receive? Was birth by vaginal birth or C-section? How long was labor? A C-section after 36 hours of labor is a different stress than a planned C-section. How was the birth? Was there birth trauma? Were antibiotics given to mom during labor or baby? How did baby look at birth? Potential risk factors for birth trauma include an uncommon fetal presentation, umbilical cord issues, fetal distress, birth injury, maternal hemorrhage, low birth weight, multiples and small size for gestational age [37]. Was medical intervention needed? Was the child taken to the neonatal intensive care unit (NICU)? Did the infant need more than 3 days in a NICU? Were there issues with colic, sleep, feeding, or gastroesophageal reflux? Was the sequential progression of development timely? Did any significant events happen around the time regression or developmental issues were first noticed? Finding the multiple risk factors and events that led to this child to develop autism can help us unravel the puzzle that leads to improvement in their lives and the lives of their families.

These are all very important questions to help in charting a course of treatment and unraveling contributing factors. Parents can do a timeline listing developmental events, vaccines (note that reactions may not be severe or immediate), illnesses, medications, stressful events, and toxic exposures such as black mold or pesticides, to aid in pinpointing where insults may have occurred.

Prenatal factors associated with ASD are under study. Several factors that are suspected to be contributors are gestational or pre-gestational diabetes mellitus, some maternal infections and other causes of maternal immune activation, valproic acid, SSRIs, organophosphates, pesticides, air pollutants, alcohol, and heavy metals. Diabetes mellitus affects fetal growth, which can increase complications during pregnancy and delivery. Diabetes can also affect fine and gross motor development and increase the rate of ASD, ADHD, and learning difficulties. It is thought maternal diabetes may cause increased fetal oxidative stress or epigenetic changes. Tight control lessens the effects of diabetes on the fetus, but does not eliminate risk [38].

During pregnancy, the demands for folate increase to support the growth and development of the fetus. Mothers with MTHFR and dihydrofolate reductase (DHFR) polymorphisms do not process folic acid well and are better supported with foods high in folate and vitamins that contain 5-MTHF (methylated folate) [39]. Both of these polymorphisms are common in parents and patients with ASD.

30.8 Gastrointestinal Symptoms

Children with ASD have a greater risk of gastrointestinal issues, especially constipation, chronically loose stools, diarrhea, gas, bloating, and abdominal pain [40]. Children with intestinal inflammation may also have sleep disturbances, behavioral issues, or unusual posturing [41]. Many adopt a posture that puts pressure on the lower abdomen to lessen pain. Those who are unable to effectively defecate on the toilet may use a squatting posture to produce a Valsalva maneuver. GI dysfunction can worsen symptoms through pain,

stress, and discomfort, resulting in such issues as agitation, anxiety, aggression, self-injury, brain fog and sleep issues.

GI symptoms can occur via different mechanisms. Pathways affecting the gut-brain axis can affect behavior and cognition. Studies have shown in children and mice that having a gluten-free diet lessens GI symptoms and improves behavior [42–44]. Gluten, a protein in some grains, can cause inflammation by multiple means including allergy, intolerance, gluteomorphin, celiac, non-celiac gluten intolerance, or contaminants in the grain. Multiple mechanisms by which gluten may cause issues can make definitive testing challenging. Modern wheat has been hybridized to produce a higher gluten content and is often desiccated with glyphosate. Some children with GI symptoms have a lymphocytic enterocolitis with dysregulated intestinal mucosal immunity and increased cytokines. Therapeutic diets can decrease inflammation [45].

Pathophysiological mechanisms that may link ASD and GI symptoms include [30]:

- Intestinal inflammation (with or without autoimmunity)
- Gluten-related issues, such as celiac, wheat allergy, non-celiac gluten sensitivity, and gluteomorphin metabolites
- Functional abdominal pain
- GI dysmotility with dysautonomia
- Gastroesophageal reflux
- Gut microbiota dysregulation affecting gastrointestinal permeability, mucosal immune function, intestinal motility, and sensitivity [46]

30.9 Mitochondrial Issues in Autism

Studies have shown children with autism to have mitochondrial issues including mitochondrial dysfunction, mtDNA (mitochondrial DNA) over-replication, and deletions more often than neurotypical children [47]. Children with mitochondrial dysfunction can show nonspecific symptoms such as anxiety and GI abnormalities as abdominal pain, constipation, reflux, nausea, and vomiting; dizziness, headache and fatigue. They may have a family history of mitochondrial disease; neurodevelopmental regression (which should be a very rare event in children); seizures; fatigue/lethargy; ataxia; motor delay; or cardiomyopathy. Oxidative stress and inflammation adversely affect mitochondria [48–50]. Robert Naviaux, MD, a mitochondrial researcher at UCSD, has proposed the cell danger response (CDR) hypothesis that could prove to be the root cause of autism, ADHD, asthma, atopy, allergies, epilepsy, Alzheimer's disease, bipolar disorder, and other chronic issues [51]. He describes it as universal metabolic response to stress or injury and suggests that these issues trace back to an abnormal persistence of a normal, alternative functional state of the extracellular ATP signaling, causing a loss of ATP. The CDR is protective until these changes become sustained. When they occur during pregnancy or the first 3 years of life, they can alter the trajectory of normal development [52].

Until we find more specific ways to support mitochondria, lifestyle, nutrition, and supplementation are helpful. Nutrients supportive of mitochondrial function are L-carnitine, coenzyme Q10, and vitamins C, D, E, and B5 [53]. CoQ10 is needed to produce ATP, B1, B2, B3, B5, and antioxidants [54].

30.10 Biomedical Assessment for Autism

There is currently a search underway for nutritional and biomarkers in ASD [55]. Many tests are useful in teasing out metabolic and nutritional issues in autism. Alterations in metabolic pathways vary according to exposures and genetic individuality.

However, collecting blood and other bodily fluids can be quite traumatic for these children. An organic acid and urine peptide test is a good place to start as urine is usually the least traumatic body fluid to collect.

William Walsh, PhD, of the Walsh Research Institute, found 85% of children on the autistic spectrum were zinc-deficient and many had an increased copper-to-zinc ratio (should be 1:1). Another study indicated children with ASD and GI disease showed less stimming and hyperactivity with zinc supplementation [56]. Optimizing zinc can improve appetite, as taste buds are more efficient with adequate zinc. Zinc can also lessen anxiety. Improving the zinc/copper balance can take 2 months to show improvement. There may be a brief period of worsening symptoms as the copper is detoxed.

30.11 Functional Lab Assessment for Autism

1. Urine for organic acid testing: to evaluate for mitochondrial function via Krebs cycle and amino acid metabolites, neurotransmitter metabolites, and microbial overgrowth – yeast, bacteria, clostridia markers, nutritional and antioxidant issues, fatty acid metabolism and oxalates as well as detox indicators related to glutathione, ammonia, and GI bacteria.
2. Urine peptide testing: gluteomorphin and casomorphin – neuropeptides can affect cognitive function, speech, and auditory integration.
3. Blood chemistry: metabolic panel, CBC, magnesium and selenium, vitamin D, vitamin C, fat-soluble vitamins, ferritin, total iron-binding capacity (TIBC), serum lead, cholesterol, RBC folate, RBC zinc, copper, and ceruloplasmin.
4. Markers of immune function and inflammation: Activated T- and B-cell subsets, immunoglobulins, cytokines, ANA, ESR, C-reactive protein, anti-casein, anti-gluten, and anti-soy IgG. Viral/bacterial markers if indicated.
5. Genetic screening: Genetic sequencing can be done by saliva or blood, which is still very expensive. It is difficult to test the entire genome through saliva unless it is possible to collect several milliliters; however several

companies can test a limited number of genes from a paper dot saturated with saliva. Some polymorphisms can be supported with supplementation. CGH (comparative genomic hybridization) array identifies small deletions and duplications to check for genetic anomalies. Note that FMR1 gene, which codes for fragile X mental retardation protein, has symptoms that can overlap with autism.

6. Hormones: thyroid function – FT3, FT4, and TSH. Low thyroid can cause fatigue and brain fog. AM cortisol or salivary cortisol. Low cortisol can be related to transition difficulties, tantrums, and anxiety.
7. Allergy: IgE, IgG – food sensitivity and delayed reactions can contribute to behavior issues. A large number of IgG food allergies indicate a leaky gut. How a child acts after eating a food should be noted. This information and appropriate laboratory findings will help to decide which foods are most important to eliminate. Diet should be as varied as possible. In some children, removing allergenic foods may cause withdrawal and worsening behavior for up to 2 or 3 weeks.
8. Oxidative stress: can be evaluated by urine for lipid peroxides indicating oxidative damage to cell membranes and 8-OHdG-oxidative damage to DNA. Blood markers: lipid peroxides, nitrotyrosine, transferrin, 8-OHdG, glutathione, cysteine/cystine ratio, and the enzymes glutathione peroxidase and superoxide dismutase. Oxidative stress is common in neuropsychiatric disorders [57].
9. Mitochondrial dysfunction (MD): fasting morning labs – lactate, pyruvate, free and total carnitine, acylcarnitine panel, ubiquinone, ammonia, CK, AST/ALT, CO2, glucose, and mitochondrial DNA sequencing. ASD has been associated with elevations in lactate-to-pyruvate ratio, CK, ammonia, AST, and decreased carnitine. Some of the newer biomarkers include buccal cell enzymology and mitochondrial antibodies [58].
10. Autoimmune testing: myelin basic protein autoantibodies indicate inflammatory demyelination, cerebellar antibodies. Anti-neuronal antibodies have implicated in severe autism [59].
11. Toxins: urine porphyrins – an oxidized metabolite of heme biosynthesis associated with genetic disorders, metabolic issues, oxidative stress, and toxic exposures to metals like mercury, lead, and arsenic or chemicals. Because porphyrins are assembled in the mitochondria, this gives information on the health of the mitochondria. Patterns of porphyrin elevations can indicate clues to specific toxicities. For example, coproporphyrin or precoproporhyrins can be associated with mercury exposure. Several labs have toxic panels that test for alkylphenols, organochlorines, organophosphates, plasticizers, PCBs, and volatile organic compounds [60].
12. Kryptopyrrole quantitative urine: tests for pyroluria, an inherited disorder that robs the body of zinc and B6. This condition may be found in ASD, ADHD, and behavior disorders, including obsessive-compulsive disorder, anxiety and depression [61]. Symptoms include poor anger control, mood swings, social anxiety, infections, sleep issues, absence of dreams, and light, sound, and tactile sensitivities. Greater than 10 mcg/dl may indicate borderline pyroluria, and greater than 20 mcg/dl is positive for pyroluria. In pyrrole disorder, B6 and zinc are rendered inactive by the build-up of HPL (hydroxyhemopyrrolin-2-one) involved in the synthesis of heme. The result is a major deficiency of B6 and zinc. Individualized doses of B6, P5P, zinc, and possibly manganese and evening Gamma linolenic acid may be helpful. This condition should be treated prior to detox. If pyrroles are an issue, results with supplementation can usually be seen in 4 weeks.

30.12 Family History and Autism

Neurologic and autoimmune issues commonly run in families [62]. Neurologic disorders found in families with autism include Asperger's, Tourette's, ADHD, depression, schizophrenia, and bipolar disorder. Autoimmune conditions in families with autism include lupus, Hashimoto's thyroiditis, type 1 diabetes, chronic fatigue, rheumatoid arthritis, fibromyalgia, and Crohn's disease [63]. A common factor linking these issues may include impaired transsulfuration and methylation pathways.

30.13 Polymorphisms in Autism

Autism has a strong genetic component. ASD is a heterogeneous disorder with marked genotypic and phenotypic variability and complexity [64]. However, genes do not cause disease or epidemics. A gene codes for how to make a protein. The protein and RNA molecules interact with one another in dance of dizzying complexity. The genome can provide many answers, as we learn its language and complex interactions.

Many genes have been associated with autism, but it is genetically heterogeneous and has interactions with environmental factors [64]. Monozygotic twin discordance studies where only one twin is affected suggest a role for non-genetic factors [65].

The CHD8 gene is one of the few genes consistently related to a small subtype of autism that occurs early in development consisting of ASD, macrocephaly with a prominent forehead, wide-set eyes and a pointed chin, GI complaints, and marked sleep dysfunction [66]. This disruption is interesting because of the comorbidities between brain development and enteric innervation.

It is thought that common gene variants contribute to the risk of developing autism. Many of these polymorphisms can be positively influenced by nutritional interventions [67] and supporting biochemical pathways, such as methylation, sulfation, and neurotransmitter synthesis metabolism. Genes considered clinically useful by integrative practitioners include those related to gut health, cellular energy, folate metabolism, methylation detox, detoxification and the methionine cycle.

30.14 Genes Affecting GI Health

HLA (human leukocyte antigen) genes may increase the risk of gluten intolerance, peanut allergy, and celiac disease.

MCM6 (minichromosome maintenance complex 6) controls the activity of LCT gene, which codes for lactase. Variants in the MCM6 gene improve lactose tolerance and lack of variants increase the risk of lactose intolerance.

FUT2 (fucosyltransferase 2), involved in methylation pathway, can lead to lower levels of bifidobacteria and prebiotics [68]. Disruptions in these genes can affect intestinal health and contribute to GI comorbidity, as well as affect the strength of the immune system.

30.15 Folate and Methylation Genes

MTHFR (methylenetetrahydrofolate reductase) is the enzyme that activates folates to 5-MTHF needed for the re-methylation of homocysteine to methionine. In studies of Caucasian and Hispanic populations, it is estimated that 40–50% of the population has at least MTHFR SNP [69], but it is estimated 90% of children with autism have a SNP in one of the MTHFR genes and tend to undermethylate. The incidence of MTHFR and MTRR SNPs vary regionally and among different ethnic groups [70]. These SNPs affect detoxification, immune function, arterial health, vascular function, and neurocognitive and mental health.

Physical signs associated with folate SNPs include midline defects such as tongue, lip ties, spina bifida [71], hypospadias, cleft palate, Mongolian spots, sacral dimples, umbilical hernia, and impaired detoxification. This author has found many babies with tongue or lip ties have at least one MTHFR gene SNP and some babies show multiple midline issues such as tongue tie, hypospadias, sacral dimple and midline birth marks.

MTHFR, FOLR (folate receptor), and DHFR (dihydrofolate reductase) gene variants may require more folate-rich food or folate supplements. However, in people who overmethylate, there can be difficulty with methyl donors which can manifest as irritability, behavioral issues, and/or hyperactivity. Methylation is affected by numerous genes, nutrition, and environment. With these SNPs, avoid folic acid in enriched processed foods and supplements as unmetabolized folic acid can lead to immune dysfunction. The MTHFR polymorphism calls for methylfolate instead of folic acid and methylcobalamin rather than cyanocobalamin. Adeno sylcobalamin or hydroxycobalamin may work better depending on MTR (methionine synthase) and MTRR (methionine synthase reductase) methionine cycle genes.

RFC: reduced folate carrier polymorphisms in the mother can affect embryogenesis and organogenesis by compromising intrauterine availability of folate products and can disrupt normal neurodevelopment.

TCN2: transcobalamin II gene encodes a protein that transports vitamin B12 from blood into cells. One variant is associated with low serum B12 and high homocysteine. Decreased brain levels of B12 can be found in autism.

30.16 Transsulfuration Pathway Genes

CBS: cystathionine beta synthase regulates homocysteine to cystathionine to the transsulfuration pathway. CBS mutations that upregulate this enzyme can cause excess ammonia, taurine, and sulfur. A diet high in sulfur and related supplements may have a negative effect with these SNPs. The active form of B6, pyridoxal-5-phosphate can work better for those with genetic variations that slow CBS activity.

30.17 Neurotransmitter Genes

COMT: catechol-O-methyltransferase helps break down catecholamines, and the neurotransmitters dopamine, norepinephrine, and epinephrine, as well as some chemicals, toxins, and estrogen. COMT affects parts of the prefrontal cortex which is involved with personality, controlling behaviors, short-term memory, planning, abstract thinking, and emotion. COMT++ individuals may have difficulty breaking down the above chemicals and may have difficulty with methyl donors, leading to hyperactivity, behavior issues, anxiety, and irritability.

GABRB3: affects the GABA receptor and has been noted in some cases of autism [72].

30.18 Genes Affecting Detoxification

GST: glutathione S-transferase detoxifies some products of oxidative stress and toxins [73].

GSTM1: (liver) and GSTP1 (lungs and brain) – responsible for making the master antioxidant glutathione [73].

PON1: Paraoxonase aids in clearing pesticides and other toxins [73].

SOD: Superoxide dismutase is an antioxidant enzyme involved in Phase 2 liver detox that converts reactive oxygen species to hydrogen peroxide to quell free radical damage [74].

CYP2C9: There are 60 CYP (cytochrome P450) genes that aid the liver in clearing toxic substances in Phase 1 liver detox [74].

Variants in CYP, Pon1, SOD, GSTM1, and glutathione can decrease the effectiveness of detoxification and lead to environmental and chemical sensitivities. SNPs are common in these genes with autism [74].

30.19 Nutritional Support

In *Changing the Course of Autism,* author Bryan Jepson states, "Diet changes often result in rapid improvements in both neurological and GI function, leading to better

absorption of nutrients, decreased GI inflammation and decreased immune system activation: subsequent improvement in sleep, bowel function, mood and immunity follow" [75].

A gluten-free/casein-free diet is a common starting point. If a GF/CF diet seems like it would be difficult for the family, a urine peptide test for casomorphin and gluteomorphin is helpful to convince the family if a GF/CF diet is worth the effort. If one or both tests are positive and the family is willing to implement the diet, improved behavior is often seen [76]. Studies on GF/CF diets are inconclusive but parents often report improvements in learning and language. A gluten-free diet could foster inadequate B vitamins, iron, and zinc as well as lower fiber intake; however, these deficiencies are easily overcome with a whole-foods diet and supplementation when needed.

A recent study showed improvement in 67 children and adults on a healthy gluten-free, casein-free, soy-free (HGSCF) diet with sequentially added nutritional supplements. The results suggest that dietary and nutritional intervention can improve nutritional status, non-verbal IQ, and other symptoms of autism [77].

In susceptible children, dietary intervention is to reduce gut inflammation so the gut can heal. For instance, a gluten-free/casein-free diet is worth trying for at least 3 months [78]. Though studies are not clear that this is a helpful intervention, parents often report improvement. Signs that a GF/CF diet could be helpful include a distant, "spaced out" effect, picky eater, diarrhea/constipation, abdominal distention, and speech and auditory issues. Gluten and casein contain high levels of glutamate and aspartate, both excitatory neurotransmitters. Glutamate is involved in memory and learning. Glutamate converts to GABA, which is calming and helps with speech. However too much glutamate inhibits GABA conversion and creates neurological inflammation [79]. A healthy gut with a flourishing microbiome and good nutrition are key for a healthy brain.

Addressing biochemical individuality in diet is key. Clues can be assessed using food cravings, diet diary, food frequency, reactions to food, symptoms, biomarkers and lab results, and genetics. After several months on a GF/CF diet, the diet can be fine-tuned, changed, or layered with other diets. The Specific Carbohydrate Diet (SCD) is helpful for bowel inflammation, continued diarrhea, and gut dysbiosis. The Gut and Psychology Syndrome (GAPS) diet was derived from the SCD. It eliminates grains, dairy, sugars, and starchy carbs. It uses fresh meat and fish and bone broths to help heal the gut. The Body Ecology Diet is helpful for yeast overgrowth, digestive discomfort, excess gas, and yeast symptoms. A Low Oxalate Diet can be helpful for discomfort in the urinary or GI tract, body pain, continued stimming, excess masturbation, and bowel issues. Oxalates cause gut inflammation and often show up high on urine organic acid tests. Calcium citrate can be used to lower oxalates with meals. Many healthy foods contain oxalates such as spinach, beets, berries, beans, nuts, and chocolate so just high oxalate foods are limited. Oxalates can be removed by soaking grains, nuts, and beans [79].

Box 30.1 Signs of Phenol Sensitivity

- Sulfate in blood and urine
- Reactions to phenol/salicylates/Tylenol
- Cravings for phenolic foods—dark fruits, apples, onions, potatoes, curly kale, cabbage
- Family history of autoimmune/neurologic issues
- Phase 2 liver detox test for sulfation

Many whole foods have a high phenolic content with many protective properties and antioxidants. However, children with autism tend to have low sulfate levels and phenol sulfotransferase (PST), leading to a decreased capacity to detoxify phenols [80]. Dysbiosis and heavy metals can also adversely affect sulfation leading to phenol sensitivity. Common symptoms of phenol intolerance include dark circles under the eyes, red face/ears, head banging, self-injurious behavior, behavior issues, hives, inappropriate laughter, diarrhea, and stomach aches [79] (▶ Box 30.1).

Finding the best foods and diet takes patience. Whenever possible, expand healthy food choices and rotate foods to lessen food reactions. Textures are often an issue. How food is prepared can alter textures to be more acceptable.

Nutrient support: Children with autism have brain dysfunction. These children operate in narrow range. Add supplements very slowly and monitor the results. A vitamin/mineral supplement designed for sensitive children can be added. Balanced essential fatty acid supplementation and healthy fats in the diet support brain health. Digestive enzymes can be helpful. For children with phenol sensitivity, No-Fenol and molybdenum can help process phenols [79].

Carnitine helps transport fatty acids in cells, needed for fatty acid metabolism and energy production in the heart and muscle. Probiotics support gut health and *Saccharomyces* helps reduce clostridia overgrowth [81]. Vitamin D can have an immunomodulatory on T helper cells and T regulatory cells [82].

Epsom salt baths or foot soaks work for some children. Epsom salt is magnesium sulfate, which can be absorbed through the skin. Start with 1 teaspoon for sensitive children and work up to ½ to 2 cups per bath for 20 minutes depending on the size of the child. Some parents report their children sleep better and are more relaxed with Epsom salt baths.

Case Study: ASD

Jack is a 2-year-old boy with developmental and speech delay and recently diagnosed with autism. He has decreased eye contact, aggressive behavior, and difficulty with transitions and engages in solitary play.

Prenatal History: Second pregnancy, which was a pleasant surprise. Mom was in good health but suffered severe nausea for the first month. At 26 weeks of gestation, Mom had a TDaP vaccine and the baby stopped moving for several weeks.

Mom had severe redness and swelling at the injection site and had difficulty lifting her arm for months. In the third trimester, she developed severe depression, which persisted postpartum.

Birth History: Labor began spontaneously at 41 weeks and lasted 21 hours. No medications were used, but mom pushed for 2 hours. Birth weight was 7.5 pounds and Apgar scores were 8 and 9. Baby's head shape was crooked. Baby was alert and nursed immediately but ineffectively.

Milk supply was low, possibly due to a history of breast reduction surgery. He initially lost 20 ounces in the first week. He breastfed for 2 months. He preferred to bottle feed and was intolerant to cow dairy and soy formula, so he was given a hypoallergenic formula and then a non-GMO sensitive formula. He spit up after every feeding. Spitting up is most often irritation of the vagus nerve (CNX) from birth trauma but can also be in response to a food that mom is eating or formula, most often cow dairy. Rarely it can be due to a congenitally lax sphincter. Difficulty latching is also a structural issue as birth trauma can cause compression of the hypoglossal nerve (CN XII), which does not have a canal yet, but traverses through a slit in the occipital condyles. He did not have a tongue tie, which is sometimes related to a MTHFR SNP.

Past Medical History: At 2 months, he had DTaP vaccine. At 3 months, he had a fever of 103 and was hospitalized for late-onset Group B strep. At 8 months, he had a second DTaP and became lethargic and miserable and lost his appetite. At 9 months, he developed repetitive play, spinning wheels of trucks, and stopped interacting in play.

Diet History: Jack has a poor appetite and is a picky eater. His diet consists of oatmeal bars, crackers, yogurt, meat, chicken, nuts, a few fruits and veggies, as well as two bottles daily of a pediatric meal replacement beverage. The meal replacement contains water, sugar, corn maltodextrin, milk protein concentrate, high oleic, safflower oil, canola oil, and soy protein isolate. Less than 0.5% of the following: short-chain fructooligosaccharides, natural and artificial flavor, cellulose gel, potassium chloride, magnesium, phosphate, potassium citrate, calcium phosphate, tuna oil, calcium carbonate, potassium, salt, cellulose gum, choline chloride, ascorbic acid, soy lecithin, monoglycerides, potassium hydroxide, m-inositol, carrageenan, taurine, ferrous sulfate, dl-alpha-tocopheryl, acetate, L-carnitine, zinc sulfate, calcium pantothenate, niacinamide, manganese sulfate, thiamine chloride hydrochloride, pyridoxine hydrochloride, riboflavin, lutein, cupric sulfate, vitamin A palmitate, folic acid, chromium chloride, biotin, potassium iodide, sodium selenate, sodium molybdate, phylloquinone, vitamin D3, and cyanocobalamin. Corn maltodextrin, soy, safflower, and canola oil are commonly from GMO crops. He prefers sweet and salty foods.

Family History: postpartum depression, depression, and anxiety.

Physical Exam Positives: well-developed child with pale skin, dark circles under his eyes, aphthous ulcers, distended abdomen, + gas, bloating, mild perioral rash, poor balance, lumbosacral area is compressed, walks with his left leg externally rotated, occipital and frontal bones show molding from birth, and head feels compressed, particularly in the occipital area. Restrictions in the occipital area can reflect on the health of the cerebellum, which is involved with motor skills, balance, and muscle memory. Poor motor skills affect social skills and communication skills.

Labs: Gluten/Casein Peptides Test – positive for both indicating a GF/CF diet should be very helpful.

In this case, both gluten and casein are being metabolized in gluteomorphin and casomorphin peptides, having opiate-like effects causing behavioral issues, brain fog, and addictive symptoms to these foods. Organic acid test showed high furancarbonylglycine, the only yeast and fungal marker that was high. Several mitochondrial markers were high, including succinic acid which may relate to a relative deficiency of riboflavin and/or CoQ10 which are cofactors for succinic dehydrogenase in the Krebs cycle.

High malic acid supports the use of niacin and CoQ10 and high aconitic acid requires glutathione to support the enzyme aconitase. High quinolinic acid/5-HIAA ratio suggests neural excitotoxicity, common in autism. Inflammation from infection or immune overstimulation, increased cortisol, or exposure to phthalates all can increase this ratio. Carnitine, which mediates the transfer of fatty acids across the membrane of the mitochondria, melatonin, turmeric, and garlic, may reduce injury to the brain by quinolinic acid.

MAO B + (an X-linked gene): associated with aggression, poor breakdown of serotonin, COMT ++ affecting methylation, neurotransmitter degradation, MTHFR C677T +-, VDR + -.

MAO-B interacts with COMT and VDR. MAO-B may present clinically with anxiety, allergy, OCD (obsessive-compulsive disorder), and tics. MAO-B++ tends to have high amines, dopamine, and PEA (phenylethylamine), whereas MAO-B -tends to have low dopamine and MAO-B + - can have up-and-down dopamine.

Treatment: Parents began a GF/CF diet and he continued his basic supplements. He began a program of osteopathic manipulative treatment aimed at releasing restricted areas of the body and improving blood flow and glymphatic drainage in the brain. (Glymphatics are essentially the lymphatics of the brain.) Within 3 weeks he began saying more words, developed better eye contact, and began interacting with his siblings more (although not always peacefully). GSH cream and ascorbyl palmitate vitamin C were added to support detoxification. Glutathione is a major antioxidant and reduces oxidative stress from free radicals, lipid peroxides, and heavy metals. Ascorbyl palmitate vitamin C is lipid-soluble and thought to be most helpful for the brain [83].

Parents were instructed to do a 20-minute Epsom salt baths twice a week and "clay play" with bentonite clay. Clay play is best done outside because plants love it but plumbing pipes do not. He continued progressive therapeutic measures with nutrient support, speech therapy, and occupational therapy (OT) and applied behavioral analysis (ABA) and continues to make progress.

30.20 ADHD

ADHD is defined as inattention, hyperactivity, forgetfulness, distractibility, and impulsive behavior, although symptoms and causes vary for each individual child. ADHD can trigger intense emotions that overwhelm the brain. These children tend to have low frustration tolerance, hot tempers, excitability, social anxiety, and difficulty with relationships. According to CDC reports in 2016, one in nine children age 2–17 in the United States has been diagnosed with ADHD. It is exploding in incidence and there is no good answer for how to treat it or prevent it. A thorough assessment by a team is needed.

Treatment should include diet modification, biomedical treatment, and nutritional supplementation as indicated, along with behavior modification, lifestyle change, and counseling. Medication can be helpful for some children, but should never be the only treatment as it has not been shown to necessarily have long-term benefits.

Shaw found that children with ADHD are behind their classmates by about 3 years in brain development, although they had precocious motor cortex development [84]. On the positive side, these children can be fun, smart, creative, and driven and, as adults, often run large companies.

One study shows the brain maturation delay theory to include subcortical structures such as the nucleus accumbens (motivation, reward circuit, involves dopamine and serotonin), amygdala (processing of memory, emotional reactions, decision-making), caudate (procedural and associative learning and inhibitory control of action), hippocampus (short-term to long-term memory), and putamen (influences learning, uses GABA and acetylcholine) [85].

ADD/ADHD is not a single issue and it is difficult to define pathology. It tends to run in families and several genes are often involved. Environmental issues are an increased issue. Similar symptoms can also be seen with other issues such as thyroid issues, lead toxicity, head injury, divorce, environmental toxins, food additives, fetal alcohol syndrome, fragile X, mitochondrial issues, developmental delays, anxiety, and food allergies.

30.20.1 Lifestyle and Environmental Factors

ADHD may be caused by or made worse by toxic exposure, trauma, food allergies/sensitivities, yeast overgrowth, and nutritional deficiencies.

Biomedical testing:

- Organic acid testing:
  1. Evaluates biomarkers for *Candida* overgrowth, which can affect brain function and sensory issues and contribute to self-stimulatory behavior, bacterial overgrowth, and neurotransmitter metabolites
  2. Clostridia toxic metabolite markers
- Lab tests: cholesterol panel, copper/zinc ratio, ferritin, vitamin D, thyroid testing, and streptococcus antibodies. Copper/zinc ratio: Elevated copper with depressed zinc can contribute to ADHD, hyperactivity, and rage behavior [86].
- Comprehensive Fatty Acids Test
- Comprehensive stool analysis
- Gluten/Casein Peptides Test – urine
- IgE/IgG food allergy/sensitivity testing including candida
- Metals hair test or toxin testing histamine levels normal range: 40–70 ng/ml. Histamine is broken down by methyl groups, so high histamine can relate to low neurotransmitters and under-methylation, depression, allergies, OCD, and hyperactivity. Low histamine can relate to high neurotransmitters and over-methylation, frustration, cries easily.
- Gene testing: MTHFR SNPs are common. Dopamine D4 receptor gene (DRD4), dopamine D5 receptor gene, COMT, dopamine transporter gene (SLC6A3 or DAT1), and MAO genes are some genes thought to be involved. Dopamine is often low.

30.21 Dr. Amen's Seven Types of ADHD [87]

Dr. Amen's clinical experience and SPECT brain scan imaging led him to delineate seven types of ADHD.

1. Classic ADHD: Inattentive, distractible, hyperactive, disorganized, and impulsive. Energetic, fun, loves to play, often walked early. Difficulty with time, getting homework done efficiently.

Cause: Brain activity is normal at rest but decreases during concentration. There is decreased blood flow to the prefrontal cortex, cerebellum, and basal ganglia. Dopamine supports attention span, focus, and motivation and is likely deficient.

Treatment: Stimulating supplements such as rhodiola, green tea, L-tyrosine, and high EPA fish oil. Physical activity especially before school and homework. Stimulant medications are sometimes used.

2. Inattentive ADD: Short attention span, distractible, disorganized, procrastinates, and daydreams.

Cause: Dopamine is deficient.

Treatment: High-protein, lower-carb diets are helpful as is regular exercise. For types 1 and 2, L-tyrosine can help build dopamine. It is best taken on an empty stomach. It can increase the brain level of phenylethylamine (PEA), a mild stimulant that can increase motivation. PEA is byproduct of the amino acid phenylalanine. (Chocolate contains PEA, explaining its longtime popularity.)

3. Over-focused ADD: Classic ADD with signs of having difficulty shifting attention and negative thought patterns or behaviors.

Cause: Dopamine and serotonin deficiencies, over-activity in the anterior cingulate gyrus, reducing flexibility.

Treatment: L-tryptophan, 5-HTP (can reduce depression), saffron, and inositol (helps boost alertness, focus, mood, and mental clarity). Avoid a high-protein diet if it triggers mean behavior. Neurofeedback can be helpful to train the brain to recruit focus brain waves.

4. Temporal lobe ADD: Classic ADD as well as learning, memory, and behavioral problems such as quick anger, aggression, anxiety, and mild paranoia.

Cause: Changes in the temporal lobe, decreased activity in the prefrontal cortex.

Treatment: Amino acid GABA is used to calm neural activity and inhibit nerve cells from over-firing or erratic firing, magnesium for anxiety and irritability, and gingko or vinpocetine for learning and memory problems. Sometimes anticonvulsant medications are used to help with mood stability.

5. Limbic ADD: This type of ADD can include depression, moodiness, negativity, irritability, social isolation, and low self-esteem. Depression tends to be cyclical, whereas ADD symptoms tend to be more constant.

Cause: Decreased prefrontal cortex activity, hyperactivity in the deep limbic (emotional center) center of the brain. Painful emotions can occur when the deep limbic system is inflamed. The deep limbic system also processes the sense of smell and affects sleep, appetite, social awareness, motivation, and drive.

Treatment: Diet and aerobic exercise. Amino acid supplements, DL-phenylalanine and L-tyrosine. DL-phenylalanine may cause anxiety, jitteriness, and hyperactivity in children.

6. Ring of fire ADD: Includes ADD symptoms with sensitivity to noise, light, clothes, touch, rigid thinking, grandiose thoughts, and unpredictable behavior. Symptoms tend to be consistent, as opposed to bipolar disorder where symptoms cycle.

Cause: Hyperactive brain especially the cingulate gyrus, parietal lobes, temporal lobes, and prefrontal cortex.

Treatment: Calming supplements GABA, 5HTP, and L-tyrosine can be helpful. Stimulant medication may worsen symptoms, if used alone. Diet to reduce allergies and inflammation and exercise are helpful.

7. Anxious ADD: Includes ADD symptoms with signs of anxiety, headaches from stress, difficulty with social interactions, insecurity, and self-consciousness.

Cause: Over-activity in the basal ganglia affecting dopamine.

Treatment: Inositol, L-theanine, Holy Basil, and magnesium promote relaxation and focus. A combination of *Magnolia officinalis* and *Phellodendron amurense* has antistress benefits and reduces cortisol [88]. Physical exercise and reducing electronic overstimulation have calming effects. Stimulant medications can increase anxiety and sleep issues as well as cause these kids to become more mechanical. If stimulant medication is needed, try the lowest dose possible.

30.21.1 General Dietary and Lifestyle Strategies for ADHD

Many children with ADHD have nutritional or metabolic imbalances, dietary issues, food allergies or sensitivities, toxic exposures, yeast overgrowth, gastrointestinal imbalances, or chronic infections that can be improved with nutrition. Diet alone will not treat attention deficit issues.

- A clean whole-foods diet is essential and can reduce pesticide accumulation [89]. This is important for all children. Encourage parents to purchase the best food they can afford.
- Avoid processed foods as much as possible. Help children recognize the effects of what they eat and the possible consequences.
- Reduce high-sugar foods and starchy carbohydrates. These foods increase insulin levels triggering hypoglycemia. This can lead to the brain secreting increased glutamate, a chemical messenger which becomes an excitotoxin in excess. Too much glutamate affects mood by causing agitation, anger, anxiety, depression, and panic attacks.
- Free glutamate is a component of many food additives such as MSG, yeast extract, calcium caseinate, etc. High-sugar diets also increase chronic inflammation. MSG and hydrolyzed vegetable protein can decrease dopamine levels.
- High glycemic diets impair delta 5 and delta 6 dehydrogenase, enzymes involved in EPA and DHA production needed for brain health. Hydrogenated oils impair cell membrane and brain function.
- Avoid allergens. The top seven are soy, wheat, cow dairy (goat milk does not contain A1 casein, which can cross-react with gluten and may be better tolerated), peanuts, tree nuts, eggs, and shellfish. Watch for food family allergies. For instance, those with latex allergies might need to avoid avocados, bananas, kiwis, and papayas.
- Gluten sensitivity can affect the nervous system and the brain. For children with a gluten intolerance, a GF diet can improve behavior and attention. Many patients with celiac disease have ADHD symptoms that improve with a GF diet.
- Avoid food additives and genetically modified ingredients. Blue #1 and #2, Green #3, Orange B, Red #3 and #40, Yellow #5 and #6, and sodium benzoate are among the many food additives that can affect focus and behavior [90]. Artificial coloring can be found in sports drinks, candy, cake, chewable vitamins, and toothpaste. Glyphosate, the active ingredient in Monsanto's Roundup herbicide, was originally licensed as an antibiotic. It destroys the microbiome of the soil and the human gut. In addition, it limits the body's ability to detoxify and blocks vitamin D. GMO foods have been modified to survive direct application of herbicides; hence eating GMO foods means ingesting glyphosate and other toxic components of the herbicide.
- Nitrites used in some cured meats such as lunchmeat, bacon, ham, sausages, and hotdogs can cause restlessness and rapid heart rate as well as increased risk of type 1 diabetes, IBS, and cancer. Artificial sweeteners can affect cognitive function and emotional balance.

- Omega-3 fatty acids can be helpful in reducing hyperactivity, behavioral issues, and learning problems. They support the executive function centers of the brain. DHA and EPA from clean fish or fish oil are most helpful as not all people can convert ALA from vegetarian sources. Wild-caught salmon also contains B6. Avoid damaged fats in refined processed foods.
- Support healthy bowel flora and healthy, daily bowel movements. A toxic gut can increase behavior symptoms, ADHD, depression, and autism.
- B-6 at 15–30 mg/kg may be helpful for focus with a B complex, EPA/DHA, multi-mineral, and probiotics.
- Vitamin D supplementation may improve cognitive function and attention and lessen hyperactivity and impulsivity in children with ADHD who are vitamin D deficient [91].
- Inositol, Bacopa, and theanine can be relaxing.
- Rhodiola rosea can improve focus. There are several good supplement formulas for improving focus; however not all are user-friendly for the pediatric population as they require cooperation and being able to swallow capsules.
- Sensory integration issues can compound ADHD and interfere with learning. Sensory integration refers to how our senses work together to process and organize incoming information.
- Exercise can enhance dopamine and norepinephrine production, which can help improve attention and focus. Regular exercise can help relieve stress, regulate hyperactivity, and improve concentration. Outdoor activity is important, including exposure to natural light. Avoid "nature-deficit disorder," a term coined by author Richard Louv [92]. Exercise before school or on the way to school as well as before and during homework is helpful. Incorporate cross-body exercises such as running, skipping, marching, or Simon Says using cross-lateral motions.
- Downtime is important too: allow time for free play, building with Legos or blocks, drawing, playing in the dirt, petting the cat, etc.
- Neurofeedback can help the frontal lobes learn to stay in a focused beta state. Studies show that the results can have lasting effects. Cognitive behavioral therapy can improve skills and habits for executive function and may improve emotional and social self-regulation.
- Essential oils: vetiver and cedarwood can calm and improve focus. Rosemary and peppermint can improve alertness and enhance memory. Frankincense brings clarity and higher cognitive function. Ylang ylang and lavender are calming.
- Sleep issues are quite common in children with ADHD. They may have difficulty falling asleep, restless sleep, or difficulty waking. Areas of the brain that regulate attention also regulate sleep. Dysregulation of the serotonin system can affect both these areas. Their internal circadian clock may be off, not releasing melatonin at the best time in the evening. This faulty signaling can contribute to difficulty with schedules and keeping track of time. The COMT gene is responsible for breaking down dopamine which helps regulate sleep. Children with COMT gene snips may have more difficulty with sleep. Medication and caffeine can also affect sleep. A regular bedtime every day, a comfortable bed, and a good sleep environment facilitate restful sleep.
- Melatonin can help with a faulty circadian clock when taken an hour before bedtime. Children's dosages are based on body weight and metabolism. GABA works for some, and sleep tea or essential oils like lavender and rosemary can be helpful. Benadryl (diphenhydramine) causes drowsiness but has been recently implicated in dementia when used regularly so it's not a good idea in children with brain challenges.
- No computers, phones, or TV in the bedroom. Turn off Wi-Fi, which is low-level microwave radiation, at night (or better yet, use wired computers). Radiation from wireless devices can delay deep non-REM sleep, which can impact learning and memory, as well as increase oxidative stress. Electromagnetic frequencies (EMF)/radiofrequency radiation (RFR) can also adversely affect immune and metabolic function. Avoid placing beds near walls that have smart meters outside.
- Avoid blue light from computers, TV, iPads, and iPhones for 1–2 hours before bed. Blue light signals the pineal gland to shut off melatonin production.
- Digesting snacks too close to bedtime can keep children awake. Warm milk, turkey, or an apple contains tryptophan, which can facilitate sleep. Avoid GMO Arctic apples.
- Parenting is a tough job. This is particularly true for parents with ADHD parenting children with ADHD. They can thrive on turmoil in relationships unconsciously because it stimulates their brain and makes them more alert. Retraining patterns of behavior or behavior modification can be a big help for families.
- Some teens with ADHD self-medicate with marijuana, often to reduce anxiety. Marijuana has negative effects on attention, memory, and learning that can last for days to weeks. The hippocampus region of the brain is important for memory, learning, and the integration of sensory experience with emotions and motivations as well as converting information into short-term memory. THC (delta-9-tetrahydrocannabinol) suppresses the way the information processing system of the hippocampus works [93].
- Executive function support is helpful. Watches and timers help with time periods needed for tasks. Break up lengthy tasks into small steps. Support emotional regulation and provide positive motivation.
- Finding the best teacher/school is essential. These children need strategies for emotional regulation, support planning for the future, externalized motivation, and encouragement.

Biomedical treatments, nutritional supplementation, and diet are an important adjunct to behavior modification, lifestyle changes, executive function tutoring, occupational therapy,

GMO foods	Glyphosate used as desiccant
Corn	Wheat
Soy	Barley
Cotton	Rice
Canola	Sugar cane
Alfalfa	Sugar beets
Wheat-soon	Canola
Sugar beet	Cotton
Squash	Beans, peas, lentils
	Sweet potato
	Rye, buckwheat
	Millet

Fig. 30.3 Recommended foods to avoid to lessen oxidative stress and inflammation

neurofeedback, and, if needed, medication. Underlying issues need to be addressed and medications should never be the only intervention because it does not provide long-term improvements in attention and learning (Fig. 30.3).

30.22 Seizure Disorders

Seizures have many different causes and can occur at any age. The term epilepsy encompasses various types of seizure disorders thought to be caused by abnormal electrical signals in the brain. Seizures in newborns can be triggered by anoxia, infection, bleeding, metabolic imbalances and drug withdrawal. Structural damage to the brain can occur in the perinatal period and during birth from vascular or cerebral trauma; later from head injury, sports injuries, bike or motor vehicle accidents, cerebrovascular accidents, as well as from intracranial tumors, metabolic diseases, toxins, vaccines, and drugs. This damage may be visible or more often invisible and most often is not seen on CT or MRI studies. Electroencephalogram (EEG) is used to look for seizure activity in the brain, but in patients with observed seizures, it is sometimes difficult to capture the activity on EEG. For seizures resulting from a traumatic cause, cranial osteopathy or cranial sacral therapy may be helpful. Seizures impacting the life of a child are most commonly treated with anticonvulsant medications. Surgery is used only if there is a specific identifiable focus. Seizures are driven by inflammation and excitotoxicity. Supportive care for children with seizure disorders includes diet, vitamins, supplements, herbs, homeopathy, mind-body techniques, and manual medicine.

A vitamin B6 (pyridoxine) deficiency can cause or worsen seizures, especially in infants and newborns [94]. B6 can sometimes help older children also. Sodium, calcium, and magnesium are necessary for stable electrical activity of the brain. Low magnesium levels can trigger seizures and may lead to low calcium levels. Low blood sugar can trigger seizures and is most common in children with type 1 diabetes taking insulin.

Low sodium can be caused by diuretics, anti-seizure medications such as carbamazepine and oxcarbazepine, or excessive water intake.

Rare inherited metabolic disorders such as pyridoxine-dependent seizures, biotinidase deficiency, and folinic acid-responsive seizures respond to supplying the missing nutrient. Pyridoxine-dependent epilepsy is not responsive to antiepileptic medication, but responds clinically and with improvements on EEG to large daily supplementation of B6. The folate receptor 1 (FOLR1) gene may also be involved.

A SNP in this gene can lead to cerebral folate deficiency that may affect social interactions, developmental delay, and seizure control.

Biotinidase deficiency can be profound or partial, depending on how severe the enzymatic defect is [95]. Symptoms most often occur between 3 and 6 months with seizures, hypotonia, developmental delay, skin issues, and respiratory problems. There are four biotin-dependent carboxylases that can be treated with biotin. This issue may be picked up on the newborn screening exam.

The ketogenic diet, developed by Russell Wilder at the Mayo Clinic in 1921, is now considered an important therapeutic option for epilepsy as well as infantile spasms [96] and is being investigated for children with autism and Rett syndrome. Despite the success in resolving or lessening seizures it provided for many children, it remained little used until it became popular in the 1990s, with the Charlie Foundation for Ketogenic Therapies. The ketogenic diet involves changing the body's primary energy source from glucose to ketones. The breakdown products of ketones, beta-hydroxybutyric acid, cross the blood-brain barrier and are used by the brain for energy. The ketogenic diet helps reduce microglial activation, brain inflammation, and excitotoxicity. Studies have shown that half of children will have a 50% improvement in seizures and about one third show a 90% improvement. A small percentile of children become seizure-free [97]. This diet is sometimes initiated under hospital conditions. "The diet is difficult," according to one mother, "but not nearly as difficult as watching your child have a seizure." It requires a lot of prep work, counting carbs, weighing food, and making substitutions that suit a child's taste, but the result can be eventual resolution of seizures in some cases or a reduction in seizures.

If the diet is successful, there are fewer emergency room visits and doctor visits and less medication which often translates to improved development. Some children with seizures prefer high-fat foods, and one study from 2015 suggests this may be helpful in predicting which children will have success with the ketogenic diet. The ketogenic diet should be managed by a neurologist and dietitian. This is a medical diet and needs supervision for side effects, efficacy, medication adjustment, and weight gain. It is initiated by fasting during a brief hospital stay.

Several other versions of the ketogenic diet that are used for seizures include the modified Atkins diet (MAD), the medium-chain triglyceride (MCT) diet, and the low glycemic index treatment (LGIT) [98]. The efficacy of the MAD diet is good and it is easier to manage, although stricter ketosis works better for some children. The modified Atkins diet

Box 30.2 Conditions Likely to Respond to Ketogenic Diet

- GLUT-1 deficiency syndrome (SLC2A1 gene)
- Mitochondrial disease
- Children receiving tube feeding or mostly formula
- Pyruvate dehydrogenase deficiency
- Myoclonic-astatic epilepsy (Doose syndrome) often presents ages 3–5 years with head drop seizures
- Dravet syndrome (severe myoclonic epilepsy of infancy (SCN1A gene)
- Infantile spasms (West syndrome)-1 study showed 2/3 have greater than 90% reduction in spasms
- Tuberous sclerosis complex—-may be more long-term treatment
- Rett syndrome

(MAD) can be started outside the hospital and does not require fasting to initiate. It should be under the supervision of the neurologist.

The advantages of the modified Atkins diet (MAD) are:

- No fluid or calorie restrictions or limitations.
- There are no restrictions on proteins as fats do not have to be weighed or measured. Typically 35% of calories for a patient on the MAD come from protein.
- Foods do not have to be weighed and measured, but carbohydrate counts are limited to 15–20 g a day.
- The MAD is easier to manage outside the home and in restaurants and is easier for the family.
- Family members can eat the same way.

MAD has a similar efficacy as the ketogenic diet (40–50% with greater than 50% seizure reduction, including approximately 15% seizure-free). It works for men and women equally and is being used in children, adolescents, and adults. Like the ketogenic diet, it is most commonly used for patients with daily seizures who have not fully responded to medications. It is under study for regions of the world with limited resources for which the classic ketogenic diet would be too difficult and/or time-consuming.

The ketogenic diet is worth trying for all seizure types and severities, in all ages and sizes (▶ Box 30.2).

30.22.1 Contraindications to the Ketogenic Diet

- Carnitine deficiency (primary)
- Carnitine palmitoyltransferase (CPT) I or II deficiency
- Carnitine translocase deficiency
- B-oxidative defects
- Pyruvate carboxylase deficiency
- Porphyria

Ketogenic diets do not work as well if there are issues maintaining adequate nutrition, a surgical focus for the seizures, or parental or caregiver noncompliance.

One challenge of the ketogenic diet has been that the recommended fat sources were not always the healthiest and contained damaged fats. By using healthy fat sources such as grass-fed butter, organic ghee, nut butters, coconut and MCT oil, olive oil, flaxseed, omega-3 fatty acids, and homemade mayonnaise or mayonnaise made from healthier fat sources, the chances for brain healing on a cellular level are improved.

Food additives such as colorings, preservatives, monosodium glutamate (MSG), and artificial sweeteners including aspartame, saccharin, and phenylalanine can trigger seizures in some people. Some ketogenic formulas contain aspartame or other artificial sweeteners. Substitute healthier sweeteners such as stevia for the artificial sweeteners often recommended.

MCT is found in coconuts, in coconut and palm kernel oil, and in smaller amounts in butter and high-fat dairy products from grass-fed cows and goats. There are four types of MCTs. Coconut oil contains all types.

- 6 carbons (C6), caproic acid
- 8 carbons (C8), caprylic acid
- 10 carbons (C10), capric acid
- 12 carbons (C12), lauric acid – known for antibacterial, antimicrobial, and antiviral properties

Fractionated coconut oil contains primarily C8 and C10, which support brain health and curb appetite.

MCTs have antioxidant and anti-inflammatory properties as they produce fewer oxygen species when metabolized to ATP. Most MCT oil products contain C8 and C10 fats. C8 (caprylic acid) converts to ketones more efficiently than C10. Ketones make great fuel for mitochondria and support their functioning. Some companies make MCT oil with a higher C8 content, which may be better tolerated. High C8 MCT oil is best given in the morning as it wakes the brain up. Dose is important as too much MCT oil can cause diarrhea in some children.

30.22.2 Ketogenic Diet Labs

Check labs prior to starting the diet and at 3 and 6 months and then every 6 months thereafter.

Urinalysis

After an 8-hour fast:

- CBC with differential
- Complete metabolic profile (SMA-20)
- Complete lipid profile (fasting)
- Selenium level
- Carnitine profile (total and free)
- 1,25-OH-vitamin D level
- A red cell fatty acid profile can help guide choices of fats

30.22.3 Supplements for the Ketogenic Diet

- Multivitamins: Because the ketogenic diet eliminates grains and limits fruits and vegetables, it is essential that children take a complete, low-carb multivitamin.

- Calcium and vitamin D: Many epilepsy medications affect nutritional status including calcium metabolism and subsequent bone loss. In addition, the diet is low in calcium sources. Heavy cream, often used in the ketogenic diet, is low in calcium. Consider the need for calcium supplements and vitamin D.
- Oral citrates can help prevent kidney stones by alkalinizing the urine and solubilizing urine calcium.
- Constipation is a common side effect of the ketogenic diet. Food choices such as MCT oil, avocados, and high-fiber vegetables like cucumbers, asparagus, and zucchini are helpful, as well as sufficient fluids, and exercise. Magnesium citrate is used to relieve constipation but check for drug interactions.
- Check nutrient depletions related to anticonvulsants and other medications for all patients. For instance, phenytoin (Dilantin), carbamazepine (Tegretol), valproic acid (Depakote), topiramate (Topamax), and gabapentin (Neurontin) can deplete B6, folate, and B12.
- Carnitine is needed for fatty acid to be transported into the mitochondria during the breakdown of fats. Fatigue and lethargy can be symptoms of carnitine deficiency. Supplement if deficiency or symptoms occur.
- Selenium: an antioxidant nutrient involved in reducing oxidative stress and preventing cardiomyopathy. Food sources include Brazil nuts, tuna, beef, chicken, turkey, and grains. Check the multivitamin for adequate amounts.

Supplements to improve seizure threshold:

- Curcumin, quercetin, carnosine, acetyl L-carnitine, resveratrol, and bioflavonoids are anti-inflammatory, potentially reducing microglial activation and excitotoxicity.
- DHA, omega-3 oils play a role in brain function, growth, and development and are anti-inflammatory and reduce excitotoxicity. Studies show a decrease in seizures in children taking omega-3s (EPA-DHA) [99]. Some children are low in arachidonic, an omega-6. Best to test with a red blood cell fatty acid test.
- Magnesium citrate is anti-inflammatory and blocks one of the main glutamate receptors in seizures. Magnesium has been shown to raise seizure threshold levels. Some forms of magnesium may be more beneficial [100]. Magnesium L-threonate crosses the blood-brain barrier and magnesium glycinate is well absorbed and less likely to cause diarrhea. However, magnesium levels are difficult to assess. An RBC magnesium test is more accurate than serum.
- Melatonin supports healthy sleep cycles and has anti-inflammatory and antioxidant properties.
- One pilot study showed that correcting vitamin D deficiency improved seizure control in drug-resistant epilepsy [101, 102].
- Grape seed extract contains oligomeric proanthocyanidins, which help protect the hippocampus. It reduces stress and supports mitochondrial function [103] (▶ Box 30.3).

Box 30.3 Medications That May Increase Seizure Frequency

- Antihistamines
- Insulin and diabetes medications
- Oxytocin
- Antidepressants
- Clomipramine
- Clozapine
- Lithium
- Fluoroquinolone antibiotics
- Methylphenidate
- Metronidazole or Tinidazole

There are herbal combinations and supplements in various cultures that have anticonvulsant properties. Also, there are herbal remedies and supplements that can have proconvulsant effects or interact with antiepileptic medications [104].

General diet guidelines include avoiding artificial sweeteners and food additives, excitotoxic food additives such as MSG, aspartame, l-cysteine, carrageenan, hydrolyzed proteins, soy proteins and isolates, soy sauce, autolyzed yeast, and caseinates. These foods can contribute to already overstimulated glutamate receptors, which can trigger seizures. Cheese, milk concentrates, and mushrooms are high in glutamate.

30.23 PANDAS and PANS

PANDAS (Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections) and PANS (Pediatric Autoimmune Acute-Onset Neuropsychiatric Syndrome) strike fear in the heart of parents who have seen their children change overnight, despite the hot debates about the existence of PANDAS for years.

PANDAS was described in the 1990s at the National Institute of Mental Health (NIMH) by Drs. Susan Swedo, Henrietta Leonard, et al., who observed cases of OCD that began abruptly, with dramatic symptoms rather than coming on gradually over weeks or months which is typical of OCD [105].

PANDAS began as a clinical diagnosis made when children and adolescents develop an *abrupt* obsessive-compulsive disorder and/or tic disorders following a strep infections. More comprehensive tests to aid diagnosis are now available.

30.23.1 NIMH Guidelines for Diagnosing PANDAS

- Presence of clinically significant obsessions, compulsions, and/or tics.
- Unusually abrupt onset of symptoms or a relapsing-remitting course of symptom severity.
- Pre-pubertal onset. Symptoms of the disorder first become evident between 3 years of age and puberty.

- Association with Group A streptococcal (GAS) infection, repeat strep, rheumatic, or scarlet fever.
- Note: In PANDAS, GAS infections may be present without apparent pharyngitis (i.e., no complaints of a sore throat).
- Association with other neuropsychiatric symptoms.

Other common symptoms listed by NIMH include:
- Parents can usually remember the day their child's behavior changed. PANS and PANDAS is characterized by an abrupt onset of obsessive-compulsive disorders and/or tics.
- Severe separation anxiety.
- Generalized anxiety.
- Motoric hyperactivity, abnormal movements, and a sense of restlessness.
- Sensory abnormalities (sensitivity to light or sounds), distortions of visual perceptions, and, occasionally, visual or auditory hallucinations.
- Difficulties concentrating and loss of academic abilities, particularly in math and handwriting.
- Increased urinary frequency or sense of urgency and/or a new onset of bedwetting.
- Irritability (sometimes with aggression) and emotional lability. Abrupt onset of depression can also occur, with thoughts about suicide.
- Developmental regression, including temper tantrums and "baby talk."

It is hypothesized that PANDAS is related to immune dysfunction at one or more levels [106]:
- Cross-reactive "anti-brain" antibodies trigger OCD, tics, and neuropsychiatric symptoms [106].
- Inflammation of the basal ganglia which are involved with movement and behavior.
- Disruption of chemokines or cytokines altering central nervous system function.

This emphasizes the link between autoimmunity and inflammation with neuropsychiatric disease.

30.23.1.1 Laboratory Testing for PANDAS

- Throat culture GABHS positive.
- Elevated antistreptolysin titers (ASO): two–four-fold rise in titer from initial infection in 1–4 weeks.
- Elevated anti-DNase B: increases from initial infection in 6–8 weeks 2- to four-fold.
- Cunningham panel: Elevated anti-neuronal antibodies such as dopamine D1 receptor, dopamine D2L receptor, lysoganglioside, tubulin, and elevated CaM kinase II – results in neuronal excitation and increased dopamine transmission [107].
- Increased basal ganglia volume on volumetric MRI.
- Elevated B-cell antigen D8/17, a possible marker of rheumatic fever, OCD, or Sydenham's chorea.
- CMP, ANA, CRP, thyroid panel and antibodies, sed rate, ferritin, immunoglobulins, vitamin D, B12, folate, gluten sensitivity and cross-reactivity, organic acid testing, genetic testing, and stool testing.
- When Group A streptococcal infection is not found, test for other infections.

Table 30.1 Factors contributing to exacerbations of PANDAS/PANS

Infectious	Other
Group A beta hemolytic strep	Psychosocial stress
Colds, Coxsackie A and B	Nutrition
Sinusitis, EBV	Medication
Mycoplasma pneumonia	Genetics
Influenza, CMV	Allergies
Varicella zoster	Chlorine
Herpes simplex	
Lyme, Babesia, *Bartonella*	
HPA axis dysfunction	

PANS (Pediatric Acute-Onset Neuropsychiatric Syndrome) may begin with an infection other than strep, environmental toxins, or immune dysfunction

Note: Titers from prior strep infection may remain elevated for months. Exacerbations of PANDAS after an initial strep infection may be caused by non-strep triggers.

Other support for PANDAS includes a positive family history of OCD, tic disorders, and autoimmunity as well as a response to antibiotics or immunomodulatory therapy such as IVIG and plasmapheresis to remove autoantibodies (Table 30.1).

30.23.2 NIMH Guideline for Diagnosing PANS [108]

1. Abrupt, dramatic onset of obsessive-compulsive disorder
2. At least two additional neuropsychiatric symptoms:
   - Anxiety, separation anxiety
   - Emotional liability: extreme mood swings, depression
   - Irritability, aggression, or severe oppositional behaviors
   - Behavioral (developmental) regression
   - Deterioration in school performance
   - Sensory or motor abnormalities
   - Sleep disturbances, bedwetting, or urinary frequency

Treatment for PANDAS and PANS: Depends on the severity of the illness and may include cognitive behavioral therapy (CBT) and antibiotics. In severe cases, IV immunoglobulin (IV IG) and plasmapheresis are used for immunomodulation to reduce offending antibodies. Address all basic nutrition,

immune, and genetic issues. Remove excitotoxins, sugar, processed foods, junk food, hydrogenated, and trans fats and allergic foods.

Support fatty acids and consider a red cell fatty acid test. Steroids can reduce symptoms, but they tend to return after stopping the drug. *Streptococcus salivarius* probiotics are helpful for some children. Selective serotonin reuptake inhibitor medications are sometimes used for OCD symptoms, but are often not be well tolerated. Occasionally a tonsillectomy is helpful if the tonsils are large, which can cause sleep apnea, and become a reservoir for strep. In susceptible children, aggressively treating infection may be helpful. Antibiotic prophylaxis has pros and cons as gut immunity is severely affected. Maintain serum 25-hydroxyvitamin D above 30 ng/mL. VDR polymorphism may need higher levels.

Case Study: PANDAS

30

Joe is an 11-year-old male who developed a severe sore throat and flu-like symptoms. Several days into the illness, he became severely agitated with aggressive and obsessive-compulsive behaviors. His mother and grandmother have a history of anxiety and OCD behavior.

Birth and previous medical history: Term birth via C-section for breech position and early preeclampsia. Apgar score was 9 and 10; he was nursed immediately and received hepatitis B vaccine on the first day of life. At 4 months of age, he received vaccines for seven diseases. He cried inconsolably with a high-pitched cry for 6 hours, was limp with no eye contact, and was taken to the emergency room for evaluation.

At age 3, he began stuttering and received speech therapy. At age 5, he had severe flu-like illness with sore throat, fever, and extreme fatigue with a negative throat culture.

He developed fear of germs, repeatedly washed his hands, and refused to come out of his room. Gradually he improved, but never to his previous baseline. He would intermittently have vocal tics.

Labs: Cunningham panel showed elevated dopamine D1 titers which can be associated with aggression. Tubulin and lysoganglioside titers were mildly elevated CaM kinase II. Vitamin D level was 29. Gene polymorphisms related to methylation which affect mood and can cause anxiety include CBS++, COMT++, MAO-A+, and MTHFD ++.

CBS genes convert homocysteine to cystathionine and are involved in transsulfuration and glutathione synthesis, ridding the body of excess sulfur amino acids as well as part of the methylation cycle. Ammonia can be a byproduct of sulfur metabolism, which can adversely affect brain function.

His SNP is related to high homocysteine and reduced CBS activity. Helpful nutrients include N-acetyl L-carnitine, B6, phosphatidylcholine, and phosphatidylserine.

MAO-A (monoamine oxidase A) is an enzyme that breaks down neurotransmitters such as noradrenaline, adrenaline, serotonin, and dopamine. It is located on the X chromosome, so men only carry one copy. It is important in regulating mood and can be linked to anxiety, OCD, and an increased risk of aggression and violence; hence it is referred to as the "warrior gene." This enzyme needs B2 (riboflavin). It may cause an intolerance of methylfolate.

In addition, adequate B12 is needed before supporting folate. With issues in CBS, homocysteine may create excess glutamate increasing anxiety.

COMT genes break down neurotransmitters and catecholamines including dopamine and norepinephrine.

COMT is involved in the prefrontal cortex, which is involved with personality, planning, emotion, behavior control, and abstract thinking. With a double COMT SNP, enzyme activity to break down dopamine can be reduced three–fourfold. Methylation SNPs can further alter the function of COMT genes. Supportive nutrients include low-dose lithium, magnesium, and B12. SAMe is sometimes helpful for some children but may increase dopamine for others.

MTHFD1 is an enzyme involved in the conversion of dietary folate.

Treatment in brief: He was treated with azithromycin and his behavior symptoms dramatically improved for a time. Then he refused to go out of the house again for fear of germs. A course of augmentin was given. His appetite was poor. He was started on a small dose of a multivitamin with hydroxocobalamin as well as lithium orotate 5 mg to support B12 and folate uptake into cells. Anti-inflammatory supplements, colostrum, healthy fats, and antiviral herbs were added and nutrients increased. Intestinal dysbiosis was treated. He received cognitive behavioral therapy. As he began to improve slowly, his appetite improved and he returned to school on a modified schedule. The Cunningham panel had returned to normal when re-checked a year later.

As we learn to deal with the increase in neuropsychiatric autoimmune disorders, all the basics of a functional medicine approach need to be addressed. For autoimmune disease to be present, there need to be a genetic predisposition, an environmental or infectious trigger, and intestinal permeability. We must have an appreciation of these interactions between the behavioral, neural, endocrine, and immune processes. The brain and the immune system are linked by the autonomic nervous system and the neuroendocrine system. Neurotransmitters and cytokines "talk" [109].

Factors include:

- Infections: bacterial, viral, and fungal
- Toxins, heavy metals, and environmental allergies and sensitivities
- GI issues: dysbiosis, intestinal hyperpermeability, food allergies, and sensitivities
- Nutritional issues
- Hormonal and immunological imbalances
- Stress, emotions, sleep, and lifestyle issues
- Neurotransmitter imbalances

The number of children suffering from developmental and mental illness, depression, anxiety, OCD, oppositional defiant disorder (ODD), ASD, ADHD, and PANS and PANDAS is increasing. It is imperative that we look beyond diagnosis and medication to address the underlying causes of these issues.

30.24 Conclusion

Neurodevelopmental and neuro-immune-psychiatric issues are increasing dramatically in children. Understanding the factors that have led to this increase allows us to work upstream to create preventative solutions and find interventions to help each child reach their individual potential. Children are not little adults. Understanding the differences in their metabolism, physiology, and body composition as well as the impact of toxic exposures prenatally and postnatally is crucial. Health care has become infinitely more complicated by chemicals, a damaged food supply, EMFs, and the condition of our air, soil, and water. For all of these diverse issues, healthy lifestyle including an individualized whole-foods diet, appropriate supplementation as indicated, exercise, sleep, stress management, and avoiding neurotoxins is important. Autism has increased from 1 in 10,000 to 1 in 45, with the majority now presenting as regressive autism. This suggests that environmental insults in utero and/or after birth involve genetic and epigenetic factors leading to oxidative stress, brain inflammation, and out-of-balance biochemistry. Autism is a treatable disorder requiring a thorough history and timeline of symptoms, diet history, functional lab assessment, and supporting biochemical individuality to improve the function of the body and the brain. This is true for ASD, ADHD, sensory deficits, learning disabilities, depression, developmental delay, behavior disorders, and other neurodevelopmental disorders. Seizures, even those resistant to medications, often respond to a ketogenic or modified ketogenic diet that can help heal the brain. Certain nutrients and a healthy lifestyle can improve seizure threshold as well as neurodevelopmental outcomes. Avoiding excitotoxic food chemicals can also help lower seizure threshhold. Neuropsychiatric autoimmune disorders present the challenge of learning how multiple systems interact, as cross-reactive anti-brain antibodies can trigger OCD, tics, and neuropsychiatric symptoms. Controlling risk factors before, during, and after pregnancy as well as cleaning up our environment and food supply is so important for future generations.

In summary, this chapter reviews an important group of neurodevelopmental problems that are increasing in children in epidemic proportions. Better answers are needed through understanding the interplay of various systems in the body including but not limited to neuropsychiatric, immunologic, gastrointestinal, genetic, and/or acquired inborn errors of metabolism with our current environment via lab evaluation and clinical assessment with appropriate treatments. Parents and caregivers are essential members of the treatment team alongside integrative and functional medicine practitioners.

31.1 Introduction to Hormonal Health

An integrative or functional medicine approach to illness involves identifying the root cause(s) and personalizing treatment plans to address those underlying causes. In this way, the approach helps patients avoid and reverse illness as they move toward optimal health. This is a giant leap forward from conventional drug-based symptom suppression and disease management approaches. Fortunately, combining integrative/functional and conventional approaches to medicine is not entirely incompatible. It is wise to integrate the best of conventional laboratory analysis, diagnostic imaging methods, and appropriate treatments, along with cutting-edge nutritional, lifestyle, biochemical, and genetically driven interventions to create the best outcomes possible for patients. This approach of integrating the best of both paradigms has been useful in developing and personalizing treatment of hormonal imbalance.

A recent report highlighted the fact that endocrine active chemicals (EACs) or endocrine disruptors may cause a variation in normal hormone function [1]. It has been found that even small alterations in hormone concentrations, especially during embryonic development, can have significant and lasting effects. Further, some EACs have the potential to impact human health at lower doses than those proposed in traditional toxicity testing by regulatory agencies, which means that some effects may be overlooked [1].

A protocol has been developed to address hormonal imbalances in a systematic way and includes nutritional influences in hormone metabolism. To be effective, an ordered evaluation followed by systematic balancing is key, as will be detailed below. Achieving optimal hormonal health happens as hormones are balanced individually and then as they begin to work in concert with each other. Hormones are like a symphony in that each hormone must not only be balanced or fine-tuned but also working optimally with other hormones to make beautiful music. In the author's experience, the orderly approach in hormone balancing begins with insulin, followed by the hypothalamic pituitary adrenal axis (hereinafter referred to as Adrenals), thyroid, and sex steroid hormones (estrogens, progesterone, and testosterone) with a final step optimizing *estrogen metabolism* in both men and women.

31.2 Insulin

Insulin is a major hormone and one of critical importance. It not only affects all other hormones, but if there is decreased insulin sensitivity or insulin resistance, it is postulated to contribute to cardiovascular disease, premature death, cancer, and dementia, to name a few [2]. Moreover, insulin resistance is a major cause of premature aging and death in both the developed and developing worlds. It is arguably our biggest global health epidemic. Human history has never before seen as many new cases of type 2 diabetes diagnosed, particularly in children [3]. The diagnosis of adult-onset or type 2 diabetes in children has climbed astronomically, increasing more than 1000 percent over the past two decades. A mere 15 years ago, only 3 percent of all diabetes cases in children were of the type 2 variety; now that number has climbed to 50 percent. Furthermore, what is shocking is that 40 percent of children are now overweight and two million are morbidly obese (exceeding the 99th percentile for weight) [4].

It is known that people with diabetes suffer vascular disease at much higher rates [5]. It is estimated that diabetics are four times more likely to die of heart disease than their non-diabetic counterparts. Furthermore, the rate of cerebrovascular accidents (CVAs) is three to four times higher in diabetics. Unfortunately, these risks do not only apply to the fully diabetic patient. Of concern, women are at an ever-increasing risk for cardiovascular disease, especially when insulin resistance is present, and women in perimenopause or menopause who suffer more hot flashes and night sweats are more likely to have undiagnosed insulin resistance [6].

The risk for cardiovascular disease also encompasses those who are considered prediabetic. Patients with prediabetes are four times more likely to die of heart disease and have a 21 percent higher risk of stroke [7]. Therefore, the prefix "pre" in prediabetes is arguably not really "pre"-disease. People with prediabetes are diseased secondary to the elevated degree of insulin resistance. Therefore, it is not the diagnosis of diabetes alone that renders the patient at high risk for major life-threatening disease but, rather, the state of insulin resistance. There is a critical need for clinicians to recognize and address insulin resistance and understand the continuum of insulin resistance. The continuum refers to the progression from insulin resistance to impaired glucose tolerance to prediabetes to diabetes. Treatment of this continuum begins with detection of early insulin resistance and of learning the tools to apply to reverse this state in order to avoid the consequences and progression to diabetes.

31.2.1 Insulin Resistance

Simply put, insulin resistance is a condition where insulin becomes less effective at lowering blood sugar [5–8]. It is the inability of insulin to facilitate glucose uptake from the blood into the cell because of poor insulin binding at the cells' receptors. The body responds to this by stimulating the pancreas to produce more insulin to ensure that glucose can leave the bloodstream and enter the cells. Initially, the body's response is effective in that the excess insulin is able to keep blood sugar in the normal range. The first sign of imbalance lies in the increased levels of insulin production.

31.2.2 Impaired Glucose Tolerance

Impaired glucose tolerance occurs when glucose rises above the normal range, despite the pancreas continuing to overproduce insulin [5–9]. The rise can be seen after meals (postprandial) or at in the fasting state. In many patients at this stage along the continuum, fasting glucose may be normal, but you will see an elevated glucose level after a meal or after a high

glycemic load. Levels are elevated but not enough to qualify the patient as prediabetic. These are the patients in which there is an elevated hemoglobin A1c (HgbA1c) despite a normal fasting glucose. Simply put, impaired glucose tolerance is when the pancreas and its insulin production are no longer able to keep blood sugar normal after a glucose challenge.

31.2.3 Prediabetes

As the pancreas continues to overproduce insulin, its ability to keep fasting blood sugar in the normal range is impaired as evidenced by a fasting blood sugar over 100 mg/dL to 125 mg/dL [5, 8, 9]. This should be considered an advanced state of disease because close behind prediabetes is the end of the continuum with type 2 DM. Therefore, prediabetes is clearly a state of major dysfunction and it is not "pre"-disease. It is a disease in and of itself.

31.2.4 Diabetes Mellitus Type 2

Diabetes mellitus type 2 is defined as fasting blood sugar of 126 mg/dL or higher or a random blood sugar of over 200 mg/dL on more than one occasion [5, 8, 9].

31.2.5 Metabolic Syndrome Vs. Insulin Resistance

The synergistic and aggregate effects of insulin resistance, obesity, hypertension (HTN), and dyslipidemia all form a construct called the metabolic syndrome [7]. Metabolic syndrome was initially coined "Syndrome X" by Gerald M. Reaven as "a constellation of lipid and non-lipid risk factors of metabolic origin." Metabolic syndrome was formally recognized by the Adult Treatment Panel III (ATP III) of the National Cholesterol Education Program (NCEP) 2004 update and identifies the significance of cardiovascular disease (CVD) risk factors [8]. Risk factors for metabolic syndrome include visceral adiposity, high body mass index (BMI), insulin resistance, and high insulin. In order to have metabolic syndrome, a patient must have three out of the following five characteristics present: increased waist circumference (greater than 40 inches for men and 35 inches for women), hypertension (blood pressure greater than 130/85 mmHg), elevated triglycerides (greater than 150 mg/dL), elevated fasting blood sugar (greater than 100 mg/dL), and decreased HDL (40 mg/dL in men and 50 mg/dL in women).

Focus has recently shifted to insulin resistance as the dominant and independent predictor of age-related diseases [10, 11]. A normal blood sugar level is less than 100 mg/dL; however, we know that risks extend below that threshold. Studies have shown that a blood sugar greater than 87 mg/dL equals a progressive increase of type 2 diabetes. Further, the lowest risk of progression from insulin resistance to type 2 diabetes is a fasting blood sugar less than 75 mg/dL.

In the United States, we have seen a rise of obesity in epidemic proportions over the past 20 years [2, 3, 5, 8, 10]. Among the American adults who are simply overweight, more than 70 percent already have prediabetes because of undiagnosed and untreated insulin resistance, with significant increased risk of cardiovascular disease and death. The unfortunate fact is that most are unaware of their condition and its risks. The awareness problem is further aggravated by the fact that there are no current national screening guidelines or reimbursement for healthcare providers to diagnose and treat insulin resistance. Guidelines and reimbursement are only available once diabetes develops. In addition, healthcare practitioners are not properly trained to diagnose or treat the largest epidemic in the United States. In sum, it is well-known that obesity increases insulin resistance and leads to diabetes. Conversely, the most important *cause* of obesity is insulin resistance that often goes undiagnosed.

31.2.6 Identifying Patients at Risk for Insulin Resistance

To determine if patients have insulin resistance, it is not as simple as looking at body habitus. According to the National Health and Nutrition Evaluation Survey (NHANES) correlation study from 1999 to 2004, up to 25 percent of normal weight patients (BMI less than 25) may be insulin-resistant [11]. Further, some patients may be insulin-resistant and still have normal fasting insulin levels, normal HgbA1c, and normal fasting glucose but are on the continuum to develop type 2 diabetes and metabolic syndrome. Important for clinicians, the underlying causes of type 2 diabetes, metabolic syndrome, and insulin resistance are reversible and preventable [5, 7] by using nutritional and lifestyle interventions. The question becomes how do we identify the patients at risk? This is best addressed by looking at the confluence of genes and metabolism, both of which underlie the abnormal patterns of function seen in hyperinsulinemia. Clinicians need to determine why and how a patient became insulin-resistant. How and where do we start? What is the root cause? How do we identify and treat insulin resistance?

31.2.7 Protocol

The author has developed a treatment protocol for insulin resistance that incorporates integrative and functional medicine principles. This starts with collecting a thorough and detailed history and conducting a complete physical examination. In the process of data gathering, it is imperative to look for basic imbalances in digestion/absorption/barrier integrity, detoxification pathways, hormone/neurotransmitter health, immune/inflammatory process, and mind/spirit equilibrium imbalance. The goal is to get to the underlying cause of illness. This allows the practitioner to connect the dots between the history and the physical exam to find clues leading to the root cause or foundation of

the dysfunction. Once the investigation into development of insulin resistance has proceeded and potential underlying cause(s) are identified, laboratory testing can be ordered and evaluated. Patients are staged along the continuum of insulin resistance at this juncture. Individualized treatment protocols are prescribed that incorporate certain basic standards (see Table 31.1).

Table 31.1 Insulin resistance assessment protocol

Poor-quality diet	Processed foods High in sugar and high fructose corn syrup Trans, hydrogenated, and saturated fats Polyunsaturated omega-6 oils (except gamma linoleic acid, GLA) Low in vegetables, fruits, and antioxidants Low in fiber
Hydration	Assess hydration status and source/content of water and liquids Can be cause of insulin resistance, i.e., look for sugar and high fructose corn syrup drinks
Food allergies/sensitivities	Modify and personalize elimination diet/ketogenic diet and/or functional testing for allergies and sensitivities
Oxidative stress and/or mitochondrial dysfunction	Assess clinically and with laboratory evaluation
Stress and adrenal dysfunction	Lack of exercise Poor sleep
Hormone imbalance	Use history and physical exam, as well as laboratory evaluation
Toxins	Heavy metals, persistent organic pollutants, endocrine disruptors volatile solvents, dirty electricity, electromagnetic radiation, suboptimal estrogen metabolism, etc.
Dysbiosis	Assess with comprehensive stool analysis
Infections	Occult esp. dental Gastrointestinal Viral, bacterial, parasitic, and fungal
Nutrient deficiencies	Including vitamins, minerals, antioxidants, amino acids, methylating factors, and essential fatty acids Assess clinically with history and physical and with functional and/or conventional testing
Prescription drugs	Prior or current use of statins or other cholesterol-lowering drug use, proton pump inhibitors, or beta blockers
Hyperinsulinemia causing insulin resistance; beta cell dysfunction	Review all above to look for root cause

31.2.8 Staging the Patient

Staging facilitates understanding of where the patient falls along the continuum of insulin resistance. It is the stage that determines the treatment and predicts how likely they are to progress to type 2 diabetes. In the continuum of insulin resistance, with wellness on one end and illness on the other, the patient progresses from insulin-sensitive, to insulin-resistant, to impaired glucose tolerance, followed by prediabetes, and then to type 2 diabetes.

The three stages and their components are described in detail below in the "Laboratory Evaluation" section. Stage 1 is when adiponectin (an adipose-derived protein) starts to decrease [11]. In stage 2, insulin is already starting to increase, and in stage 3, proinsulin (the prohormone precursor to insulin) increases [11]. Not everyone moves through these stages smoothly, as there may be variations in timing and presentation. We also know that there may be some patients who fall between type 1 and type 2 diabetes, related to an underlying autoimmune disease [12, 13]. Overall, these stages are valuable as each stage will direct proper treatment. For instance, if a patient is found to have insulin resistance and hyperlipidemia, it is the insulin resistance that is driving the hyperlipidemia and the progression to glucose intolerance and prediabetes. Consequently, we treat insulin resistance first.

31.2.9 Laboratory Evaluation

Laboratory evaluation is an important tool to help guide assessment of the patient's stage along the continuum of insulin resistance. Although not all insulin-resistant patients develop diabetes, it is insulin resistance that is the underlying problem driving metabolic syndrome and chronic disease, such as cardiovascular risk. Consequently, it is very important to identify those with insulin resistance early and promptly treat them to halt and/or reverse disease progression. Laboratory assessment is critical.

Most test result ranges in conventional laboratory analysis are very broad. This occurs because the lab is aggregating multiple patients' ranges who are considered normal although disease may be present at an early stage; these ranges are not functional ranges. A general guideline to determine abnormality is to look at the upper third and fourth quartile when assessing conventional lab values for glucose and insulin while looking at the first and second quartiles when assessing micronutrient levels. This gives a more functional/integrative medicine reference range that may guide intervention. It is important to understand that although the value may be in a normal range according to the conventional lab, early disease and dysfunction may be present. This helps when analyzing results for patients who can only afford to undergo conventional insurance-covered laboratory evaluations and do not have access to more extensive laboratory testing.

31.2.9.1 Hemoglobin A1c

Hemoglobin A1c (HbA1c) was originally developed to determine if diabetic patients were being compliant with their glucose-lowering medication [8, 14]. Put simply, it measures the amount of glucose bound to the hemoglobin molecule and reflects levels of glucose for the previous 90 to 120 days. It was not developed as a screening tool, although it is currently being used as one.

With this in mind, what does it mean if a HbA1c is elevated? Where does the elevated HbA1c place the patient on the continuum? HgbA1c is an independent risk factor for cardiovascular mortality: "The predictive value of HgbA1c for total mortality was stronger than that documented for cholesterol concentration, body mass index and blood pressure." [14]. If HbA1c is 5.4 percent or higher, the patient has impaired glucose tolerance and increased risk. If the HbA1c is increased, the patient is having episodes of hyperglycemia. However, it might only be elevated postprandially and not in the fasting state. Consequently, patients must check the postprandial blood sugars both in the laboratory and at home. With insulin resistance it is imperative to preserve pancreatic beta cell function and aggressively address the underlying cause of the dysfunction.

31.2.9.2 HOMA-IR

The homeostatic model assessment for insulin resistance (HOMA-IR) is a calculation based on plasma levels of fasting glucose and insulin [15, 16]. It is used to assess insulin sensitivity. There may be better ways of assessing insulin resistance.

31.2.9.3 Adiponectin, Insulin, and Proinsulin: Staging the Progression of Insulin Resistance to Prediabetes and Type 2 Diabetes

Adiponectin is a protein hormone that is produced in fat cells and helps regulate glucose levels and fatty acid breakdown [17]. Adiponectin is protective against atherosclerosis, modulates fat tissue production and breakdown, promotes insulin sensitivity, and decreases hepatic glucose and lipid production. Biologic adiponectin levels decrease prior to increases in insulin levels; therefore it can be considered a marker of insulin sensitivity. Other markers assessed by laboratory evaluation for insulin sensitivity include insulin, proinsulin, HbA1c, fasting, 30 minute, 1 hour and 2 hour glucose levels, a 30 minute, 1 hour and a two-hour insulin level after a 75 gram glucose load. Both conventional and specialty laboratories can provide these tests. While a specialty lab plots the results in graphical form with functional ranges, conventional labs give numerical values that can be plotted in graphical form by the practitioner. With optimal control and regulation of glucose, adiponectin will be normal, fasting insulin will be 5–7 mIU/L, HbA1c will be 5.3 percent or less, and fasting glucose will be less than 75 mg/dL. The risk of diabetes significantly increases when the fasting blood glucose is greater than 87 mg/dL [6].

In *stage 1* insulin resistance, adiponectin is declining while fasting insulin remains normal [11, 17]. Postprandial insulin might be elevated, but the primary determining factor of stage 1 is a normal fasting insulin. Proinsulin, glucose readings, HOMA-IR, and HbA1c are all usually normal, although HOMA-IR could be slightly elevated. Adiponectin is the key factor that needs to be restored. Low adiponectin is a marker for insulin resistance, making the patient more at risk for dyslipidemia. Decreasing adiponectin also tends to be associated with increasing inflammatory markers. With that, there is increased risk for vascular injury and increased risk of progression along the continuum toward type 2 diabetes [11, 17].

Treatment includes diet and lifestyle changes. Focus is on body composition and making sure patients are eating a healthful diet. Experts recommend a Mediterranean-type, low glycemic load diet, but the diet needs to be personalized to the individual [18].

In *stage 2* insulin resistance, adiponectin levels are decreasing, insulin is starting to increase, while proinsulin remains normal [11, 17]. There may be early beta cell impairment. In stage 2, HOMA-IR is higher than normal and may be associated with a high postprandial glucose. At this stage, fasting glucose may be borderline elevated while random and postprandial sampling of glucose may be mildly elevated but at times be normal. Stage 2 treatment usually consists of diet and lifestyle changes and supplementation. Pharmacotherapy should not be started at this stage, but rather in early stage 3 and even then, there is the potential for reversal with diet, nutrition, lifestyle modification and nutraceutical support. Again, this is case dependent.

In *stage 3* insulin resistance, proinsulin is increasing, indicating the pancreas is struggling to keep glucose normal. The pancreas is attempting to excrete insulin as fast as it is manufactured and before the final cleavage has happened. In stage 3 there is low adiponectin, high HOMA-IR, high insulin, elevated proinsulin, possibly high glucose, and high HbA1c [11, 17]. There are some patients who can maintain normal or close to normal fasting glucose even in the face of these abnormalities. However, with glucose challenge testing, the post-challenge glucose level will be high. In most cases, the postprandial glucose will elevate with a high glycemic load meal. Despite these findings, the patient may not be classified diabetic. This group might not even fulfill the established criteria for prediabetes, as the American Diabetes Association definition for prediabetes is a fasting glucose level of 100–125 mg/dl [8]. The overarching treatment aim in stage 3 is to preserve beta cell function. Having patients check postprandial glucose levels also helps the patient learn what foods increase their glucose level.

31.2.10 Treatment

► Box 31.1 presents the approach for the treatment of insulin resistance. It will be necessary to address and re-address these factors both at baseline and throughout the course of treatment.

Box 31.1 Insulin Resistance Treatment Protocol

- Foundation is nutritional support: Wholesome food that is fresh, whole, unprocessed, organic, colorful, fermented, high in omega-3 fatty acids
- Identify the underlying functional imbalances, prioritize, and address
- Personalize an elimination diet or modified ketogenic diet according to individual patient needs
- Lifestyle modification: Individualized stress reduction, alcohol consumption, smoking cessation, sleep
- Exercise: Tailor to individual patient needs
- Nutritional supplementation: Personalized based on clinical exam and laboratory testing
- Mind-body-spirit connection: Find and foster purpose and meaning in life as well as gratitude, and explore history of trauma that may be preventing compliance and development of treatment protocol
- Assess possible need for pharmacological treatment based on functional testing, patient needs, and response to above approach

© Copyright 2012 Filomena Trindade MD, MPH. All rights reserved. Reprinted with permission of the author

31.2.10.1 Dietary Management

Dietary management with healthful whole foods for patients with insulin resistance results in decreasing insulin stimulation and increasing insulin sensitivity [19–26]. Dietary modifications to decrease insulin release always begin with an initial assessment to explore the patient's intake of fiber, good and bad fats, types and quantity of protein, and simple and complex carbohydrates, as noted above. Education of patients about the quality of dietary components and helping them understand glycemic load is imperative at this early stage. Crucial is the fact that food components are important signaling molecules that are not often found in processed foods [27]. Many phytochemicals work as tissue-specific kinase response modulators (SKRMs). Kinases are a group of enzymes with multiple functions that include facilitating insulin function. SKRMs are going to affect cellular communication and cellular signaling. Some dietary phytochemicals that modulate these pathways include berberine, cinnamon, ginseng, quercetin, resveratrol, green tea extract, and hops extract.

Components of this type of diet include organic, fresh, whole, unprocessed, colorful food. It is important to make sure patients have protein at every meal and snack. Emphasize elimination of sugar, trans fats, some saturated fats, and food allergens. Patients need education regarding inflammatory foods, including gluten, dairy, soy, corn, and nightshades. An elimination diet may be helpful to identify and remove any dietary source of inflammation. Also address the areas of dysfunction or imbalance in laboratory assessment and prioritize. Depending where the patient is on the continuum, it may be necessary to start nutraceuticals that increase cellular responsiveness to insulin, including chromium, alpha-lipoic acid, magnesium, CoQ10, and protein kinase modulators, to name a few [27–35]. See Table 31.2.

31.2.10.2 Exploring Detoxification

Body burden of environmental toxins is known to be another underlying problem triggering insulin resistance [36–39]. Toxic endocrine disruptors affect estrogen and estrogen metabolism and are known to result in the etiology of type 2 diabetes mellitus [36–38]. Low-dose organochlorine pesticides and polychlorinated biphenyls predict obesity, dyslipidemia, and insulin resistance among people free of diabetes [36–38]. Heavy metals may also be a problem and can contribute to insulin resistance [39]. The liver enzyme, GGTP, in the high normal range is associated with insulin resistance. It may be helpful to monitor GGTP and consider it a predictor if it is 30 IU/L or higher. If it is over 40 IU/, then glutathione production needs to be improved.

31.2.10.3 Exercise

As exercise is an important tool for intervention in insulin resistance, it is critical to assess how much a patient is moving. It is imperative to design an appropriate exercise regimen for each patient that incorporates aerobic exercise and weight training and re-evaluate adherence to the program at regular intervals with change as needed. It is wise to review the published studies with patients and give them the choice between diet, lifestyle, and physical activity versus medications with their potential side effects. Typically, in the author's practice, patients choose diet and lifestyle changes for management. Patients need to be informed that if they do not change their diet and lifestyle, the outcome will likely be increased cardiovascular disease and progression to type 2 diabetes. Are they willing to take those risks? When explaining how diet, nutrition, exercise, and lifestyle modifications have been proven superior to prescription medications [40], patients express amazement and choose to succeed with this approach.

According to the World Health Organization, adults 18–64 should do at least 150 minutes of moderate-intensity aerobic physical activity throughout the week or at least 75 minutes of vigorous-intensity aerobic physical activity throughout the week or an equivalent combination of moderate- and vigorous-intensity activity [41]. Aerobic activity should be performed in episodes of at least 10 minutes' duration. For additional health benefits, adults should increase their moderate-intensity aerobic physical activity to 300 minutes per week or engage in 150 minutes of vigorous-intensity aerobic physical activity per week or an equivalent combination. Muscle-strengthening activities should be done involving major muscle groups on 2 or more days a week. Exercise alters skeletal muscle metabolism and improves glucose uptake, reduces low-density lipoprotein, raises HDL, lowers blood pressure, and reduces inflammation and oxidative stress [42]. In a Diabetes Prevention Program Research Group 2002 study, 3234 people with prediabetes were randomized to placebo, metformin, or lifestyle modification (≥7% weight loss and ≥ 150 min/week of physical activity) for 2.8 years [40]. Compared to the placebo group, lifestyle intervention decreased incidence of type 2 DM by 58 percent. Metformin (850 mg BID) decreased type 2 diabetes mellitus by only 31 percent.

Table 31.2 Micronutrient recommendations for insulin resistance

Chromium [35]	Generally, give 400 mcg/daily if insulin-resistant Likely most effective if deficient but difficult to test
Vitamin D [32]	Test 25(OH)D and supplement as appropriate (or supplement 2000–5000) IU/daily Vitamin D levels should be 50–80 ng/ml, depending on whether other medical conditions are present A study showed a positive correlation of 25(OH)D concentration with insulin sensitivity and a negative effect of hypovitaminosis D on beta cell function Subjects with hypovitaminosis D are at higher risk of insulin resistance and the metabolic syndrome Increasing 25(OH)D from 10–30 ng/mL can improve insulin sensitivity by 60%
CoQ10 [28, 29]	Supplement in patients with metabolic syndrome, insulin resistance, hypertension, or mitochondrial dysfunction Dose depends on functional levels: Optimize to >2 mcg/mL (plasma) In a patient with high oxidative stress or mitochondrial dysfunction, may need to supplement at a much higher dose 120 mg/day of coenzyme Q10 improves glycemic control and blood pressure in NIDDM 200 mg of CoQ10 daily improved HgA1C and blood pressure in NIDDM patients
Alpha-lipoic acid [30, 31]	Doses of 600 to 1800 mg/day may improve insulin sensitivity 600–1200 mg/day of ALA may improve microcirculation and diabetic polyneuropathy
Magnesium [33, 34]	Epidemiological studies show that high daily mg intake is predictive of a lower incidence of NIDDM Poor intracellular mg concentration is found in NIDDM and in hypertensive patients Daily mg administration in NIDDM patients and in insulin-resistant patients restores intracellular mg concentration and contributes to improve insulin sensitivity and glucose uptake Magnesium supplementation has been shown to improve insulin sensitivity Patients have a hard time absorbing magnesium intracellularly Buccal swab is the best way to assess intracellular magnesium Patients with low magnesium are at a slightly higher risk for atrial fibrillation and arrhythmias Many of these patients may also need potassium. Magnesium glycinate may have less effect on the gut causing loose bowels, and it is generally well absorbed Starting dose 200–400 mg of a chelated magnesium and increase to bowel tolerance if normal kidney function is established

31.2.10.4 Stress and Autonomic Dysfunction

Stress and autonomic dysfunction have a powerful impact on progression of insulin resistance and contribute to cardiovascular disease. To assess autonomic dysfunction, an important tool to incorporate is heart rate variability [43, 44]. As heart rate variability lowers, there is progression from insulin resistance to impaired glucose tolerance to diabetes. Of interest in patients with coronary artery disease, lower heart rate variability has also been correlated with impaired pancreatic function. Visceral fat (not subcutaneous fat) has also been associated with lower heart rate variability as well. In patients with either diabetes or a family history of diabetes, those genetically predisposed to NIDDM have more visceral fat and lower insulin sensitivity compared with those unaffected individuals [45]. Knowing these connections, the dysregulation of the autonomic nervous system can now be linked to visceral adiposity and insulin resistance.

31.2.10.5 Sleep

Sleep is another important factor in the management of insulin resistance. Lack of sleep can affect insulin resistance in several different ways as it can cause inflammatory-related insulin resistance, changes in glucose metabolism, altered appetite, and hypothalamic-pituitary-adrenal axis dysfunction [46]. Sleep deprivation may lead to insulin resistance and subsequently to diabetes mellitus. For those with metabolic syndrome, recommended average sleep times range from 7 to 9 hours per night and ideally should be 8 hours [46]. It is also critical to ask patients about the quality of their sleep. Are they waking up multiple times? Are they feeling rested when they wake up? Is there snoring? Obstructive sleep apnea can affect insulin resistance and metabolic syndrome through poor oxygenation. In addition, many patients with obstructive sleep apnea have undiagnosed insulin resistance.

31.2.11 A Final Word on Insulin Resistance

We have established that insulin resistance is a disease contributing to numerous chronic and life-threatening conditions and affects countless patients, many of whom go undiagnosed. The good news is that insulin resistance, as well as the progression to diabetes, can not only be prevented but can be treated and reversed. Therefore, it is our responsibility as clinicians to track down early cases of insulin resistance before they advance into later stages along the continuum and to reverse whatever damage may have occurred. Likewise, it is our duty to offer an effective protocol to those who already suffer from a clinical diagnosis of prediabetes or diabetes.

Integrative and functional medicine tools help identify the underlying dysfunctions and the root causes in a personalized manner. Using clinical evaluation, as well as laboratory measurements including adiponectin, fasting insulin, proinsulin, HgbA1c, postprandial insulin, and glucose, the clini-

cian can assess where the patient lies along the continuum of insulin resistance. Once the stage of insulin resistance has been identified, a personally tailored treatment plan is prescribed to reverse beta cell dysfunction and prevent further progression to diabetes. As needed, treatment options may address any of the following areas of a patient's life: diet, sleep, stress, exposure to toxins and ability to detoxify, exercise, and/or micronutrient consumption. In conclusion, by way of acknowledging the role of insulin resistance in the bigger picture of obesity, diabetes, and cardiovascular disease, we are able to recognize how vitally important it is to incorporate the effective diagnosis and treatment of insulin resistance into clinical practice.

31

31.3 Adrenal Dysfunction

We live in a world that is increasingly stressful and often coupled with sedentary lifestyle practices. Many people eat processed foods lacking in nutritive quality at most meals. Each day we are exposed to a skyrocketing number of synthetic chemicals in our personal care products, the food we eat, the water we drink, and the air we breathe. Our minds are constantly distracted by relentless electronic stimulation. Societies have collectively induced self-psychological and economic slavery. This is our world. The shocking part is this way of life is accepted and considered normal and the dysfunction may be difficult to perceive, much less find successful life balance. In this environment, feeling anxious and/or depressed is an understandable reaction to the overwhelming stimuli of a typical modern lifestyle.

31.3.1 What Is Adrenal Dysfunction?

The adrenal glands are bean-shaped organs situated above the kidneys with secretions that are required for maintenance of life [47]. They are made up of an outer region or cortex and an inner region or medulla. The hormones of the adrenal cortex are steroids and act at the level of the genome to regulate expression of genes for operation of important processes. There are three major categories of adrenal steroid hormones, mineralocorticoids, glucocorticoids, and androgens, and all are essential for maintaining internal equilibrium [47]. The adrenal medulla produces two important hormones, epinephrine and norepinephrine, that play a critical role in the response to stress. The catecholamines affect the cardiovascular, respiratory, excretory, and skeletal systems and equip the body for fright, fight, or flight. An important function of the adrenal glands is to provide dynamic balance or homeostasis of the hormonal systems whether in rest or stress.

The job of the adrenals when it comes to homeostasis during stressful events is to handle the disruption in hormones. Their handling of stress is akin to managing a bank account – it's your *adrenal* bank account. If you have a lot of adrenal reserve, it means you can spend on the account. Thus, many people choose to spend frivolously early in life when reserves are naturally higher. As we grow older, however, it behooves us to pay more attention to the adrenal savings account and work to replenish any debt or accumulated depletion. No matter what age, we must learn to manage our adrenal bank account and live within our means. That means choosing diet, lifestyle, hobbies, and sleep patterns that work to regenerate what has been lost. If we do not do this, there are consequences.

There is a threshold of stress that our adrenals can handle within a healthy range. Beyond that threshold, however, damage is done. This threshold setpoint differs for each of us and is very much like the stress on a violin string. Insufficient tension produces a dull, raspy sound. Too much tension makes a shrill, annoying noise or snaps the string. However, just the right degree of pressure can create a magnificent tone. Similarly, we all need to find the proper level of stress that allows us to perform optimally and make melodious music as we go through life.

A problem arises for many when they overspend their adrenal reserves and find themselves broke. In other words, we reach a level at which we can no longer adapt to further stress and have lost adrenal resilience. When this occurs, the body can no longer cope with stress as it once had and the effects are deleterious. Under normal circumstances, once an acute threat has passed, the stress response becomes inactivated and levels of stress hormones return to baseline levels [47]. This translates into resilience (see Table 31.3). In this case, we are using the normal relaxation response to recover from stress. However, if there is unremitting stress, we can then reach a point where adaptation can no longer occur and adrenal dysfunction ensues. The hypothalamic-pituitary-adrenal axis responds to the unremitting stress by downregulation at the level of the adrenal glands, and that is what we are calling Adrenal dysfunction. The actual mechanisms involved are not yet fully understood. Adrenal dysfunction is composed of three stages which were described by Hans Selye in the 1930s, although some controversy surrounds this classification [48]. Selye called the series of stages "the general adaptation syndrome," described in Table 31.3.

Table 31.3 Stages of adrenal response

Stages of adrenal response	
Stage 1: Arousal	Both cortisol and DHEA increase with episodic stress, but recovery returns to baseline This may or may not be asymptomatic
Stage 2: Adaptation	Cortisol is chronically elevated and DHEA declines Symptoms of stress arise such as anxiety attacks, mood swings, depression
Stage 3: Exhaustion	Adrenal insufficiency yields low cortisol and DHEA levels Patients present with depression and severe fatigue

Based on data from Ref. [48]

Modern life poses ongoing stressful events that are not short-lived. When we lose our resilience, we progress to stage 2 adrenal dysfunction or "the adaptation phase." If we continue to borrow from our account as our savings dwindle, then we progress further to stage 3 (Table 31.3). At this point, stress becomes chronic. This continual exposure to stress puts us at risk for many other health problems. Patients at this stage often struggle with severe fatigue or chronic fatigue syndrome, fibromyalgia, hair loss, premature hormone loss or hormone imbalance, weight gain, autoimmune disorders, suppression of the immune system, arthritis, anxiety, and depression [49–51].

Adrenal dysfunction, when at the severe maladaptation stage, is generally referred to as adrenal fatigue. The term adrenal fatigue has been inaccurately used to refer to any of the stages of adrenal dysfunction. Correctly, it should strictly refer only to the third stage of adrenal dysfunction. Patients may present with a variety of symptoms of adrenal gland dysfunction that include fatigue, low energy, weakness, moodiness, anxiety or depression, muscle and bone loss, hormonal imbalance, insomnia, and skin problems, among others. Also common is an overreaction to stress in which a minor event causes a disproportionate reaction of anger, irritation, or sadness.

31.3.2 What Causes Adrenal Dysfunction?

Chronic unremitting stress is the leading cause of adrenal dysfunction and the term stress can refer to physical *or* psychological stress [49–51]. For example, physical stress could include environmental toxin exposure, infections, nutrient deficiencies, hormone imbalances, allergies, and certain prescription medications. A nutrient-poor diet high in sugar, simple carbohydrates, food preservatives, alcohol, or stimulants such as caffeine leads to adrenal dysfunction. These foods can cause the blood sugar to spike, and in response, the adrenal cortex may produce excess cortisol, which over time can lead to hypothalamic pituitary adrenal dysfunction. Psychological stress could be related to events such as divorce, an unhappy marriage, a stressful job, difficult family life, lack of social or familial support or history of past or current abuse (physical, sexual or psychological). It could also come in the form of perceived stress. For instance, reliving past trauma or worrying about what people may be thinking takes the same physiologic toll as an immediate stressful event. The body doesn't know the difference between psychological stress – real or perceived – and a physical emergency. To the body, stress is stress, whether physical or psychological or both, and both are equally detrimental.

31.3.3 Assessment and Treatment of Adrenal Dysfunction

One useful laboratory evaluation for adrenal dysfunction is a four-point or 6-point salivary cortisol test. The latter is the 4 point salivary cortisol throughout the day with the Cortisol Awakening Response (CAR). Salivary cortisol concentrations reflect the free, biologically active fraction of cortisol in the plasma, and tests of it provide results that are of greater diagnostic significance than plasma total concentrations alone [52, 53].

The author has developed a three-legged stool approach with an optional fourth leg, if needed, to treat adrenal dysfunction. At the most basic level, the first leg of the approach covers modifications in nutrition and lifestyle. Eating organically grown, phytochemically dense foods that are devoid of fillers and preservatives is the foundation for recovery. Meals need to have a low glycemic load and good sources of clean protein. The majority of the plate, about two-thirds, must be composed of vegetables and a few servings of low-glycemic-load fruits. Chewing food appropriately must be emphasized and hydrating well with clean water is critical. The first leg also includes the lifestyle component that incorporates exercise and dealing with trauma. Exercise recommendations should be appropriate for the stage of adrenal dysfunction. A person in stage 1 adrenal dysfunction with high cortisol levels would need more of an aerobic program, whereas someone in stage 3 needs more gentle movement that will not cause further stress to the system. It is important to address the level of stress and discuss how to best modify it. It is crucial to emphasize hobbies that are enjoyable and a relaxation protocol that works for the individual patient. Further, trauma or history of abuse must be explored. According to Bethel Van der Kolk in his book: The Body Keeps the Score (brain, mind, and body in the healing of trauma) we must address and heal trauma in order to restore health. This book reviews the scientifically proven ways to heal trauma by rewiring the brain including eye movement desinsitization and reprogramming (EMDR), neurofeedback, emotional freedom technique (EFT) among others. It is an essential read inorder to help patients fully recover from adrenal or HPA axis dysfunction.

The second leg involves tailored nutraceuticals that help heal and reverse the adrenal dysfunction. This includes nutraceuticals such as B-complex with B6 in the activated or P-5-P form, 5-MTHF, biotin, B5 or pantothenic acid, omega-3 fatty acids, vitamin C, magnesium, and zinc [54–68]. Pantothenic acid has the added benefit that it can enter the steroidogenic pathway early at the level of pregnenolone. This is particularly important for those patients who don't want to use hormonal replacement as higher doses of pantothenic acid, up to 1500 mg per day, may be used. Zinc is an important mineral that helps with healing. See Table 31.4.

The third leg of the three-legged stool consists of adaptogens. Adaptogens are herbs and botanicals that help the body adapt to the stressors and may facilitate communication between the adrenals and the higher centers of the brain [69, 70]. Examples include *Rhodiola rosea* (tyrosol, salidroside, rosiridin), *Eleutherococcus senticosus* (eyringin, eleutheroside E), *Schisandra chinensis* (schizandrin), *Panax ginseng* (ginsenosides), and *Withania somnifera* (sitoindosides). For the reader interested in greater detail, please explore the references provided.

Table 31.4 Nutraceuticals for adrenal dysfunction

Pantothenic acid (B5)	Stimulates ability of adrenal cells to secrete progesterone and corticosterone 500–1500 mg/day Enters early in steroidogenic pathway Can lead to increase in downstream adrenal hormones. Induces adrenal hyperresponsiveness to ACTH stimulation
B6 (ideally P5P)	50–100 mg/day Higher need due to stress. A co-factor in energy production
Folate (5MTHF)	400–800 mcg/day Co-factor in energy production
Magnesium	400–600 mg/day of chelated form Co-factor in many reactions of the Krebs cycle. Low magnesium increases the release of stress hormones. Magnesium decreases nocturnal ACTH secretion
Zinc	The glucocorticoid receptor, like all steroid receptors, is a zinc-finger transcription factor >300 human enzymes require zinc 30–50 mg/day balance with copper (10–20:1 ratio)
Vitamin C	Preferentially concentrated in adrenal glands and lost in times of stress from adrenal cortex
Omega 3	Blunts the stress response. Decreases cortisol and epinephrine 1000–3000 mg depending on co-existing pathologies
Vitamin D	2000 IU/day Reduces latent virus reactivation with increased stress

Based on data from Ref. [54–68]

An optional fourth leg may be necessary at times and includes hormonal supplementation. Hormonal supplementation may help the adrenals recover more quickly and may assist both the brain and adrenals to re-establish their balance and connection with one another [71–73]. The most common hormones that may be considered are DHEA and pregnenolone, but these are recommended in very low doses. It is strongly recommended that hormones only be used when the other three legs are in place and more support is needed. Fortunately, in many cases, the first three legs are satisfactory interventions to bring the hypothalamic-pituitary-adrenal axis back to balance.

31.3.4 A Final Word on Adrenal Dysfunction

The two most important aspects of addressing adrenal dysfunction are to stage the patient and understand the root cause of the dysfunction. Then and only then can a personalized approach utilizing functional and integrative medicine tools be tailored to the individual needs of each patient. With focus and attention to the nutritional content of the diet, lifestyle modification, and supplementation with vitamins, minerals, adaptogens, and possibly hormones, the good news is that it is possible to achieve a complete recovery from adrenal dysfunction.

31.4 Thyroid

A brief review of the physiology of thyroid function is essential here. The hypothalamus produces thyroid-releasing hormone (TRH), which signals the pituitary to release thyroid-stimulating hormone (TSH), which then acts on the thyroid gland to make 95 percent thyroxine (T4) and 5 percent triiodothyronine (T3) [74]. The liver and kidneys are responsible for converting T4 to T3. Free T3 is the active form of the hormone. When properly functioning, thyroid hormone keeps metabolism in control.

The thyroid is an endocrine organ that is susceptible to nutritional and environmental challenges [36, 37]. There are many disruptors of thyroid hormone function, including food sensitivities and/or food allergies, toxins, infections, nutrient deficiencies, stress, sleep deprivation, pharmaceutical drugs, adrenal dysfunction, oxidative stress, stress in general, and changes in the gut microbiota. These disruptors are extremely important because suboptimal thyroid function has far-reaching consequences.

Some consequences of low thyroid hormone include fatigue, weight gain, depression cardiovascular dysfunction (including dyslipidemias and atherogenesis), glucose intolerance or insulin resistance, and poor pregnancy outcomes [75, 76]. Inhibitors or promoters of proper thyroid hormone function will be divided according to the location of operation. First, at the level of the thyroid gland or at the conversion of T4 to reverse T3 (RT3) or to T3, there are factors that contribute to or inhibit proper thyroid function. Factors contributing to proper production of thyroid hormones include the nutrients iron, iodine, tyrosine, zinc, selenium, vitamin A, vitamin E, vitamin B2, vitamin B3, vitamin B6, vitamin C, and vitamin D [77–84]. Factors that inhibit proper production of thyroid hormone include stress, infection, trauma, radiation, medications, fluoride and bromine (antagonist to iodine), toxins such as pesticides, Hg, Cd, Pb, and autoimmune diseases such as celiac disease [36, 37]. Minerals important for conversion of T4 to T3 by deiodinase enzyme include selenium and zinc. Factors that increase conversion of T4 to RT3 include stress, trauma, low-calorie diets, inflammation and cytokines, toxins, infections, liver and/or kidney dysfunction, and certain medications. Factors that improve cellular sensitivity to thyroid hormones include vitamin A, exercise, and zinc. Factors that promote or inhibit conversion of T4 to T3 by a deiodinase enzyme are provided in Table 31.5.

Table 31.5 Factors that facilitate or inhibit deiodinase conversion of T4 to T3

Facilitate	Micronutrients Vitamins: A, E, riboflavin, etc. Minerals: selenium, potassium, iodine, iron, zinc Hormones Cortisol Growth hormone Testosterone Insulin Glucagon Melatonin
Inhibit	Micronutrient excesses or deficiencies Selenium deficiency Iodine Other micronutrient deficiencies Hormones Excess estrogen Oral contraceptives Prescription medications Excess cortisol, catecholamines Chronic illness (cytokines, free radicals) Long-term hospitalization Compromised liver or kidney function Poor-quality diets Deficient protein Excess sugar Environmental toxicity Heavy metals Herbicides, pesticides Polycyclic aromatic hydrocarbons

31.4.1 Assessment

For overall assessment see Table 31.6.

When evaluating laboratory results for thyroid testing, it is important to realize that most conventional laboratories have not adopted the optimal reference ranges that have been promoted by current literature and used in integrative/functional practices. Instead they use standard reference ranges that have been developed by tabulating results from multiple patient samples who were considered normal without regard to level of dysfunction. In appropriate circumstances, red blood cell heavy metal testing may be done for acute ongoing exposure, and urinary heavy metals may be used for assessment of total body load. Urinary testing can be done with or without provocation with a chelator. However, if ordering a provoked 24-hour or 6-hour urinary test, make sure patient will tolerate this challenge. A chronically ill patient may not be able to tolerate provocation.

Table 31.6 Assessment of abnormal thyroid function

Symptoms	Memory and concentration problems Diffuse headache, migraines Depression; melancholia Constipation: hard or pellet-like bowel movements and decreased frequency Low libido Reactive hypoglycemia Hypotension Hypoglycemia Poor tolerance to stress and exercise Fatigue Hair loss Poor concentration Cold extremities Headaches		
Physical exam	Dry skin, elbow keratosis, brittle nails Diffuse hair loss Puffy face, swollen eyelids Edema in legs, feet, hands Elevated cholesterol, generally LDL Easy bruising Prolonged Achilles tendon reflex Keratoderma Enlarged thyroid gland		
Laboratory testing and ranges	TSH Free T4 Free T3 Total T3 Anti-peroxidase antibodies Anti-thyroglobulin antibodies Anti TSH receptor antibodies rT3 Total T3 (TT3) Free T3/free T4 TT3/rT3 CBC and ferritin RBC selenium RBC zinc 25-OH vitamin D Serum vitamin A Urinary fasting morning spot iodine Celiac panel Toxic metals as indicated by history and physical exam Food sensitivity testing	*Functional ranges*	*Conventional ranges*
		TSH: 0.4–2/2.5 mIU/L	(0.4–5.5)
		Free T4: 15–23 pmol/L	(9–23)
		Free T3: 5–7 pmol/L	(3–7)
		Total T3: 120–181 ng/dl	(76–181)
		Thyroid antibodies: WNL	
		rT3: 11–18 ng/dl	(11–31)
		FT3/FT4: >0.33 TT3/RT3: >6	

31.4.2 Treatment

Treatment should begin by first focusing on lifestyle modifications and supplementation. After this has been optimized, the final intervention may include hormonal therapy, if necessary. Special attention is directed to removing the offending cause or causes and supplementing the deficiencies as appropriate. Recommendations include a dietary plan that is low in reactive foods. Choices for the plan include foods that are high in pre- and probiotic content and high in phytonutrients and balanced in the omega-6/omega-3 ratio. The plan

Table 31.7 Thyroid function and the relationship to other hormones

Hormone	
Adrenal	High adrenal activity impairs 5′ deiodinase leading to higher T4, lower T3, normal or elevated TSH Low adrenal activity may result in lower T4, higher T3, normal or elevated TSH Excess adrenaline can desensitize T3 receptors leading to T3 resistance, higher T3, despite symptoms of hypothyroid With excess adrenaline, the body compensates by lowering T4 leading to symptoms of hypothyroid but often the patient intolerant of thyroid supplementation (always balance adrenals first)
Sex steroid hormones	Hypothyroidism stimulates CYP3A4 leading to increased production of 16αOHE1 Hypothyroid decreases concentration of SHBG which causes more bioavailable E2 and testosterone Hyperthyroid increases SHBG leading to less bioavailable E2 and testosterone Hypothyroidism associated with less deactivation of cortisol to cortisone (hyperthyroidism leads to the opposite)

should strive to reduce inflammation by reducing saturated fats, damaged fats, and trans-fatty acids. Critical for the patient is ensuring sufficient sleep, exercise, hydration, and stress reduction techniques. Evaluating for adequate social and community support is key.

Key nutrients to consider supplementing include selenium, zinc, iron or ferritin, iodine, vitamin D, and vitamin A [77–84]. Zinc and selenium are especially important minerals to consider. For example, a low T3/T4 ratio may be related to impaired zinc and/or selenium status. Remember to begin with food first; Brazil nuts are particularly high in selenium and zinc and may be recommended before supplements. When needed, supplementation has been associated with modest changes in thyroid hormones and with a normalization of T4 and RT3 plasma levels. Iron deficiency impairs thyroid hormone synthesis by reducing the activity of heme-dependent thyroid peroxidase. Evaluate ferritin levels by laboratory testing instead of iron alone and supplement with ferritin when levels are low. Supplementation is recommended at levels of 80–100 mg/ml in women and slightly higher in men. Further, iron-deficiency anemia blunts and iron supplementation improves the efficacy of iodine supplementation [77–84]. Typical amounts to consider are selenium, 200–400 mcg; zinc, 15–30 mg; vitamin D, 2000 IU; vitamin A, 2000 IU; iodine, 150 mcg; and iron, 15–20 mg (in a menstruating woman). Important points to consider for thyroid function and the relationship to other hormones are listed in Table 31.7.

31.5 Sex Steroid Hormones

Sex steroid hormones for this discussion will refer broadly to estrogen, progesterone, and testosterone. In the author's experience, if insulin sensitivity, adrenal function, and thyroid status have been addressed, the sex hormones may no longer need special attention or additional hormone replacement. In other words, there may be imbalances in sex hormones due to problems with insulin sensitivity, adrenal function, or thyroid status. It is important to assess sex steroid hormones by laboratory testing since abnormalities may be present in men and women of all ages and not just in the perimenopause, menopause, or andropause stages. ▶ Box 31.2 details the approach to the sex steroid hormone assessment.

Box 31.2 Assessment of Sex Steroid Hormone Balance

- Thorough history including past medical history, childhood and family history, hobbies
- Evaluation of insulin, adrenals, thyroid, sex hormones (including ovarian function), steroidogenic cascade, and estrogen metabolism
- Balance all hormones in specific order as outlined
- Consider estrogen metabolism/genomics
- Consider the effect of hormone balancing before drugs
  - Food and lifestyle management first
- Assessment of impact of hormones in the individual
- Decision to give hormones and informed consent
- Consider best route of delivery
- Regular reassessment of hormone levels and symptoms

It is strongly cautioned not to begin bioidentical hormone replacement without adequate evaluation first. Since women with increased or persistant vasomotor symptoms (VMS) are at higher risk for cardiovascular disease due to insulin resistance [6, 85], it is imperative to screen for insulin resistance prior to balancing the sex hormones. Much has been written about hormone replacement therapy with respect to potential increased risk of heart disease and breast cancer [6, 85–88]. It has been stated that hormone replacement therapy should be considered in these women to avoid these increased risks [85]. If VMS are significantly associated with insulin resistance, it may also be postulated that women with insulin resistance would have a greater need for menopausal hormone treatment than those without insulin resistance. In this regard, there is the possibility of a beneficial effect with replacement of menopausal hormones in patients with insulin resistance.

In women beginning in pre- and perimenopause, progesterone and testosterone levels decline before estrogen levels decline. For menstruating women, it is helpful to measure progesterone in the luteal phase on days 19–21 of the cycle and the estrogens during the follicular phase on days 10–12 to evaluate the respective peaks. Further, if we focus on

optimizing estrogen metabolism for both men and women, theoretical risks from hormone replacement may be mitigated [89]. Daily unremitting stress is associated with early decline in progesterone and estrogen in younger women. Because of its position at the beginning of the steroidogenic pathway, progesterone may be diverted down the pathway to the stress hormone, cortisol. This is related to the physiologic need to respond to stress for survival, which is immediate and pressing. In addition, environmental toxins compete with our innate hormones because they are endocrine disruptors and/or xenoestrogens that disrupt hormone signaling. In men, testosterone levels are declining at much younger ages related to exposure to environmental toxins [90, 91].

As emphasized above, if there is an imbalance in baseline insulin sensitivity, adrenal/HPA axis function, or with thyroid gland, begin by repairing these baseline abnormalities. However, if after fixing the root causes sex hormone replacement is needed, studies show that transdermal bioidentical estrogen and testosterone, as well as micronized oral or transdermal progesterone, are generally safe and may not increase a woman's risk of heart disease or breast cancer if prescribed appropriately [92–98]. It is necessary to measure hormone levels and evaluate estrogen metabolism and then follow these levels on a regular basis if hormone replacement is begun to ensure safety. Use non-synthetic hormones. Progestins are an example of synthetic hormones which are associated with increased cardiovascular risks, as demonstrated in the Women's Health Initiative study [86, 96].

Hormone level baseline assessment should include progesterone, testosterone (both total and free), sex hormone-binding globulin (SHBG), albumin, estradiol, estrone, and estriol. With values for SHBG, albumin, and total testosterone, the bioavailable testosterone can be calculated in men and women. The testosterone is tightly bound to SHBG, while testosterone is not tightly bound to albumin; thus the bioavailable amount is important to consider. Follow-up laboratory evaluation is critical any time hormone replacement is prescribed. Testing should also include downstream metabolites.

When identifying declining levels of progesterone early in the peri-menopause, supporting adrenal function and adding chasteberry or vitex may be sufficient to abate symptoms and restore function [99–101]. Low testosterone levels can be enhanced in women with low doses of sublingual DHEA such as 5–10 mg twice daily along with detoxification support, particularly in the conjugation pathways of methylation and glutathione. DHEA, when supplemented in men, tends to go downstream to estrogens, while in women it is converted to testosterone due to the activity of the different enzymes in men and women. In men, addition of zinc and general detoxification are recommended. In addition, flaxseed meal in both men and women at two tablespoons per day can enhance detoxification and help with hormonal imbalance symptoms. The extract of Rheum rhaponticum (ERr 731), also known as Estrovera in the United States, Canada, and South Africa, has been used for menopausal symptoms with success [89, 102–104]. In addition to helping with hot flashes, it also helps with the anxiety and mood changes that often accompany hormonal imbalances [105]. Estrovera, or Err 731, binds to estrogen receptor beta, which may be protective for hormone-related cancers. The central functions relevant to climacteric complaints are proposed to be mediated via estrogen receptor beta (ERbeta) activation [106].

To allow for smooth estrogen metabolism, supporting phase 2 conjugation detoxification enzymes, especially methylation with activated B vitamins and supplements such as alpha-lipoic acid, N-acetyl cysteine, selenium and liposomal glutathione, can be helpful. Studies have shown that reducing the levels of estrogen-DNA adducts could prevent the initiation of human cancer [107–109]. The dietary supplements N-acetylcysteine and resveratrol also inhibit formation of estrogen-DNA adducts in cultured human breast cells and in women [110]. These results suggest that the two supplements offer an approach to reducing the risk of developing various prevalent types of human cancer.

31.6 Conclusion

Addressing hormonal issues in a systematic way is critical to discovering the root cause of hormonal imbalance. This is most effective when addressing insulin dysfunction first, followed by adrenal support, followed by addressing thyroid issues, and lastly balancing the sex steroid hormones along with their metabolism. This approach allows the practitioner to fix underlying imbalances without resorting to hormone replacement in many, if not most, cases.

32.1 Introduction

Reproduction is one of the most basic biological processes, yet it is also among the most mysterious. On one level, human reproduction merely requires the fusion of two haploid gametes, forming a diploid zygote. This zygote must then divide 40 times, amassing 1.4 trillion cells in the process (assuming the average weight of a newborn is 3250 g) [1]. The resulting conglomeration of cells is then ready to enter the world as a human infant. This newborn, however, is not merely a mass of molecules. It is a highly organized and immensely complicated network of other living organisms. Some of these organisms are endogenously derived (the 1.4 trillion human cells) [2], while others are acquired exogenously. Of those acquired, some are inherited (mitochondria), some are acquired within the womb, and still others are acquired as the fetus is exposed to the environment during and following childbirth [3].

Within the microenvironment, each of these cells has its own nutritional requirements, need for waste management, and defense against invaders. They all serve some unique purpose within the larger community that is a human organism. For endogenously derived cells, each cell's purpose is expressed through its phenotype. A cell that migrates to the heart will develop phenotypical characteristics of a cardiac cell, whereas a cell that migrates to the liver will develop characteristics of a hepatic cell. Despite clear phenotypical differences, both cells are genetically identical. The environment determines a cell's ultimate phenotypical expression, whether in the promotion of physiology or pathology.

The environment, therefore, is one of the key determinative factors in the health of an organism. Nutrients, as largely exogenous molecular influences, make up an important part of this environment, and variations in the type and quantity of such influences can significantly alter physiology. It is within this context that we will explore the dynamics of reproduction. The goal of this chapter is to help the reader understand the complexities inherent in reproduction and to create effective strategies for determining an appropriate nutritional intervention. This chapter is not, nor is it intended to be, a comprehensive catalogue of nutritional influences on reproduction.

32.2 Microenvironments and Complexity

Reproduction is a biological imperative and our bodies have evolved to survive and reproduce. As a result, the successful treatment of reproductive issues often has more to do with removing impediments to reproduction than directly facilitating conception. While both strategies merit consideration within any given case, it should be noted that the direct facilitation of conception through assisted reproductive technologies (ART), such as in vitro fertilization (IVF), even in the youngest and most fertile population, has a success rate of less than 50%. By the time a woman is 43 years old, she has a less than 4% chance of achieving a successful pregnancy through ART [4].

Interestingly, when ART techniques are combined with other modalities designed to address factors influencing the uterine environment, significant increases in pregnancies and live birth rates have been reported [5–7]. As we will explore, the uterine and ovarian microenvironments are essential factors in reproduction. The status of these microenvironments, however, is intimately entangled with the status of the relative macroenvironment of the organism. Indeed, many reproductive pathologies are merely one aspect of a larger clinical picture. For example, endometriosis is a condition that affects 10–15% of reproductive-age women and is associated with reduced fertility [8]. Researchers noted a significant association between endometriosis and pigmentary traits, including an increased number of cutaneous nevi, freckles, and those with sun-sensitive skin [9]. While the precise relationship between pigment and endometriosis has yet to be elucidated, it has been shown that women with endometriosis have a higher risk of melanoma [10]. Furthermore, both melanoma and endometriosis have been associated with environmental toxins, including PCB and organochlorine exposure [11]. One's ultimate toxic burden, while strongly correlated with the dose and type of toxic exposure, is also largely influenced by one's detoxification capacity for such toxins. In the case of PCBs, biotransformation occurs via the cytochrome P450 1A1 enzyme (CYP1A1) [12]. It was found that individuals with genetic polymorphisms in the gene that codes for CYP1A1 (A4889G) have significantly higher risks of cancer [13] and endometrial hyperplasia [14]. Similarly, genetic polymorphisms in other genes, such as the GSTM1 gene involved in the regulation of glutathione S-transferase (and thus protection from PCBs), were associated with an increased risk of endometriosis [15]. Because GSTM1 is also involved in detoxification of electrophilic compounds including carcinogens, therapeutic drugs, and other environmental toxins and products of oxidative damage, any findings related to issues in glutathione-mediated detoxification pathways warrant an inquiry into GSTM1 and other polymorphisms. In the case of GSTM1, the frequency of the particular polymorphism rs366631 in the general population is 50–78% (depending on race) [16]. Therefore, it is more likely than not that a patient presenting with endometriosis will develop a number of seemingly unrelated pathologies.

Endometriosis has also been shown to have a strong inflammatory component in both its pathogenesis and the resulting pathophysiology. Consequently, endometriosis has been associated with an increased risk of cardiovascular disease [17]. Vascular insult and atheromatous plaque progression are commonly found with endometriosis-associated coronary heart disease and can also be found in the general population of women with unexplained infertility [17–18]. While there are many systems affected by inflammation, an attempt to uncover the source of such inflammation should be made. As inflammation is an immune-mediated response, it comes as no surprise that endometriosis has been associated with infectious agents. Less intuitive is that infectious influence is not restricted to pathogens local to the reproductive

tract. Take *Helicobacter pylori* (*H. pylori*), for example. *H. pylori* is not known to infect the genital tract or associated nervous or glandular structures, yet it is significantly more prevalent among infertile men and women than among healthy controls [20]. Extra-reproductive pathogens influencing reproduction are not limited to *H. pylori*. Periodontal disease, for example, was also significantly associated with endometriosis [20]. It has been subsequently hypothesized that systemic autoimmune disorders and possibly endometriosis may be an inflammatory response to seeded periodontal bacterial pathogens [20]. A variety of local pathogens have also been associated with an increased risk of developing endometriosis. Some of these include the human papillomavirus, *Escherichia coli*, *Chlamydia trachomatis*, and *Mycoplasma genitalium* [21–22]. In addition to pathogens, inflammation can be induced by autoimmunity. In women with endometriosis, the presence of autoantibodies is a common feature [23].

Aside from the cardiovascular, toxicological, reproductive, and immune factors, endometriosis has perhaps most strongly been associated with endocrine pathology. Indeed, estrogen is often considered to be one of the most important factors in the pathogenesis of endometriosis [24]. What is less well known is that progesterone resistance may play an equally important role [25]. Progesterone resistance can result from various etiologies, one of the more important of which is via modulation of the endocannabinoid system (ECS). The cannabinoid receptor type 1 (CB1-R), for example, has been found to have essential reproductive functions [26] and appears to be responsible for progesterone's anti-inflammatory actions. Indeed, within the reproductive tract, the uterus contains the highest concentration of CB1-R ligands, and the activation of CB1-R seems to be directly involved in implantation. Altering the endocannabinoid system by inhibiting progesterone (a CB1-R ligand), or through direct exogenous ligand exposure (via cannabis use), resulted in reproductive malfunctions [25].

Other hormones have been associated with endometriosis as well. For example, low levels of vitamin D were found in women with endometriosis and associated pelvic pain [27]. Excessive exposure to thyroid hormone, for example, in Graves' disease, was also associated with endometriosis [28], as were genetic polymorphisms in the renin-angiotensin system [29].

Emotional factors were also found associated with endometriosis, with stress contributing to the development and severity [30]. Interestingly, endometriosis patients with high stress had lower salivary cortisol than controls, leading researchers to postulate that the hypocortisolism may be an adaptive response [31].

While there are many other factors that can influence endometriosis and reproduction in general, this example illustrates the importance of approaching infertility as a "nonrandom" occurrence. Different infertility etiologies are genetically and clinically linked with other diseases, and researchers suggest that we should be treating infertility problems using phenomics, rather than viewing infertility as an isolated and exclusive disease of the reproductive system or HPO/HPA axis [32].

As the previous example illustrates, there are many etiological and pathophysiological factors involved in reproductive pathology. Many of these factors overlap and form an interconnected web. Organizing the masses of information can be challenging. One useful model has its roots in Chinese medicine, where they describe all phenomena as some combination of three levels: material/structural, energy/function, and informational (which includes psychospiritual factors). While all phenomena will have some interaction with each of these factors, there tends to be a dominant factor. To illustrate this concept, let us examine a common reproductive pathology: uterine leiomyomas (fibroids).

A fibroid is a structural anomaly that can inhibit reproduction through a number of potential mechanisms, the primary of which is usually some form of physical obstruction. While hormone modulation and potentially certain phytochemicals can inhibit the growth and even regress the tumor [33], many of the therapeutic targets used to accomplish this are antagonistic to reproduction. Estrogen and progesterone, for example, are known growth factors for fibroids. Downregulation of ovarian steroid hormones using a GnRH agonist often results in tumor regression [34]; however, reproduction is not possible under such conditions and the therapy is only approved in the short term. Other hormonal and potentially nutraceutical therapies, such as epigallocatechin gallate (EGCG), work by modulating aromatase or directly inhibiting cellular reproduction [35–36]. In cases of infertility, inhibiting cellular reproduction would be counterproductive. As a result of a lack of options, fibroids suspected of causing infertility are often surgically excised, yet the 8-year recurrence rate for laparoscopic myomectomies is 76% [37]. Such a high recurrence rate may be the result of the failure to address antecedents or triggering events. Indeed, physical activity [38], lower BMI [39], intake of fruit, intake of preformed vitamin A [40], and sufficient sunlight exposure [41] have each been independently associated with lower incidence of fibroids. In animal models, activated vitamin D3 (1,25(OH)2D3) shrank uterine fibroids [42], lending further weight to the epidemiological data [41]. Genetic factors have also been found to play a role [429].

While a number of nutrients have been explored in the treatment of fibroids, human studies are lacking. As a general proposition, correlations between animal studies and human studies are largely disappointing. A review of the highest impact animal studies found only 10% resulted in a treatment approved for use in patients [43]. Thus, animal studies are not reliable predictors of human response. In addition, and as we'll see later in the chapter, many nutritional supplements seem to have dose-dependent biphasic effects: promoting or inhibiting the same function. Genistein, for example, was found either to proliferate or inhibit human uterine leiomyoma cells, depending on the dose [44].

In summary, uterine fibroids have a structural component, being the mass itself and the potential to physically obstruct important aspects of reproduction. They also

have a functional component, which covers the etiology and pathophysiology of the fibroid and includes its antecedents, triggering events, and mediators. There are also psychological and informational aspects, including possible genetic and stress components.

As the aforementioned example illustrates, structural abnormalities are often the result of functional or informational problems. Therefore, when dealing with structural issues, an attempt should always be made to identify and address any confounding informational and functional issues.

32.3 Examining the Structural Layer

Structure dictates function. While this is a mantra of biology, as we will discuss, the converse is also true. Structural issues can present on a macroscale, such as a uterine fibroid, or on a microscale, such as improper protein structures or folding. Within reproductive pathophysiology we can roughly divide structural issues into direct and indirect.

Direct structural issues are gross anatomical abnormalities that can change how the reproductive process functions. Hydrosalpinx, ovarian cysts, endometriomas, fibroids, and polyps are all examples of masses that have potential for causing direct structural issues. Within male fertility, these may relate to varicoceles and other tumors, as well as morphological defects in sperm.

Indirect structural issues occur where structural damage or morphological anomalies interfere with cellular communication, often leading to over- or underproduction of hormones or other ligands. This form of structural issue has significant overlap with the energy/function level; however, if the structural level is not addressed, it is very difficult to correct the functional aspects. Therefore, the ideal therapeutic target is usually the structural abnormality and its antecedents. An example of this is a Leydig cell tumor (LT), which can secrete sex hormones resulting in reproductive problems. In men, an LT can lead to feminization, loss of libido, erectile dysfunction, and gynecomastia. In women, they can lead to masculinization, anovulation, amenorrhea, clitoromegaly, and increase in musculature. Treatments aimed at inhibiting the effects of estrogen or testosterone are of limited benefit and destruction of the tumors is necessary to stop the process [45].

Not all tumors, however, should be treated surgically. While a common procedure, aspiration of ovarian cysts has not been found to be effective at increasing fertility outcomes [46] and the "effects of surgical treatment are often more harmful than the cyst itself to the ovarian reserve" [47].

While tumors are one of the more common indirect structural issues, tissue damage is another. Head injuries, for example, can cause damage to the hypothalamus, resulting in hypopituitarism with elevated prolactin levels [48]. Scar tissue from abdominal surgeries or endometriosis can lead to pelvic adhesions and even infertility [49]. The formation of masses in the blood (i.e., clots) are also a common cause of reproductive problems [50]. These can inhibit blood flow or lead to ischemia and are a well-known risk factor in recurrent miscarriage and suspected factors in implantation failure [50]. Clots are an interesting subset of structural issues because nutritional intervention can be very effective. Nutraceuticals such as nattokinase, lumbrokinase, *Desmodium styracifolium*, and *Sargassum fulvellum* have strong fibrinolytic activity [51]. Many Chinese herbs have also been shown to inhibit a number of prothrombotic pathways [51]. Dietary factors can also influence clotting risk, with red and processed meats tending to increase thrombotic risk and fruit, vegetables, and fish decreasing risk [52]. Unfortunately, most studies incorporating meat are poorly designed. Red meat from grass-fed cows, for example, has a completely different nutritional profile than the same meat from grain-fed cows. An analysis done by the Weston A. Price Foundation with the University of Illinois found that "[t]he ratio of omega-6 to omega-3 fatty acids was over 16:1 for the grain-fed tallow but only 1.4:1 for the grass-fed tallow." It should be noted that a higher n6:n3 ratio has been found to be associated with higher thrombotic risk [53]. Therefore, studies discussing "meat" (or any other class of foods without specifying type or source) should be approached with significant skepticism.

Structural impingement of nerves or blood vessels may also result in altered function of a variety of systems. While high-quality data are lacking, biological mechanisms exist whereby spinal or other nerve impingement may negatively impact sexual and reproductive function [54]. Where such patho-mechanisms are suspected, manual manipulation such as massage, chiropractic, or osteopathic manipulation should be explored.

Finally, we have structural damage to DNA. The cause of such damage is often reactive oxygen species (ROS) or reactive nitrogen species (RNS). As will be discussed later in the chapter, this can cause damage leading to poor oocyte quality or oocyte destruction.

32.4 Examining the Functional Layer

Function is life. It is what separates an organism from an inanimate object. The term "function" is a concept. The means of executing that concept is energy. Therefore, energy is one of the most important and fundamental requirements for life and, as a consequence, for reproduction. Indeed, the body seems to have evolved to suppress reproductive function in response to energy deficits [55]. The energy cycle has four basic aspects: production, storage, delivery, and utilization. While energy storage and delivery can be important factors in reproduction, we will focus this discussion on production and utilization.

32.4.1 Energy Production

Efficient energy production occurs primarily through oxidative phosphorylation within the mitochondria. Indeed,

the estimated number of mitochondria per cell can give us some idea of the energy requirements of the function of a given tissue. For example, a skeletal myocyte has been estimated to contain over 3500 mitochondria [56], whereas a cardiac myocyte, which is active all the time, contains almost 7000. In contrast, the number of mitochondria in an oocyte (mature egg cell) is close to 800,000 [57]. The mitochondrial requirements of an oocyte are therefore orders of magnitude higher than other cells. It comes as little surprise therefore, that one of the most fundamental sources of embryo failure is the inability to produce sufficient energy [58].

While the quantity of mitochondria is certainly important for energy production, the quality of energy production is equally important. For proper function, mitochondria need both substrate and cofactors. With aerobic respiration, the substrates are pyruvate and oxygen with pyruvate being primarily a glucose derivative resulting from glycolysis. Glycolysis, however, occurs within the cells and therefore glucose must efficiently enter such cells. Suboptimal glucose transport is thus correlated with poor fertility outcomes. Polycystic ovary syndrome (PCOS), for example, is a condition that affects up to 20% of women [59] and is highly associated with insulin resistance [60]. While women with PCOS have an ordinary number of primordial follicles, the number of primary and secondary follicles is significantly increased. However, despite the large quantity of follicles, the growth of such follicles often arrests prematurely. Without a dominant follicle, anovulation results. For those women with PCOS that do ovulate and achieve pregnancies, the incidence of spontaneous abortion is as high as 73% [59]. Improved control of glucose, however, may result in significantly improved pregnancy outcomes [61].

Oxygen is essential for human life and reproduction. Oxygen utilization level within the oocyte was found to be a predictor of reproductive success [62]. Consequently, the availability, perfusion, transport, and utilization of oxygen should be examined in the context of reproduction. For example, pulmonary issues can predispose women to fertility difficulties [63], as can issues with oxygen transport [64]. Once oxygen is in the cell, the mitochondria require a number of nutrient cofactors for proper function. Electron transport chain (ETC) cofactors include nicotinamide, thiamine, riboflavin, succinate, and coenzyme Q10 (CoQ10) [65].

The aerobic metabolism of energy is a delicate balance. The reduction of oxygen produces ROS, including superoxide and peroxide anions, which can damage DNA and cellular structures and is associated with fertility decline [66]. At the same time, ROS and RNS are important facilitators of ovulation, folliculogenesis, implantation, and even ovarian steroidogenesis [67]. A study measuring follicular fluid ROS levels found increased ROS was a marker predictive of in vitro fertilization (IVF) success [68]. Optimal ROS levels change depending on the location and timing of the reproductive cycle and, as such, the indiscriminate use of antioxidants could be detrimental to fertility [69].

32.4.2 Energy Utilization

While energy production is essential, of equal importance is its utilization. We can broadly classify the use of energy through the related concepts of communication and interaction. Communication allows for interaction and, while a very broad topic, we will narrow our focus to how the way we interact and process our environment influences reproduction.

The process of communication deals with signal distribution, be it electrical, chemical, or otherwise. The nervous system, as a mediator of brain signaling, is intimately involved in almost every aspect of reproduction [70]. Insults to the nervous system can inhibit proper reproductive function, whether from disease process, emotions, or exposure to environmental or immunological challenges [71–75]. Chemical signaling, whether endocrine, paracrine, or autocrine, is indispensable for human reproduction [76–78]. Disruption in chemical signaling can also come from disease process, emotions, and exposure to environmental and immunological factors [79–81]. In addition, there seem to be other communication and delivery mechanisms that are more amorphous, such as quantum entanglement within neural networks [82] and the meridian theory of Chinese medicine which posits a network of channels covering the entire body. While research is ongoing, there have been a number of recent studies affirming that biophysical characteristics at acupuncture points are in fact different from non-acupuncture points [83]. The modulation of these communication routes via acupuncture has been found to improve a variety of fertility issues, including improvement in markers of poor ovarian reserve [84]; premature ovarian failure [85]; ovulation frequency in women with PCOS [86]; sperm count, motility, and morphology [87–89]; and so forth.

There are many physiological and pathological intricacies to the facilitation and inhibition of the process of communication and transformation. Some of the more important facilitating molecules include hormones and various nutrient cofactors.

32.4.3 Hormonal Factors

The primary role of hormones is to carry particular messages from one site to another. Sex hormones, including progesterone, androgens, and estrogens, are essential to reproduction, but there are many other hormones involved as well. Some of these include gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin (PRL), oxytocin, inhibin, activin, prostaglandin F2a, PGE2, human chorionic gonadotropin (hCG), placental lactogen, relaxin, thyroid hormones, DHEA, insulin, anti-Mullerian hormone, albumin, SHBG, cortisone, melatonin, and angiotensin. While a thorough investigation of the interactions of these hormones is beyond the scope of this survey, we will review selective interactions to further demonstrate the role of systems biology within reproduction.

During the follicular phase, the hypothalamus sends low-frequency, high-amplitude pulses of GnRH to the anterior pituitary, which responds by secreting FSH. FSH then stimulates the aromatization of androgens within the granulosa cells to create more estrogen. However, LH is just as important as it stimulates the theca cells to produce the androgens that are aromatized [90]. FSH also stimulates follicular growth. As follicles grow, they produce more estrogen. Estrogen, in turn, helps develop the uterine lining, stimulates vaginal lubrication, upregulates expression of progesterone receptors, and increases vasopressin and oxytocin production in preparation for ovulation. With respect to FSH, estrogen has a bimodal effect, first inhibiting FSH through a negative feedback loop until E2 levels reach 2–4 times the early follicular level. At that point, the response of the hypothalamus switches to a positive feedback that results in a surge of gonadotropin production, though a number of factors, including insufficient oxytocin levels and elevated melatonin levels, may inhibit the LH surge [91]. The LH surge prevents further growth of nondominant follicles and causes final oocyte maturation to begin, a process involving the renin-angiotensin system. As a result, the use of ACE inhibitors may interfere with this process [92].

Following the LH peak, the outer granulosa layer stops aromatizing androgens and, with the help of other hormones like melatonin [93] and angiotensin and renin [94], switches to progesterone synthesis. During ovulation, the follicle is ruptured via the degradation of the follicular wall by enzymes such as collagenase, plasminogen activator, and gelatinase. After release of the oocyte, the follicle (corpus luteum) primarily secretes oxytocin, progesterone, estrogen, and inhibin.

Oxytocin (OT) is believed to facilitate sperm transport to the proper fallopian tube [95], is anxiolytic, and seems to be a cofactor in angiogenesis [96]. Progesterone converts the endometrium to the secretory stage, thickens cervical mucus to block sperm transit, and decreases the maternal immune response. Progesterone also has anxiolytic effects, perhaps to help minimize the negative impact of stress on implantation [97], and helps to control oxytocin levels. While OT seems useful to facilitate sperm transport, continued myometrial contractions may interfere with implantation. Indeed, the use of OT antagonists following IVF was associated with increased implantation rates [98].

Like OT, PRL has important bimodal functions in reproduction. While PRL is necessary for embryo implantation and can rescue stress-threatened pregnancies by preventing progesterone degradation [99], its presence in sufficient quantities at the wrong time can inhibit ovulation through suppression of GnRH. Perhaps this is how vitex agnus-castus (VAC) improves fertility in some women, as it was found to lower PRL levels equivalent to the dopamine agonist bromocriptine [100]. However, caution should be exercised in administering VAC to eu-PRL individuals, as low prolactin may have unwanted effects on fertility.

Melatonin is present in significant amounts in follicles [93] and peaks during the luteal phase. The cyclical nature of melatonin throughout the reproductive cycle is essential as prematurely elevated levels may suppress ovulation [101]. In the luteal phase, melatonin plays a number of important roles, particularly in the maintenance of progesterone levels and in the reduction of oxidative stress. Indeed, melatonin's antioxidant effects are strong enough to help prevent premature ovarian failure in chemotherapy-treated females [102] and to significantly extend the reproductive life of hens [103]. As melatonin levels decline with age, the likelihood of poor oocyte quality due to oxidative damage increases significantly [104]. In pregnancy, melatonin readily crosses the placental barrier and has an essential role in protecting the fetus from oxidative damage [104]. It also appears to be a crucial component in proper fetal development, particularly in the prevention of neurodevelopmental disorders. Low levels of melatonin are associated with autism spectrum disorders (ASD) [104]. As melatonin secretion occurs mainly at night in the absence of light, it is essential to reinforce the importance of proper sleep hygiene. Minimization of nocturnal light is important to maintain proper melatonin levels. Exposures to as little as 285 lux for 2 hours were sufficient to negatively impact melatonin levels [105], though filtering out blue light via orange-tinted safety glasses seems protective [106].

Following ovulation, the oocyte is released into the peritoneal cavity where the fimbriae at the end of the nearest fallopian tube facilitate its entrance. Propulsion of sperm and oocytes within the fallopian tubes is accomplished through a complex interaction between peristaltic waves, ciliary activity, and the flow of tubal secretions [107]. Fertilization typically occurs in the ampulla of the fallopian tube, with sperm able to live for up to 7 days waiting for the arrival of the oocyte [108]. While it has often been assumed that ovulation only occurs once per cycle, multiple batches of maturing eggs have been observed in nearly all human subjects and multiple ovulations per cycle in 10% [109]. This perhaps explains why the rhythm method of contraception tends to be unreliable [110], though there are other factors, such as pheromones, that can trigger ovulation [111] and could influence rhythm method failures.

Upon fertilization, it takes the embryo ~4–6 days to travel from the fallopian tube into the uterus where it spends ~3 days in the uterine cavity prior to implantation. During this time, the embryo is nourished solely through fluids in the uterine cavity. Therefore, fat-soluble vitamins and iron are particularly important [112]. The endometrium then absorbs the fluids to allow contact between the blastocyst and the uterus. Failure of fluid absorption (endocytosis) significantly increases implantation failure [113]. The invasion of the embryo into the uterus then begins. This is an inflammatory process and the use of anti-inflammatory medication may be counterproductive. For example, dexamethasone administration for 4 days inhibited implantation in 80% of rats given E2. However, injecting two doses of histamine reversed these effects. [114]. Therefore, eating fermented or other foods high in histamine may help facilitate implantation. Similarly, PGE2 reversed dexamethasone-induced implantation inhibition [114].

There are many hormones involved in implantation, including thyroid hormone, E2, P4, PRL, CRH, melatonin, and PGE2. [115–118]. If hCG or other signals are not received indicating implantation, hormone levels drop, triggering menstruation. If hCG is detected, the body begins preparation for a pregnancy.

From a treatment standpoint, there are many dietary strategies to modulate hormones. One common strategy is the use of natural aromatase inhibitors, such as flavonoids. In particular, chrysin, naringin, naringenin, hesperetin, eriodictyol, and apigenin [119–120] are among the compounds shown to have significant inhibitory effects on aromatase. Tea polyphenols can also inhibit aromatase, with black tea having significantly more potent effects than green tea [119]. A variety of other phytocompounds, particularly from a variety of herbal medicines and foods, are also effective [119]. Genistein and quercetin, on the other hand, induced aromatase with a 2.5- and 4-fold induction, respectively [121]. Aromatase modulation should be attempted only relative to the patient. In diseases often characterized by estrogen-dominant states such as endometriosis, aromatase inhibition may be therapeutically indicated. However, in cases of androgen dominance, such as PCOS, this would be counterproductive. Strongly inhibiting aromatase may result in poor reproductive outcomes, and there is some evidence that it could induce autoimmune disease [122]. Indeed, estrogen seems to be an important regulatory hormone for development of peripheral T regulators and therefore can help maintain immune tolerance. Estrogen was also found to be an important factor in embryo implantation [123].

Cortisol is released by the adrenal glands in response to stress and low blood sugar. Increased cortisol levels have been associated with untimely increases in gonadotropin and progestin levels during the follicular phase, impending ovulation and implantation [97]. It has also been associated with early pregnancy loss [124]. During pregnancy, elevated cortisol is associated with intrauterine growth restriction, preterm labor, preeclampsia, and chorioamnionitis [125]. In contrast, cortisol was also found to have beneficial effects on stimulating hCG secretion and promoting trophoblast growth [125]. The adverse effects of cortisol are unlikely to stem from normal physiological secretion, but rather from stress-induced production. Cortisol levels are upregulated by caffeine, stress, and sleep deprivation. They are downregulated by relaxation, massage, intercourse, magnesium, vitamin C, n3 fatty acids, and having fun or laughing. Estrogen also increases cortisol levels [97].

32.4.4 Nutrient Factors

Nutrition is one of the most important factors in the survival and reproduction of any organism. Indeed, nutrition provides substrates for both structure and function. In reproduction, proper nutrition has been found to be essential for fertility and proper fetal development [126]. To begin with, nutrition provides the substrates for energy production. Reproduction requires a tremendous amount of energy expenditure. It is estimated that over a normal gestational period with normal fetal weight gain, the caloric requirement is 78,000 kcal [55]. Calories, however, are not a sufficient metric; the type of caloric intake is also important. Numerous food substances have been found to impair fertility. For example, trans-fatty acid intake was inversely associated with sperm count [127]. Replacement of 1% energy of saturated fatty acids with 1% energy of long-chain n3-PUFAs more than doubled live birth rates [128]. Caffeine consumption (coffee, tea, sodas, etc.) in both men and women was associated with a greater than 70% increase in the risk of pregnancy loss [129] and alcohol more than doubled the risk of miscarriage [130]. Study results on alcohol and caffeine, however, have not been consistent [131]. Sugar consumption reduced live birth rates [132] and adding just one serving of poultry per day resulted in a 32% higher chance of developing ovulatory infertility [133–134]. Interestingly, no other meats had this effect, though both meat and fish have toxicological concerns that are known to negatively impact fertility [131].

In contrast, proper nutrition has consistently been found to increase fertility [131]. High-quality food should be free of pesticides and as natural as possible. Organic foods avoid endocrine damage from pesticide residues. Indeed, such residues were associated with fertility problems including reduced semen quality in men and a lower probability of pregnancy and live birth in women [7, 135]. The Mediterranean diet was examined in relationship to fertility and found to significantly improve live birth rates [136] and reduced the risk of preeclampsia [137]. On the other hand, caution is warranted for patients on restrictive diets. Carbohydrate restriction in the form of avoiding whole grains may be counterproductive, as whole grain intake was associated with a 51% higher probability of live birth [138]. Consumption of fruits and vegetables was positively correlated with healthy birth weight [139], and tomato juice, in particular, improved sperm motility [140]. Consistent use of a prenatal multivitamin resulted in a 55% reduction in the risk of miscarriage [129], stillbirths [141], preeclampsia, preterm labor, and small gestational-age babies [142]. Intake of iron, zinc, folic acid, calories, and protein was also found to be higher in fertile women, specifically in the form of meat, nuts, dried fruit, and green leafy vegetables [143].

Specific nutrients have also been found to exert important influences on fertility; however, whether a nutrient is beneficial or detrimental is often dose-dependent. For example, levels of iron (Fe), copper (Cu), and magnesium (Mg) were found to be lower in males with sperm motility issues, yet excess Fe and Cu (especially if a person is positive for hemochromatosis or Wilson's disease) both impaired sperm parameters and could lead to impotence [144, 145]. Zinc (Zn) levels were found to be significantly higher in fertile men than in non-fertile men, and seminal Zn levels were positively correlated with improved sperm count and morphology [146]. High levels of Zn, however, produced the opposite effect [147]. Selenium was found to reduce the risk of miscarriage, preeclampsia, preterm labor, and gestational

diabetes [142]. Deficiencies in selenium have also been associated with reduced sperm quality. However, too much selenium reduced sperm quality [148–149].

Vitamin D, technically a hormone, regulates calcium, magnesium, and phosphate homeostasis and plays an important role in fertility. Low levels of vitamin D are associated with a decrease in sperm count and motility, along with an increase in abnormal sperm morphology. High vitamin D levels were found associated with poor sperm count, motility, and morphology [150]. Furthermore, elevated vitamin D levels in follicular fluid reduced fertilization rate and embryo quality [150], and higher values of vitamin D were associated with a lower possibility of achieving pregnancy [150]. Indeed, the activated form of vitamin D (1,25(OH)2D3) is transferred through the placental barrier, where it can leach out embryonic skeletal calcium stores, potentially compromising postnatal survival [150]. A significant portion of vitamin D's effects on fertility is thought to be its influence on calcium homeostasis. One study examining vitamin D-deficient subfertile mice found that calcium supplementation restored fertility [151]. Indeed, calcium plays a major role in fertility as calcium ion oscillations initiate embryogenesis [152].

Magnesium (Mg) also has important influences on fertility. Mg ions were found to preserve fertility on exposure to ionizing radiation [153]. Women supplementing with 300 mg of Mg were found to have fewer instances of intrauterine growth retardation, preterm labor, preeclampsia, gestational diabetes mellitus, leg cramping, pregnancy-induced hypertension, and abnormal weight gain. The Cesarean delivery rate was 67% lower, and children born to these women had higher Apgar scores when compared to women taking only 100 mg of Mg daily [154].

Maternal intake of folic acid during pregnancy was found to lower the risk of autism spectrum disorder (ASD) [155], neural tube defects, cardiac malformations, and cleft palate [156]. However, one report found that excessive levels of folate and vitamin B12 in the blood increased autism risk by 17,600%. Excess levels were defined as more than 59 nanomoles per liter of folate and more than 600 picomoles per liter of B12. While this has not yet been confirmed, a bimodal effect of folic acid would be commensurate with other nutrients [157].

Vitamin C (AA) can also help protect the reproductive system from oxidative stress. It is also important during follicular growth [158] and to help prevent reproductive damage from lead and other toxins [159]. AA was found to protect the fetus from epigenetic damage due to maternal smoking [160] and to help reverse testicular damage in diabetic rats [161]. A dose of 500 mg/day of time-release vitamin C was found to almost double pregnancy rates [162].

While many other nutrients may influence reproduction, the above examples make it clear that many nutrients can either improve or impair fertility. Clinicians should therefore consider careful evaluation of nutrient status prior to commencement of a supplement regimen in support of reproductive health. In addition to supporting physiology through proper nutrition, avoidance or neutralization of inhibitory factors is of equal importance. These factors often arise as a result of environmental exposures. Indeed, in modern times where nutrients are relatively easily accessed, toxicological concerns have become increasingly prominent.

32.4.5 Reproductive Toxicology

There are over 80,000 chemicals registered for use in the United States, and 2,000 new ones introduced each year [163]. While many chemicals have been found to cause reproductive harm, most of the chemicals in use have never been tested. According to the *New York Times*,

> MANY Americans assume that the chemicals in their shampoos, detergents and other consumer products have been thoroughly tested and proved to be safe. This assumption is wrong. Unlike pharmaceuticals or pesticides, industrial chemicals do not have to be tested before they are put on the market… [Furthermore,] companies are not required to provide any safety data when they notify the [EPA] about a new chemical, and they rarely do it voluntarily ... If the EPA does not take steps to block the new chemical within 90 days or suspend review until a company provides any requested data, the chemical is, by default, given a green light... [164].

In such an environment, a toxicological evaluation becomes essential. Official determinations of safe levels of potentially toxic substances may err by orders of magnitude. This is the result of most toxicity studies examining isolated elements. Real-world exposures are rarely isolated and substances considered harmless at low levels can become highly toxic when combined. For example, experiments where mercury was administered at a level that kills 1% of a test population (LD1) and then combined with an amount of lead that kills 0.05% of a test population (1/20 of LD1) killed 100% of the animals [165]. This is one of the reasons for adverse event reporting at dosages deemed safe in controlled trials.

A second important toxicological principle is that route of administration can exponentially increase the toxicity of various substances. For example, safe levels of GI exposure can be highly toxic if given parenterally. A study looking at the LD50 for cholinesterase inhibitors found the LD50 for oral Ciodrin was more than 40 times higher than the LD50 for intravenous and more than 15 times higher than subcutaneous administration [166]. Finally, toxicity dosage is not linear. Researchers examining aluminum oxyhydroxide (AlO(OH)), the primary adjuvant for vaccines, found that "[n]eurobehavioural changes, including decreased activity levels and altered anxiety-like behaviour, were observed compared to controls in animals exposed to 200 μg Al/kg but **not** [emphasis added] at 400 and 800 μg Al/kg." They concluded that "[Al] injected at low dose in mouse muscle may selectively induce long-term Al cerebral accumulation and neurotoxic effects; and that 'the dose makes the poison' rule of classical toxicology appears to be overly simplistic" [167].

It should also be mentioned that, for obvious reasons, most controlled toxicological studies (including the ones we will be citing below) are done in nonhuman, animal models and extrapolated to humans despite the imperfect correlation.

Toxins are ubiquitous in the environment with common sources including food, air, water, electronics, cleaning supplies, pesticides, insecticides, pharmaceuticals, nutraceuticals, and medical procedures. Reproductive toxins in food can arise "naturally" or through contamination with food additives. For example, grains naturally attract mold growth. As such, cereal grains designated for consumption are frequently contaminated with mycotoxins such as zearalenone that are highly toxic to the reproductive system, lead to the degeneration of oocytes [168], and inhibit sperm viability [169]. Rice, particularly the bran, has been shown to contain high levels of arsenic (discussed further below) [170], a compound that is highly toxic to the reproductive system. Arsenic can cross the placental barrier, inducing developmental toxicity and even fetal death [171]. It also damages male fertility, reducing testis size and interfering with spermatogenesis and steroidogenesis [172], though quercetin may ameliorate some of the negative impact on the male reproductive system [173]. The bran of rice contains 10× the arsenic levels of polished rice; thus brown rice has much higher arsenic levels than white rice. In addition, proper preparation of rice can significantly reduce arsenic levels. Cooking with a water-to-rice ratio of 12:1 was found to reduce arsenic levels by 57% [174].

Other common metals that have significant reproductive toxicity include cadmium, mercury, lead, and aluminum. Cadmium (Cd) is found in various foods such as shellfish, mushrooms, cereal grains, chocolate, potatoes, and other vegetables (usually acquired from the soil), as well as cigarettes, gasoline combustion, fertilizers, PVC, ceramic glazes, textiles, and paints [175]. A combination of zinc and selenium was found to ameliorate Cd damage to ovarian tissue. Vitamin C, retinol and blueberries also significantly reduced the negative impact of Cd exposure. Low-protein diets on the other hand increase cadmium toxicity, presumably due to lower access to cysteine – necessary for metallothionein synthesis [176–178].

Mercury is commonly found in seafood, fluorescent light bulbs, vaccines, contact lens solutions, makeup, and skin creams. Dental amalgams contain 50% elemental mercury and may produce a significant amount of vapor, as it is consistently released from amalgams and absorbed by the human body [179]. Modern amalgams are higher in copper, causing still higher mercury emissions [180]. While it was previously believed that mercury released from dental amalgams was not harmful, new findings dispute this [181]. Heat can increase the release of mercury vapor, as can electromagnetic fields [181]. Exposure of patients, for example, to radiofrequency emissions from conventional Wi-Fi devices increased mercury release from dental amalgams [182]. Consequently, researchers have urged pregnant women with dental amalgams to minimize their exposure to electromagnetic fields [181].

Mercury is highly toxic to the reproductive system and all mercury compounds can cause fetal harm [183]. Methylated mercury easily crosses the placental barrier and denatures DNA. It can also induce chromosomal aberrations, increasing aneuploidy incidence [183]. Garlic is a relatively safe compound that effectively inhibits the embryotoxicity of methylmercury [184] and, given its safety and efficacy profile, should be considered prophylactically for persons of reproductive age with potential mercury exposure. A variety of other compounds have also been found to attenuate the toxic effects of mercury compounds and should be considered both in treatment and prophylaxis. Examples include selenium [185], cysteine and methionine [178], alpha-lipoic acid [186], niacin [187], chrysin [188], and vitamin C [189]. Interestingly, morphine [190] and prolactin [191] were also found to have protective effects.

Arsenic (As) is commonly found in water, seafood, chicken, pork, wine, tobacco, rice, nutritional supplements, and wood. It is highly embryotoxic and tends to cross the placental barrier, inducing irreversible defects in the developing fetus and embryo. It also damages testicular function, resulting in reduced count and motility [192]. Arsenic also inhibits steroidogenic enzymes 3β- and 17β-hydroxysteroid dehydrogenase, whose activity is essential in the production of progesterone, testosterone, and estrogen [193]. A number of compounds have been found to inhibit arsenic-induced toxicity. These compounds include vitamin C [194]; vitamin E [195]; alpha-lipoic acid [196]; vitamin B12; carotenoids; flavonoids such as quercetin, naringenin, and silymarin; and organic forms of calcium, iron(II), and zinc. Of note, the inorganic forms of these metals can be problematic in combination with arsenic [197]. Amino acids, such as cysteine and methionine, were all found to mitigate arsenic's toxic effects. Selenium, specifically, decreases teratogenicity of As [178].

Lead (Pb) is commonly found in soil, dust, drinking water, paints in older homes, crystal, some ceramic glazes, imported foods, batteries, chocolate, and nutritional supplements [198]. Pb has been associated with sterility, spontaneous abortions, stillbirths, and neonatal deaths [197]. It can also reduce semen morphology, motility, count, and volume [199]. Fetal exposure to Pb can result in impaired cognitive development and was even associated with an increase in criminal arrests in early adulthood. For every 5 μg dL^{-1} increase in blood Pb levels by 6 years of age, the risk of being arrested for a violent crime as a young adult increased by almost 50% [200]. Omega-3 fatty acids were found to significantly decrease brain damage due to lead exposure [201]. As Pb mimics calcium, vitamin D increases Pb absorption and its deposition into the bone and the kidneys [178]. Phosphorus, on the other hand, decreases bone retention of Pb [178]. Zinc supplementation decreases Pb GI absorption and tissue accumulation [178].

Aluminum (Al) is the third most abundant element in the earth's crust, yet it is highly neurotoxic [202]. It is found in a wide variety of commonly used products such as baking powder, sugar, and salt (as an anticaking agent), a bleaching agent in white flour, antiperspirants, lotions, infant formulas,

parenteral nutrition (TPN) [203], antacids, and cheeses [204]. It is also contained in vaccines in biologically significant amounts [167] routinely recommended for pregnant women [205–206]. Following prenatal exposure, Al transplacentally traverses and accumulates in the fetal tissues in amounts that can adversely influence fetal development [192]. Pregnancy enhances susceptibility to Al toxicity. In developmental studies, Al has been shown to cause bone abnormalities, fetal internal hemorrhaging, neurodegeneration, and immune system activation [192, 202, 207]. Silica has been shown to chelate Al [208]. In one study, the consumption of 1 L of silicon-rich mineral water daily for 12 weeks significantly reduced the body burden of Al and improved cognitive function in Alzheimer's disease patients [209]. In addition, vitamin E and selenium [210], vitamin C [211], green tea leaf extract [212], and curcumin have all been shown to reduce the toxic effects of Al.

Organophosphates (OPs) and carbamates (CMs) are the most commonly used pesticides in agriculture and have been shown to induce reproductive toxicity, developmental toxicity, and endocrine disruption [192]. OPs are irreversible acetylcholinesterase (AChE) inhibitors and operate similarly to nerve gases, such as sarin. AChE inhibitors have also been shown to disrupt cell replication and differentiation. OPs and CMs are also potent endocrine disruptors and were found to disrupt normal sexual differentiation, ovarian function, sperm production, and pregnancy [192]. OPs and CMs are common residues on a variety of foods, including peaches, apples, nectarines, popcorn, pears, corn, and grapes [213]. Not surprisingly, an organic diet was found to significantly lower dietary exposure to OPs [214]. Quercetin has been shown to protect against multi-OP pesticides [215]. Vitamins C and E [216] and lycopene [217] also have protective effects.

Polychlorinated aromatic hydrocarbons (PAHs) are a large group of chemicals that are byproducts of combustion. Typical sources include combustion of coal, wood, and biofuels for cooking, cigarette smoke, and vehicle emissions. Food preparation is a common source as well, with PAHs resulting from a variety of food processing techniques, including curing, drying, smoking, roasting, grilling, barbecuing, and refining [218]. PAHs have a broad range of antifertility actions. For example, PAH exposure was found to destroy oocytes [219] and damage sperm DNA [220]. It also has toxic effects on embryonic development [192]. Low-dose repeated exposures were found to be substantially more toxic than a single high-dose exposure [219], thus emphasizing the importance of limiting dietary and environmental exposures. PAHs are also xenosteroids and can significantly influence a wide variety of serum hormone levels, including estrogen, progesterone, androgens, PRL, and LH [192]. Ellagic acid, epigallocathechingallate, chlorophyllin, and benzyl isothiocyanate were found to ameliorate toxicity from PAHs, though the protective effect depended on the type of PAH [221]. Vitamin C had the paradoxical effect of increasing PAH toxicity by interfering with superoxide dismutase in one study [222] and, along with vitamin E, demonstrated antigenotoxic effects in another [223].

There are many other common chemicals that negatively impact fertility. Polychlorinated biphenyls (PCBs) and dioxins are highly toxic persistent organic pollutants (POPs). Dioxins are the primary toxic constituent of Agent Orange, for example. They are lipophilic byproducts of combustion (wood, coal, petroleum, etc.) and the manufacture of chlorine products, such as bleach and paper manufacturing [224]. Over 90% of human exposure is through food [225], with approximately 41% of exposure from dairy products, 38% from beef ingestion, and an overall load of 98% from animal products [226]. Dioxins can be found in much smaller amounts in hygiene products such as toilet paper and diapers [227], though the contribution to disease at such low concentrations has not been confirmed. Dioxins can lead to ovarian dysfunction and have been implicated in the pathophysiology of endometriosis [228]. Transformation of the aryl hydrocarbon receptor (AhR) is the initial step of dioxin toxicity [229]. Catechins, flavonols, and flavones are natural antagonists of AhR. Chlorophylls, lutein, quercetin, carotenoids, and green tea catechins also inhibit AhR transformation. Among foods, AhR transformation inhibition was found with spinach, citrus fruits (particularly lime, grapefruit, and lemon), sage, rosemary, oregano, peppermint, clove, olive oil [230], coffee [231], and cacao [232]. However, a number of these components had biphasic activity: acting as an AhR antagonist at low doses, while high doses had agonist (and therefore potentially toxic) effects [231–232]. The biphasic activity of many substances serves as a reminder to utilize caution with aggressive dosing.

PCBs are similarly lipophilic and environmentally persistent and travel up the food chain. They are reproductive toxins that can induce a reduction in the number of ovarian follicles and may induce premature ovarian failure [233]. Semen abnormalities have also been induced by PCBs [233]. A study on mink found PCBs from fish ingestion caused complete, though reversible, reproductive failure [234]. Placental transfer also occurs with PCBs but not readily. Lactation, however, can be a significant source of PCB exposure for the neonate [235]. PCBs were widely used in electronic equipment manufacturing and, prior to their use being banned in 1979, were ubiquitous. Fortunately, environmental levels have begun to decline in recent years; however, seafood, meat, and dairy products are still significant sources of exposure. Vitamins E and C [236] and quercetin [237] were found to be protective. EGCG was found to inhibit PCBs xenoestrogenic effects as well [238]. However, as with dioxins, many of the substances that ameliorated negative effects from PCBs had biphasic effects and could inhibit or promote toxicity depending on circumstances [239].

Phthalates (PHTs) are another group of lipophilic and ubiquitous compounds used to make plastics flexible and as lubricants. Unlike PCBs, PHT is currently used everywhere. Some examples include PVC pipes, paints, children's toys, sex toys, food containers, sandwich bags, infant care products, electronics, and cosmetics. While the primary route of exposure is through food, considerably higher levels of exposure come from hospital environments [240]. For example, large

amounts of PHT are leached from intravenous (IV) tubing [241] and PVC bags housing IV solution [242]. It is also added to the enteric coating in pharmaceutical pills [243]. From a reproductive standpoint, PHTs easily cross the placenta and act as anti-androgens, reducing testosterone and negatively impacting male reproductive development. In females, they also act as endocrine disruptors, inducing PCOS [244], endometriosis, adenomyosis, and fibroids [245], interfering with steroidogenesis, and inhibiting ovulation by suppressing the LH surge. Interestingly, they were found to act as antagonists to the G protein-coupled cannabinoid 1 (CB1) receptor [246]. Endocannabinoids are important in the regulation of successful reproduction. Plasma levels of anandamide (AEA, an endocannabinoid ligand) fluctuate throughout the menstrual cycle and pregnancy. Successful implantation and pregnancy seem to require lower levels of AEA, whereas higher levels are found during the follicular phase, and a surge of AEA occurs during active labor. Not surprisingly, the use of exocannabinoids (such as marijuana) has been found to increase the risk of adverse pregnancy outcomes [247]. CB1 receptors have been found in the brain tissue of fetuses and are important contributors to neuronal diversity during early CNS development [248]. Oxidative stress was found to play a critical role in how PHT induces neurotoxic effects [249]. Selenium was found to protect the male reproductive system from PHT damage [250], as was vitamin E [251]. Paradoxically, administration of vitamin C or resveratrol increased PHT-induced oxidative damage [252]. However, if vitamin C was combined with vitamin E, it significantly inhibited testicular injury [253]. Finally, PHTs (and bisphenol A) were found to disrupt circulating vitamin D levels in pregnancy [254]. As adequate vitamin D is essential for proper reproduction, pregnancy, and fetal development, levels should be monitored closely. Significant protective effects of vitamin D during pregnancy were found where serum 25(OH)D exceeded 30 ng/ml [255].

In addition to material-based functional interference, we are also exposed to large amounts of electromagnetic radiation (EMR) with potentially significant implications for reproduction. The electromagnetic spectrum can roughly be divided into ionizing and nonionizing radiation at approximately 2417 THz/124 nm. This falls in the upper ultraviolet spectrum (UVC). UVB, the wavelengths responsible for tanning and necessary for vitamin D production (280–320 nm) [256], are too long for ionization, yet UVB radiation can lead to DNA damage, leading to apoptotic keratinocytes and increasing cancer risk [257].

While the reproductive toxicity of ionizing radiation is well described [258–259], the growing body of literature demonstrating toxic effects of nonionizing radiation has not received widespread acknowledgment. Nonionizing radiation (NIER) is a ubiquitous, potentially deleterious modern environmental influence that may greatly impact both female and male reproduction and overall health. A review of the scientific literature regarding immunological effects of NIER stated: "it must be concluded that the existing public safety limits are inadequate to protect public health, and that new public safety limits, as well as limits on further deployment of untested technologies, are warranted" [260]. NIER is absorbed by living tissue [261], leading to a variety of adverse effects including reproductive, immune, neurological, psychiatric, and oncologic effects [260, 262–265].

From a reproductive standpoint, NIER has been found to cause a variety of disturbances including increased miscarriage rates [262], preterm births [266], fetal growth abnormalities [267], neurodevelopmental issues [268], disturbances in semen parameters [269], and hormonal disruption [269]. The most common sources of exposure are from cell towers, power lines, transformers, power meters, mobile phones and watches, wireless routers, cordless telephones, and microwave ovens [270]. Common mobile phone usage involves leaving phones in pockets, on belt clips, in bras, and resting them on one's abdomen while pregnant. The unique location of the testes and temperature sensitivity makes them more susceptible to NIER penetration and damage. In males, NIER has been shown to reduce seminiferous tubule diameters [271–272] and tunica albuginea thickness [273]. It has also been found to induce changes consistent with oxidative damage, including reductions in CAT and SOD activity [272], lipid peroxidation, and DNA damage [273]. NIER can also decrease spermatozoa formation [271], impair motility [274], create sperm aggregation [275], and decrease fertilization potential [276].

In females, NIER induces oxidative stress and increases apoptosis in endometrial tissue [277–278] with significant reductions in ovarian primordial follicles [279–280] and increases in follicular atresia, apoptosis, and stromal fibrosis [280].

In pregnancy, exposure to 900 MHz frequencies (common in cordless and mobile phones) during pregnancy in rats resulted in male offspring with a higher apoptotic index, greater DNA oxidation levels, lower sperm motility and vitality, and altered seminiferous tubules [281]. Female offspring with in utero exposure to NIER had a decreased number of ovarian follicles [282], broken oocyte nests, binucleate primordial follicles, loose stromal cells, cytoplasmic vacuolization, greater follicular atresia, and chromatin condensation [283].

Some natural substances have been examined for their ability to counteract NIER-related damage. *Cordyceps*, a type of fungus rich in selenium, was shown to reduce testicular damage by increasing sperm formation and decreasing apoptotic spermatogenic cells [271]. Melatonin was found to prevent DNA damage in male germ cells [284], and vitamins C and E protected the testes from oxidative damage with increased total glutathione and glutathione peroxidase levels and reduced lipid peroxidation values [285]. It should also be noted that, like many nutrients, NIER may have a biphasic activity that is dose-dependent. Some studies have found NIER improved reproductive outcomes. For instance, rats exposed to NIER at 900 MHz had increased sperm motility and testosterone levels, improved sperm morphology, and lowered tail abnormalities, though it also had the result of increasing precocious puberty [286]. Lastly, of particular

importance is a review of the mobile phone safety literature. Panagopoulos et al. [287] observed that 50% of the studies using simulated mobile signals found no effects, in sharp contrast to studies using real exposures to mobile signals which resulted in an almost 100% effect rate. The reader should note it is inappropriate to use simulated exposures for safety data when sources of real-world exposures are available.

Glyphosate (GLY) is a now ubiquitous, broad-spectrum herbicide brought to the consumer market in Roundup. Exposure has been linked to a wide range of health problems including reproductive problems, autism, Parkinson's disease, Alzheimer's disease, and cancer [288]. In males, it has been found to impair sperm motility [289–290] and concentration [290–291], cause testicular lesions [290], and impair mitochondrial function [289]. When combined with soy, GLY was associated with a decrease in testosterone levels, degeneration of Sertoli and Leydig cells, and a decrease in seminiferous tubule diameter [292]. In females, GLY resulted in changes to granulosa cells [293], abnormal uterine development, and increased risk for neoplasias [294]. GLY reduced fecundity by inducing endometrial morphological abnormalities and decreasing the expression of estrogen and progesterone receptors [295]. It also disrupted steroidogenic acute regulatory (StAR) protein expression [296]. Offspring had higher levels of oxidative damage, lipid peroxidation, lower levels of glutathione [297], and skeletal alterations affecting the cephalic and neural crests [298–299].

Perinatal exposure to GLY negatively impacted the set point of the hypothalamus-pituitary-thyroid axis [300]. Neuropsychiatric effects were commonly found with predispositions to attention-deficit hyperactivity disorder [301], anxiety [302], depression, reduced locomotor activity [302], and glutamate excitotoxicity in the hippocampus persisting throughout adulthood [303–304].

Finally, a curious study found GLY-induced dysbiosis, characterized by reduced *Firmicutes* and increased *Bacteroides* ratio in female rat gut microbiota, but not in males [305]. *Bacteroides* can be commensal, mutualist, or pathobiont [306]. Increased levels can lead to reproductive pathogenic states, such as antibiotic-resistant bacterial vaginosis [307]. Changes in vaginal microflora by pathogenic organisms can lead to infertility [308]. Women with asymptomatic vaginosis and women with bacterial vaginosis both had higher incidences of infertility [308]. Low levels of microflora, *Firmicutes*, may contribute to infertility. In a study comparing normal vaginal flora to women with infertility, it was found that healthy women's flora contained on average 27.8% *Firmicutes*. Infertile women averaged only 3.5%. Therefore, GLY may increase risk of infertility through modulation of the female microbiome. In addition, Group B Strep, Gram variable coccobacilli, and *Trichomonas vaginalis* were found in infertile women but not in healthy women. Furthermore, 25% of a healthy woman's flora consisted of diphtheroids and *Micrococcus*, whereas infertile women had none of these organisms. While *E. coli* and *Enterococcus* spp. were found in both groups, there were two to four times as many in infertile women.

GLY has multiple targets of interference, including oxidative damage [297]; excitotoxicity [304]; microbiome disruption [305]; inhibition of aromatase [309]; depletion of iron, cobalt, molybdenum, copper, tryptophan, tyrosine, methionine, and selenomethionine [310]; disruption of the intestinal barrier [311]; and breakdown of tight junctions [312]. There is a paucity of studies on mitigation of GLY toxicity. Lignite extract was recently shown to inhibit GLY-induced intestinal permeability [312]; however, the study was conducted by a nutraceutical company on its own product and should be independently verified. Despite the lack of data, evaluating patients on the above targets and addressing individual shortcomings may prove clinically useful in GLY mitigation.

While presented here, it should be noted that the evidence for reproductive toxicity from GLY, and the toxicity of GLY and other chemicals in general, is the subject of intense debate and controversy [313]. The topic has also become a wider political debate involving the safety of genetically modified organisms (GMOs) as a whole. There are many studies establishing the safety of GLY and GMOs [314]. However, the weight and reliability of evidence should be approached with caution [315]. With GMOs and GLY having very significant public health implications and concerns, the precautionary principle should be evoked [316].

32.4.6 Reproductive Immunology

"One of the most remarkable aspects of reproductive biology is the simple fact that a healthy woman with a fully functional immune system can successfully carry a semiallogeneic pregnancy to full term without immune rejection" [317]. Indeed, tolerance of the rapid growth of an invasive mass, from implantation through fetal development, has been described as "pseudomalignant" or even a "physiological metastasis" [318]. A number of immune cells, such as natural killer cells (NKs), regulatory T cells (Tregs), effector T cells (Teffs), and dendritic cells (DCs) populate the maternal-fetal interface [318]. For many years, it was believed that recurrent pregnancy loss often resulted from an overactive maternal immune system. However, results obtained by direct suppression of the maternal immune system were disappointing [317]. In contrast, studies examining the role of Tregs, and particularly peripheral Tregs (pTregs), have suggested that pTregs play a major role in governing fetal immune tolerance [317] and are believed to be the primary suppressors of the immune response [319]. The ability of Tregs to effect immune tolerance is dependent on the maintenance of low levels of L-tryptophan (TRP) locally [320]. This is accomplished through the metabolism of TRP by the iron-dependent enzyme indoleamine 2,-3-dioxygenase (IDO) expressed by DCs. Perhaps paradoxically, free iron prevents TRP degradation [321], potentially resulting in reduced fetal tolerance.

The expression of IDO is enhanced by PGE2 [322], a downstream metabolite of arachidonic acid (AA) requiring

cyclooxygenase 2 (COX-2) for conversion. Inhibition of COX-2 has been found to constrain IDO activity [323]. Therefore COX-2 inhibitors, including NSAIDs such as aspirin (which irreversibly binds to COX-2 [324]), should be used with caution in pregnant women or those trying to conceive. Aspirin is prescribed to many women undergoing in vitro fertilization (IVF) under the hypothesis that it may improve blood flow to the implantation site; however, studies have not found a clear benefit [325] and paradoxically it may prevent successful pregnancy. COX-2 induction was found to be crucial in implantation [326]. In mice, for example, deletion of the gene encoding for COX-2 (Ptgs2) resulted in complete female infertility [327], as did the removal of the PGE2 receptor (EP2) [328].

The facilitation of Treg activity has multiple targets. Some include increasing dietary AA (e.g., chicken, eggs, beef, turkey, and pork [329]), facilitating AA's conversion to PGE2 (via COX-2), inducing COX-2 directly, or minimizing the use of COX-2 inhibitors. One can also directly facilitate Treg activity, for example, through the use of short-chain fatty acids (such as butyrate), although medium-chain fatty acids (such as coconut oil) and long-chain fatty acids (such as DHA) inhibit Treg activity [330–331]. It is noteworthy that plants and animals contain multiple chemical compounds often having ligands for multiple targets that can produce seemingly contradictory results. For example, butyrate can inhibit COX-2 [332], suggesting that it may downregulate Treg production, yet it was shown to increase pTregs specifically [333]. Seafood can be a significant source of AA, yet it shuttles conversion of AA to PGE3 instead of PGE2 [334], making EPA and DHA supplementation potentially counterproductive in cases of immunological infertility.

A number of other substances can modulate Treg activity. For example, vitamins A (as retinoic acid) and D were found to increase Tregs, as was gluten [335]. In general, where increased Tregs are found, it is often unclear whether the substance is increasing Tregs directly or whether the Tregs are increasing as a response to control an inflammatory immune response induced by the substance. In the case of gluten, this may be a worthwhile evaluation. Those on a gluten-free diet were found to have significantly decreased percentages of circulating Tregs [335], suggesting that arbitrarily restricting gluten may turn out to be counterproductive to fertility.

Another important substance in optimizing Treg function is folate. Researchers found that Tregs express high levels of folate receptor 4 and folate depletion via methotrexate (MTX) resulted in significantly reduced numbers of Tregs [432]. As MTX inhibits dihydrofolate reductase (DHFR), those with genetic polymorphisms in the DHFR and/or MTHFR genes may also experience poor Treg survival. Therefore, genetic and functional evaluations of folate status can be important factors in treating infertility.

Commensal microbes have also been found to facilitate Treg activity. Probiotic mixtures such as *Lactobacillus acidophilus* and *Bifidobacterium longum* were found to increase immune-modulating activities of Tregs by increasing expression of FoxP3, an important component of immune tolerance. Other organisms were also found to increase FoxP3 expression, including *Bifidobacterium infantis 35624*, *Lactobacillus rhamnosus* GG (ATCC 53103) and *Bifidobacterium lactis* (Bb-12), *Lactobacillus salivarius* and *Lactobacillus reuteri* (ATCC 23272), a probiotic mixture called VSL#3, and *Helicobacter pylori* [335].

Not all organisms that facilitate Treg activity are beneficial for fertility. The immune interaction with microbes is complex and the same microbe can be pathogenic in some instances and beneficial in others. *H. pylori,* for example, may upregulate Treg efficacy to prevent its own destruction. As a consequence, it may have a protective role in some autoimmune diseases [336] and in reducing stroke risk [337], while increasing susceptibility to gastric cancer [338] and infertility [19]. In the case of infertility, anti-*H. pylori* antibodies have been found in the cervical mucus and there is evidence that cross-reaction with sperm may occur inhibiting sperm progression and thus fertility [339].

The reproductive microbiota play an exceedingly important role in reproduction. Endometrial microbiota consisting of less than 90% *Lactobacillus* species was found to significantly decrease implantation [60.7% vs 23.1%], pregnancy [70.6% vs 33.3%], ongoing pregnancy [58.8% vs 13.3%], and live birth [58.8% vs 6.7%] rates [340]. A vaginal microbiome composed solely of *Lactobacillus* seems to produce the highest chances of a successful IVF outcome [341]. In contrast, the isolation of *Staphylococcus* species or *Enterobacteriaceae* from the cervix or vagina resulted in substantially lower pregnancy rates [342]. Likewise, a preponderance of *Clostridium perfringens, Bacteroides* sp., *Staphylococcus aureus*, and *S. epidermis* were associated with fewer pregnancies [341].

Chlamydia trachomatis (CT) infection is the most prevalent sexually transmitted disease in the world [343], affecting 1.6 million people in the United States annually [430]. Infertility is estimated to result in 3% of infected women and 2% will have adverse pregnancy outcomes [345]. It can also cause male sterility [343], though the percentage of the population affected is unclear due to poor testing methodology. Non-pharmaceutical interventions show significant potential in treating CT infections and can be used alone or to potentiate standard antibiotic therapies [344]. Polyphenols, such as flavones (apigenin, luteolin, acacetin), flavonols (quercetin, myricetin, morin, rhamnetin), natural coumarins (methoxypsoralen), and gallates, are all highly active chlamydia inhibitors [344]. Lipid compounds such as capric acid, monocaprin, and lauric acid caused a greater than 10,000-fold reduction in the infectivity titer with monocaprin having a greater than 100,000-fold inactivation rate [344]. Peptides including melittin, isolated from bee venom, and cecropin, isolated from cecropia moths, also exhibit anti-CT properties. Vaginal lactobacilli such as *L. vaginalis, L. brevis, L. gasseri*, and *L. crispatus* had strong inhibitory effects on CT as well, with *L. crispatus* having the highest efficacy [344].

Many other infections can lead to infertility. Indeed, 15% of male factor infertility is estimated to be due to infectious

agents [19]. Some of these agents include protozoa such as *Toxoplasma gondii*, which can cause endometritis, impaired folliculogenesis, ovarian and uterine atrophy, amenorrhea, and reduced semen quality [431]. Mycoplasma species, particularly *M. hominis* and *M. genitalium*, *Ureaplasma urealyticum* [346], *Neisseria gonorrhoeae, Gardnerella vaginalis, Trichomonas vaginalis* [347], *Candida albicans, Listeria monocytogenes* [348], and others, have also been implicated in impairing fertility and have been associated with increased miscarriage rates [349]. Other common organisms that were associated with increased miscarriage rates include *human herpesvirus*, *Cytomegalovirus* [350], *Chlamydia trachomatis* [351], *Mycoplasma hominis* [346], and *Peptostreptococcus* spp. [352].

While microbial diversity in the gut is believed to confer health benefits [353], bacterial diversity in the vagina was found to be associated with vaginal inflammation and reduced implantation [354]. Normal vaginal microbiota is dominated by *Lactobacillus* species, especially *L. crispatus, L. iners, L. gasseri,* and *L. jensenii* [355]. The proportions of various species differ among various ethnic groups and also change during pregnancy, with an increase in *Lactobacillus* species and a decrease in anaerobic species as pregnancy progresses [356].

Abnormal vaginal microbiota (AVM) composition, such as in bacterial vaginosis (BV), aerobic vaginitis (AV), or abnormal vaginal flora (AVF), has been implicated in a variety of adverse fertility and pregnancy outcomes, including increased risk of preterm birth. While antibiotics can eradicate BV in pregnancy, the increased risk of preterm birth is not altered [357]. The destruction of beneficial bacteria may also have adverse consequences on the health of the baby, and even a short course of antibiotics can have lasting adverse consequences on the gut microbiome [358].

A review found that prophylactic antibiotics during the second and third trimesters, though reducing infection, do not reduce adverse pregnancy outcomes and morbidity. Instead, they result in short- and longer-term harm for children of mothers exposed to antibiotics, including neonatal death [359–360]. In contrast, prophylaxis and treatment of AVM with *Lactobacillus* species (*Lactobacillus rhamnosus HN001* and *Lactobacillus acidophilus GLA-14*) were found to effectively inhibit both AV and BV with a 100% inhibition of all studied pathogens (*S. aureus, E. coli, G. vaginalis*, and *A. vaginae*) after 48 hours [361]. Two studies suggested that the use of oral fermented milk or vaginally administered yogurt reduced the risk of preterm birth [362]. In contrast to antibiotics, administration of probiotics during pregnancy has been associated with increased resistance to respiratory infections, reduced IgE-associated disease burden, and reduced incidence of atopic eczema in children. In mothers, a reduction in blood glucose and increase in glucose tolerance have been observed [362].

Other strategies to reduce microbial and immunological burden include aversions during pregnancy. Indeed, up to 80% of women experience some form of food aversion, nausea, and/or vomiting in the first trimester [363–364], with nausea and vomiting being associated with reduced risk of pregnancy loss [365]. Meat (which includes poultry [366] and fish), for example, is a common aversion, as are coffee, sour foods, beans, and rice [364]. As discussed previously, meats are high sources of TRP, which needs to be kept at lower levels, at least locally to maintain immune tolerance of the fetus. TRP is also necessary for the replication of many intracellular microorganisms such as *Chlamydia trachomatis* [321], and an aversion to sources of high TRP may be essential for suppressing the replication of such organisms. Beans are high in iron, which, as discussed previously, may impair TRP breakdown. Sour fruits, such as citrus, often contain COX-2 inhibitors [367–369] and rice may contain significant levels of arsenic, which has been associated with spontaneous pregnancy loss [370]. Thus, food aversions, nausea, and vomiting in early pregnancy may play an important physiological defense mechanism for maintaining a healthy pregnancy. Therapies to suppress these reactions, whether pharmaceutical or natural, should be approached with caution.

While the interface between immunology and infertility is vast, when dealing with fertility challenges, immunology must be carefully considered. Testing for the presence of pathogenic microorganisms and addressing them with antimicrobials may be insufficient or even counterproductive. While antimicrobial therapy may be necessary in some instances, consideration for the totality of the microbial terrain and the body as a whole is essential for optimal reproductive outcomes.

32.4.7 Exercise

Immune modulation can also come from exercise. Low-intensity exercise reduces cortisol levels, whereas moderate- to high-intensity exercise increases them [371]. Indeed, athletic women are much more likely to experience reproductive cycle dysfunction [372]. A dose-response relationship in nonobese women between vigorous physical activity (of 5 hours or more per week) and delayed time to conceive was found [373]. On the other hand, for overweight or obese women with infertility, a combination of reduced calorie diet and aerobic exercise significantly improved pregnancy rates [374]. Interestingly, the improved chances of pregnancy in these women held true for natural pregnancies only. For IVF, diet and exercise did not seem to change pregnancy chances significantly [357]. During pregnancy, the amount of exercise was proportional to the risk of miscarriage, with hazard ratios (HR) increasing, beginning with 75 minutes of exercise per week (HR 1.8) and increasing to an HR above 3 for 420+ minutes per week through week 18 of pregnancy [375]. After week 18, those exercising had reduced risk of miscarriage. It is worth noting that even those engaging in low-impact exercises (dancing, walking, hiking, aerobic) had twice the risk of miscarriage. Those engaged in high-impact exercise (jogging, ball games, and racket sports) had 3.6x the risk of miscarriage. Swimming was the one sport that did not seem to increase miscarriages, though swimming is often a source of

chlorine exposure which was found to increase risk of birth defects [376]. For men, vigorous exercise was associated with reduced fertility rates, particularly in endurance athletes [372]; however, moderate exercise does not seem to have any negative impact.

32.5 Examining the Informational Layer

Information is what gives meaning. Information is not only messages themselves, but also how messages are interpreted and processed. There is significant overlap between the informational, functional, and physical layers because information is what drives everything. Any physical structure requires information to be built. Any function requires information to instruct it. Therefore, information is central to all physiological processes. It has been assumed that the brain is the central repository of information and thinking; however, recent advances in quantum effects are questioning this assumption [377–378]. Whether the mind is local or nonlocal to the brain, thoughts and attitude can significantly influence reproduction. For example, a woman's level of positive expectation related to motherhood and a man's quality of integration between the wish for a child and sexual relationships were found to be significant predictors of a couple's fertility status [379]. The effects of psychological stress on fertility outcomes have been studied during IVF cycles, with lower perceived stress at the time of embryo transfer being associated with improved pregnancy rates [380]. Women with higher anxiety and depression scores on the day of pregnancy detection were less likely to be pregnant [6], whereas lower levels of norepinephrine and cortisol at the time of oocyte retrieval as well as lower levels of cortisol at the time of pregnancy test were associated with favorable pregnancy outcomes [6]. These findings suggest that therapy and stress reduction techniques may provide important benefits to infertile couples. Indeed, a meta-analysis found psychological interventions improved pregnancy rates, though they ironically did not improve mental health measures [381].

32.5.1 Genetics

Genes are a structural source of information that can be either a direct or indirect source of infertility. Direct genetic issues generally fall into two major categories: inborn and acquired. Inborn faults span a wide variety of genetic syndromes, including fragile X syndrome, Kartagener's syndrome, myotonic dystrophy, Noonan syndrome, Klinefelter syndrome, 47,XYY syndrome, Y chromosome microdeletions, and polymorphisms in many genes, including DAX1, CBX2, NR5A1, WNT4, GNRH1, DAX1, KISS1, MTHFR [382–383], and so on. Some of these are directly responsible for infertility and some indirect. An example of a direct genetic cause of infertility is Klinefelter syndrome (KS). KS is a relatively common (1 in 500 men) condition characterized by additional X chromosomes. This leads to azoospermia (absence of sperm in semen). As a consequence, female fertilization is not possible without assisted reproductive technologies, specifically IVF-ICSI.

32.5.2 Innate Genetic Issues

An example of how a common genetic issue can have a wide range of influences indirectly leading to infertility can be found with a gene involved in folate metabolism. Folate is an essential nutrient for both fertility and pregnancy. Women with the highest intake of folic acid reduced the chances of anovulatory infertility by 59% [384]. While fortification of foods with folic acid is controversial due to potential associations with cancer and the masking of vitamin B12 deficiency [385], in terms of pregnancy, folic acid fortification has been called one of the "most significant public health measures for the prevention of pregnancy-related disorders" [386]. Significant sources of folates include edamame, arrowroot, chickpeas, peanuts, lentils, wheat germ, sunflower seeds, spinach, avocado, broccoli, artichokes, and asparagus.

One of folate's primary functions is to help run the methionine cycle that generates S-adenosyl-L-methionine (SAM): the primary methyl donor for most biological methylation reactions [387]. The rate-limiting step in the methyl cycle is controlled by the enzyme 5-methylenetetrahydrofolate reductase (MTHFR), which converts 5, 10-methylenetetrahydrofolate into 5-methyltetrahydrofolate (5MTHF). A gene of the same name codes for the MTHFR enzyme. There are a number of polymorphisms that occur in this genetic pathway, the most researched of which is the C665T transition (previously known as C677T). Women with a C665T mutation had reduced numbers of oocytes, lower serum estradiol concentrations at ovulation [384], higher risk of recurrent implantation failure [388], higher risk of neural tube defects [389], and a 6.3-fold increase in early miscarriage risk [390]. Paternal MTHFR mutation is also a risk factor for recurrent pregnancy loss [391]. Homozygotes have a nine-fold increase in the odds of idiopathic male factor infertility [392].

MTHFR polymorphisms are extremely common with around 50% of whites and Hispanics and 12% of African Americans having one or more mutations. Consequently, MTHFR-related methylation issues may be encountered frequently in a clinical setting. Methylation is essential to life as it is one of the primary tools of epigenetic control of our genome. It enables the body to silence a gene without modifying the structural composition. Methylation is also necessary for immune modulation, histamine metabolism, energy production, cellular repair, detoxification, and a number of other processes. Polymorphisms in the MTHFR gene can reduce the efficiency of methylation, causing a number of both direct and indirect consequences. As methylfolate plays an important part in the metabolism of homocysteine to methionine, an MTHFR polymorphism, particularly in the absence of adequate levels of vitamins B2 [393], B6, B12 and folic acid [394], frequently leads to elevated homocysteine (Hcy) levels. From a reproductive standpoint, elevated Hcy

has been associated with poor oocyte quality [395], unexplained female sterility [396], fertilization failure [397], recurrent pregnancy loss [398], NMDA excitotoxicity (which can impair early brain development) [399–400], oxidative damage [401], premature ovarian failure [402], and paternal-cause recurrent pregnancy loss [391]. Therefore, it is prudent to test Hcy levels in patients with known or suspected methylation defects.

Correcting an MTHFR deficiency can have far-reaching effects. For example, vitamin B2 was shown to nullify the negative influence of MTHFR polymorphisms on Hcy levels [393], though its impact on other MTHFR related issues remains to be investigated. Currently, the most logical and popular strategy of bypassing an MTHFR deficiency is supplementation with 5MTHF, the metabolic end product of the MTHFR enzyme. While studies have indicated 5MTHF supplementation has theoretical benefits over folic acid supplementation [403], clinicians frequently prescribing 5MTHF have described severe negative reactions that have yet to appear in the medical literature [404]. While the precise mechanism of these reactions is unclear, there are reasons to believe it may involve methyl trapping [403].

Conversion of homocysteine to methionine is facilitated by methionine synthase (MS). MS requires methylated vitamin B12 in order to convert Hcy to methionine. Under normal circumstances, vitamin B12 is methylated by 5MTHF. 5MTHF then loses its methyl group, becomes THF, and is further metabolized into other non-methylated folates required for other physiological processes including proper DNA and RNA synthesis. If all the cobalamin molecules are pre-methylated (e.g., when supplementing with methylcobalamin, a popular form of vitamin B12), 5MTHF will not be able to give its methyl group to cobalamin and consequently will be unable to form the other folates necessary for proper physiology. One strategy to circumvent this problem is to avoid combining 5MTHF and methylcobalamin. Instead, supplementation with the most common natural forms of cobalamin, adenosylcobalamin or hydroxocobalamin [405], may be considered, as these are unmethylated and will still require methyl groups from 5MTHF to run the methionine cycle. If methylcobalamin is required, then supplementation with the so-called "synthetic" folate (folic acid) will provide the other folates to varying degrees [403] and potentially avoid some of the reactions to 5MTHF.

32.5.3 Neural Tube Defects and Folate Supplementation

Appropriate access to folate is critical for proper fetal development. One of the great successes of targeted nutritional intervention has been in the reduction of neural tube defects (NTDs) via folic acid supplementation. NTDs are a group of birth defects related to the brain, spine, or spinal cord, with spina bifida and anencephaly being the most common presentations. Suspicions of the NTD-folate relationship began in 1964 when Hibbard demonstrated an association between folate deficiency and NTDs [406]. Red cell folate (RCF) was subsequently found to be an independent risk factor for NTDs [407]. While folic acid has extensive data conclusively demonstrating its efficacy in significantly reducing the incidence of NTDs [406], other forms of folate may also be effective.

The three most widely available forms of folate are folic acid (FA), folinic acid (FLA), and 5MTHF. FA is an oxidized form of folate that is often mischaracterized as an "unnatural" or "synthetic" folate. FA, in fact, has been isolated from spinach, chickpeas, tomatoes, green beans, and cabbages [408]. From the standpoint of reproduction, the main advantage of FA is the volume of research establishing safety and efficacy, particularly in the prevention of neural tube defects (NTDs). Studies have found FA alone reduces the risk of NTDs by up to 70% [409], though this was at a dosage of 4 mg/day. More moderate dosages (800 μg) combined with other vitamins and minerals, including vitamins B12, B6, and B2, reduced the risk by up to 90% [410]. The general consensus of recommended periconceptional daily folate intake ranges from 400 to 800 μg [409–410], with an assumption that an additional 200 μg of folates will come from the diet. For women with a previous history of NTDs, the daily recommendation is 4 mg [409].

People with MTHFR C665T polymorphisms are at an increased risk for NTDs [403], presumably due to a 30–70% decrease in the activity of MTHFR and therefore in the production of 5MTHF. In Europe, depending on the area, this polymorphism affects one third to half of the population [411]. It is therefore a significant public health concern. Consequently, supplemental 5MTHF has been hypothesized to be superior to folic acid and is being recommended as a substitute due to its perceived ability to bypass MTHFR [412]. Unfortunately, the mechanism by which folic acid protects against NTDs is unknown and only 13% of NTDs could be attributed to the MTHFR C665T mutation [413]. Recommendations for substituting FA with 5MTHF are based largely on serum and/or RBC folate levels achieved by 5MTHF administration, rather than from studies on actual NTD incidence. Such assumptions, while theoretically sound, do not account for potentially unique properties of the different folates. For example, FA was found to have free radical scavenging properties [414]. As oxidative damage is a well-established risk factor influencing the incidence of NTDs [415], the unique antioxidant properties of FA may be a significant contributing factor in its efficacy. In such a case, prescribing other folates could paradoxically result in a significant increase in NTD incidence. While future studies may establish 5MTHF to be equivalent or even superior to FA in reducing NTD rates, it is not supported by the current state of evidence.

32.5.4 Risk Factors of Folic Acid

While FA is effective in reducing NTD incidence, its use is not without risk. Unlike 5MTHF, FA can mask symptoms of a vitamin B12 deficiency, especially in dosages above

1 mg [409]. Vitamin B12 deficiencies can result in permanent neurological damage. Consequently, testing serum B12 and methylmalonic acid may be prudent when supplementing with FA, particularly in higher doses. Co-administration of vitamin B12 should also be considered, taking into consideration the potential risk of methyl trapping if methylated B12 is used.

A more recent concern with supplemental FA has surfaced with the discovery of unmetabolized folic acid (UMFA) in serum. This occurs when supplemental FA is used in concentrations above 200 μg [403]. The significance of UMFA is currently unclear. One group, for example, found UMFA levels associated with lower natural killer cell (NK) cytotoxicity [416]. However, this association was only found in a subset of older women (60–75 years old). Interestingly, the researchers also found a decrease in NK cytotoxicity for a subset of subjects with elevated serum levels of 5MTHF. It is unclear at this time what the significance of these findings is. While UMFA may ultimately prove to confer certain risks, the greater issue may be with too much folate. What constitutes "too much" is an individual analysis. Where metabolism of folates is genetically impaired (e.g., in cases of DHFR or MTHFR deficiencies), the use of FLA or 5MTHF has theoretical benefits, but lacks clinical data.

As clinical decisions at times precede evidence, in cases where a clinician has concerns regarding DHFR and/or MTHFR deficiencies and folic acid is not producing desired biochemical changes, one may consider the use of other folates. Dosages of up to 200 μg of 5MTHF are theoretically equivalent to the first 200 μg of FA (which is completely converted to 5MTHF prior to absorption). Where DHFR polymorphisms exist, FLA may be a second option to bypass the need for DHFR (see ◘ Fig. 32.1). However, it should be emphasized that, at the time of this writing, neither 5MTHF nor FLA have been sufficiently established in studies where NTDs are the outcome measure [409]. In mouse models, FA and FLA achieved different effects in preventing NTDs and dosage data on FLA in humans for such purposes is lacking [409]. Regardless, monitoring homocysteine levels, SAM/SAH ratios, and whole blood histamine may be prudent when supplementing MTHFR-deficient patients.

32.6 Acquired Genetic Issues

Acquired genetic issues are typically in the form of DNA damage, which results from primarily endogenous insults [417]. Reactive oxygen species (ROS), aldehydes from LPO, some estrogen metabolites, methylation agents, reactive nitrogen species, and reactive carbonyl species are some of the common pathways to DNA damage, with the most studied being ROS and the resulting oxidative damage [417]. One of the most important endogenous sources of ROS is mitochondrial, via the electron transport chain and nitric oxide synthase reaction. ROS are implicated in a variety of reproductive issues. Oxidative damage to sperm DNA was found to be an important contributory factor in the etiology of male infertility [418] and a likely cause of genetic diseases in offspring [419]. ROS, while important facilitators of oocyte maturation, ovulation, and implantation, correspond to poor embryo quality where elevated levels were detected in follicular fluid [420]. ROS further leads to spontaneous aneuploidy [421] and contributes to cellular aging in general [422]. Where exposure to elevated levels of ROS is likely, such as in chronic inflammatory conditions, the use of antioxidants may be of benefit [423]. Antioxidants, such as N-acetylcysteine; melatonin; vitamins A, C, and E; folic acid; myoinositol; zinc; and selenium, had only weak evidence of improving fertility outcomes [423]. In such studies, it is rare to find an assessment of the patients' antioxidant status prior to treatment. There is often an assumption that antioxidants are "good" and oxidative stress is "bad." As a result, antioxidants may be overemphasized, leading to what has been termed in the scientific literature "antioxidative stress" (AOS) [422]. AOS may interfere with the immune system's ability to fight bacteria and essential defensive mechanisms for removal of damaged cells, including those that are precancerous and cancerous [422]. Therefore, individualized evaluations of the ratio of ROS to antioxidants should be encouraged prior to supplementation.

Another common etiology of acquired genetic issues that can have profound effects on reproduction is epigenetics [424]. In essence, epigenetics is a modification in the function of specific genes that does not modify the DNA sequence [425]. Epigenetic changes can be stimulated by a variety of factors including social interactions, psychological state, diet, seasons, diurnal fluctuations, disease exposure, toxic chemicals, drugs, financial status, exercise, microbiome, therapeutic drugs, and alternative medicine [426].

Epigenetic changes involve histone modification through a variety of mechanisms, the most studied of which is methylation [427]. Such epigenetic modifications are heritable [424]. For example, paternal diet was found to influence insulin secretion, glucose tolerance, and lipid profiles in offspring [425]. There is now increasing evidence suggesting that environmental factors can have negative effects on epigenetic processes controlling implantation, placentation, and fetal growth [428]. Epigenetic factors that negatively impact fertility can arise directly, such as by not having enough access to methyl groups to methylate DNA, or indirectly, such as through modification of environmental factors, both of which have been discussed previously. Addressing these causes requires a careful examination of the totality of a person's life. However, one of the primary controllable influences on our genes and reproductive health is nutrition.

32.7 Summary

In summary, reproduction is perhaps the most important biological mandate presenting unique challenges in modern times. Recognizing and analyzing the interplay of biological

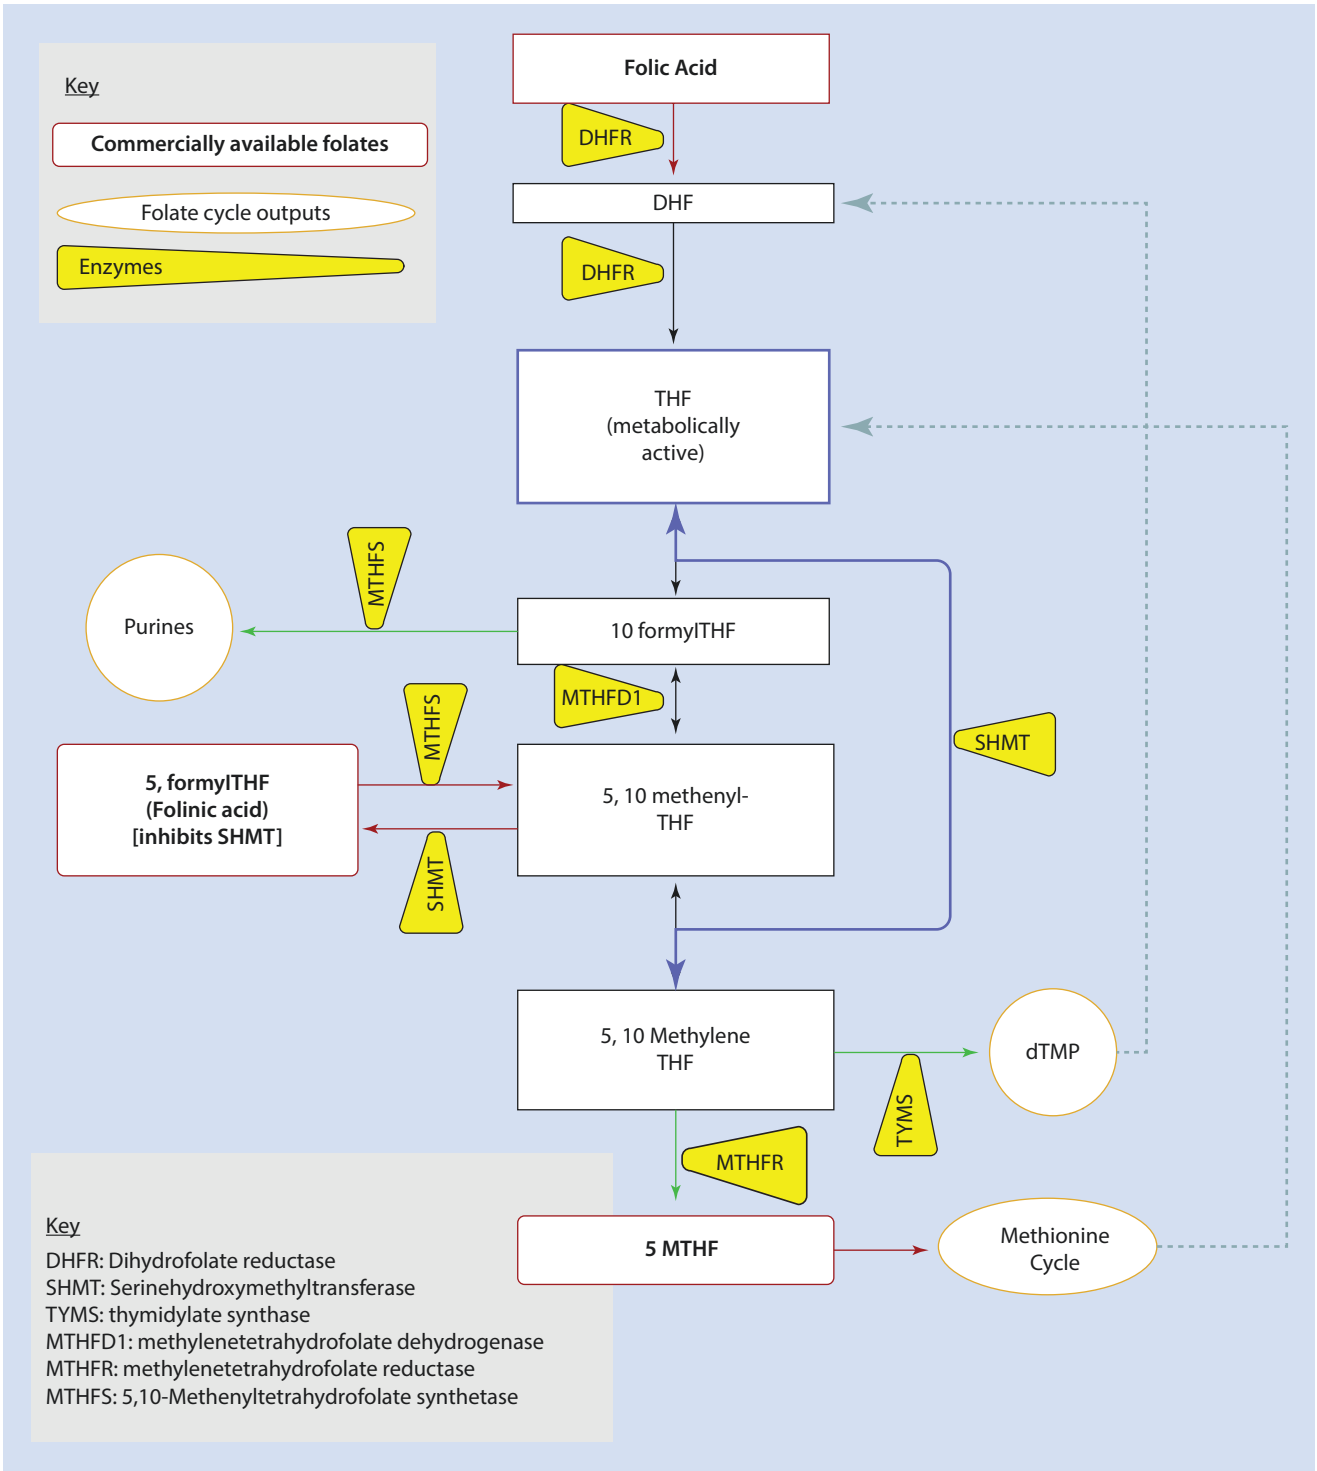

Fig. 32.1 Selective folate metabolism

systems is essential to the optimization of clinical results. Furthermore, generalized statistical modeling that fails to account for a patient's unique combination of genetic, environmental, social, and psychological factors can contribute to the persistence or iatrogenic aggravation of reproductive conditions. Considering these factors will both improve a patient's overall health and optimize their reproductive efficacy.

33.1 History and Definition of Chronic Disease

Chronic disease is a relatively new phenomenon that began around the time of the industrial revolution when machines took over the work of men, with recognition beginning after World War II. Unhealthy lifestyle behaviors are at the root of the global burden of noncommunicable diseases and account for about 63% of all deaths [1]. Common and costly, most chronic diseases are preventable, noting that 60–70% of primary care visits in developed countries are for preventable conditions [2].

According to the World Health Organization (WHO), "Noncommunicable diseases (NCDs), also known as chronic diseases, are not passed from person to person. They are of long duration and generally slow progression. The four main types of noncommunicable diseases are cardiovascular diseases (like heart attacks and stroke), cancers, chronic respiratory diseases (such as chronic obstructive pulmonary disease and asthma) and diabetes." [3]

There has been a significant shift to noncommunicable diseases, as noted in the 2010 Global Burden of Disease (GBD) estimates. Years lived with disability (YLD) as a result of communicable, maternal, neonatal, and nutrition-related diseases decreased by 19.5% between 1990 and 2010, while YLD due to chronic disease increased: cardiovascular diseases by 17.7%; chronic respiratory disease by 8.5%; neurological conditions by 12.2%; diabetes by 30.0%; and mental and behavioral illnesses by 5.0% [4].

33.2 Underlying Origins of Chronic Disease

Causes of chronic disease can be loosely categorized into primary, secondary, and tertiary management groupings characterized by the level of control one has over them. With primary causes, there is little control as they have occurred either transgenerationally or within the womb. Secondary causes are those that there is some control over during one's lifetime such as diet, smoking, or exercise. The tertiary category focuses on preventing or managing the chronic disease based on what is known about the individual by identifying such risk markers as low serum vitamin D levels, chronic inflammatory markers, a low nutrient-dense diet, high intake of trans fats, and genomic risk (e.g., celiac disease) and addressing post-diagnosis complications of these conditions.

33.3 Primary Origins

33.3.1 Genetic

A person's genes are one factor in determining whether chronic illness develops early in life, in later years, or if at all. Genetic predisposition to a chronic disease involves the presence of one or more gene mutations and or combination of alleles. The presence of gene mutations or alleles may not be abnormal, but environmental influences and multiple interactions may determine disease occurrence. The risk of developing chronic disease is influenced by genetics and exposures to gene-altering conditions and interactions with these exposures. Whether our inherited genomes are the primary causes of chronic diseases or just part of the equation is still being investigated. A study of monozygotic twins from Western European countries was used to estimate population attributable factors of 28 chronic diseases. Of 1.53 million deaths in 2000, 0.25% was attributable to genetics plus shared exposures. Genetic population attributable factors ranged from 3.4% for leukemia to 48.6% for asthma. Cancers had the lowest population attributable factors (median, 8.26%), while neurological (median, 26.1%) and lung (median, 33.6%) diseases had the highest population attributable factors [5].

The increasing incidence of obesity is a public health concern that has far-reaching consequences. It is associated with the development of several of the chronic diseases that are impacting health and healthcare globally. Genetic links to obesity have been identified and, combined with sensitivity to environmental cues, may provide at least one explanation for how genetic risk for obesity may promote unhealthy eating behaviors. Using well-known obesity gene FTO rs9939609 SNP in a sample of 78 children, ages 9–12 years, Rapuano et al. observed that children at risk for obesity exhibited a stronger response to food commercials than children not at risk. These results suggest that children who are genetically at risk for obesity respond to reward signals stronger than those not at risk, which in turn may lead to lifelong unhealthy eating behaviors [6]. In addition, this polymorphism has been related to increased BMI and obesity throughout life, as well as type 2 diabetes, and influences food intake and food choice but not energy expenditure [7].

33.3.2 Epigenetic

Recognition of the origins of chronic disease during early periods of development may provide the key to understanding, preventing, and treating chronic diseases in the future. It is now well understood that early life events play a major role in the development of chronic disease later on. The four critical periods for the development of obesity may very well be the same for other chronic, non-obesity-related disease. These periods of development are prenatal, early childhood, adolescence, and pregnancy [8].

The social determinant of health, defined as any nonmedical factor directly influencing health, including values, attitudes, knowledge and behaviors, family, neighborhood, and social network, has recently attracted interest among researchers. Social disadvantage is compellingly related to health throughout life [9]. Environmental factors, including diet, nurturing, and socioeconomic status, are closely linked to one's genetic code and have the propensity to leave biochemical marks on the genome. Factors such as physical and geographic characteristics of neighborhoods including food deserts, air quality, lead paint exposure, racial disparity, or

inequality influence health, including neuroendocrine, developmental, immunologic, and vascular pathways. Information can provide an adaptive advantage or a disadvantage to offspring depending on timing and duration of the interaction between the individual and his or her environment. Early childhood social disadvantage has been shown to have an impact on later child and adult health, socioeconomic well-being, and cognitive ability. Under the right circumstances, as listed above, as well as maternal behavior, environmental signals may result in patterns of epigenetic marks in offspring that reflect those of the parent. Evidence supports the direct impact of early life experiences on epigenetic patterns in specific loci on the genome. Negative early life experiences have been linked to differences in epigenetic patterns for genes related to drug addiction, mental health, and obesity [10].

Telomeres, the crucial part of the human cell that influences aging, have also been shown to be associated with environmental and social stress. Although telomere shortening may be related to normal aging, accelerated telomere shortening has been linked to a number of acquired disease processes, including inflammation-connected cancers and coronary artery disease. Some research has proposed that stress increases the oxidative burden on the cell, damaging and reducing telomere length [11].

33.3.3 Preconception and Intrauterine

The intrauterine period appears to be one of the most sensitive times for formation of epigenetic variability influencing development and risk for a range of diseases that can develop later in life [12]. Obesity, cardiovascular disease, type 2 diabetes, stroke, metabolic syndrome, and osteoporosis later in life all appear to be related to in utero influences that result from small size and thinness at birth. Studies reviewed by Barker demonstrated that retarded growth in utero and infancy is strongly related to cardiovascular disease mortality and some of its known risk factors, proposing three explanations for the findings:

1. Birth weight is merely a marker for adverse environmental influences that appear later in life.
2. Genetic influences early in life shown as growth failure later appear as degenerative diseases, implying that genes related to low birth weight are related to adult-onset degenerative diseases.
3. Most likely, the relationship between early retarded growth and adult disease is due to long-term effects on physiology and metabolism caused by an unfavorable environment during critical periods of development [13].

The well-known Dutch Winter Famine study further revealed the long-term health outcomes of approximately 40,000 children born to mothers with gestational famine during pregnancy as a result of Nazi blockage of food supply lines during World War II. Early gestation appeared to be the most vulnerable time for developing fetuses. Those conceived during this period were found to be at higher risk for impaired glucose tolerance, obesity, schizophrenia, and depression and had an increased atherogenic lipid profile that was more than twice normal. They were more responsive to stress and were at double the rate for coronary heart disease and performed worse on cognitive tests. In addition, changes in reproductive function including earlier menopause, breast cancer, and changes in insulin-like growth factor were observed [14–16].

33.3.4 Early Life Experiences

Childhood abuse and neglect as well as maternal nurturing have been shown to have an adverse effect on adult cognition and development of psychiatric disorders. Through rodent studies, researchers have been able to demonstrate that rats who were neglected in early postnatal periods exhibited methylation of the brain-derived neurotrophic factor gene (BDNF) throughout the lifespan. As they grow up, these rodents mistreat their own offspring, and these offspring also have significant DNA methylation [17].

As far as other chronic illnesses, most data come from studies of prenatal famine during the Dutch Winter Famine. Although not as widely studied, famine postnatally is also associated with a higher incidence of coronary heart disease in women and their offspring. Children small at birth exhibited higher levels of adipose tissue as compared to lean tissue, and they exhibited more insulin resistance. Small size at birth, low weight gain during infancy, and a rapid increase in body weight/BMI during childhood are associated with metabolic syndrome, hypertension, and coronary heart disease in adulthood [18].

A recent study that looked at the children of 5034 mothers in New York State who delivered between 2008 and 2010 assessed five developmental domains (fine motor, gross motor, communication, personal-social functioning, and problem-solving ability). The study of maternal and paternal obesity, believed to be the first of its kind, established the relationship between maternal obesity and delays in fine motor development, while paternal obesity associated with delays in personal-social development. The results regarding child development were not the only facts of interest in this study, as maternal obesity was also related to paternal obesity and lower socioeconomic status. Additionally, obesity was associated with an increased likelihood of smoking, being diagnosed with gestational diabetes or hypertension, and lower likelihood of alcohol intake, multivitamin use, and fish oil supplementation during pregnancy [19].

33.4 Secondary Origins

33.4.1 Stress

Stress affects people of all ages. Life is full of stress, and it is known to have both positive and negative effects on health. When stress helps the body overcome lethargy or enhance performance, it can be positive. Short-term stress can boost the immune system, but long-term, chronic stress resulting in

fatigue or inability to cope is a promoter of chronic disease and early aging. Environmental (experiential), psychological (emotional), and biological (physiological) stress can have different results on and between individuals. Chronic stress is inflammatory due to injury or infection, poor diet, quality of life including socioeconomic factors, smoking, and emotions. Increased stress can result in oxidative stress that depletes nutrient stores or increases nutrient requirements as a result of damage to the body from disease or injury. Emotional stress is a major contributing factor to six of the leading causes of death in the United States: cancer, coronary heart disease, accidental death, cirrhosis of the liver, respiratory diseases, and suicide. Chronic stress has an immunosuppressive effect that interferes with the body's ability to elicit a prompt and effective immune response. Longer exposure to stress also makes it less likely that the body can shift from adaptive response (as in fight-or-flight response) and shifts to detrimental changes at the cellular level and then broader immune system function [20].

33.4.2 Smoking

It is widely accepted that smoking is a leading cause of morbidity and mortality, not only in the United States but worldwide. Tobacco use is a modifiable risk factor for numerous chronic diseases including cancer, cardiovascular disease, diabetes, inflammatory disease, and pulmonary-related illnesses. A study conducted by Campos et al., in Brazil, found that one in ten persons with chronic disease smoked, lightly but daily, and also lived with someone who smoked. Most patients had either hypertension, diabetes, or chronic kidney disease, all comorbid conditions that are negatively impacted by cigarette smoke [21].

Smoking is considered a risk factor for chronic obstructive pulmonary disease (COPD), although not all smokers develop the disease. Use of tobacco products in persons with reflux disease is contraindicated due to its lower esophageal sphincter pressure lowering effect and decreased salivation. Additionally, smoking increases the risk of esophageal and lung cancer. Cigarette smoking also exerts a toxic effect on osteoblasts, increasing the risk for and incidence of osteoporosis [22].

There is no risk-free level of exposure to smoke. Secondhand smoke, as well as smoking itself, no matter how much, leads to rapid and sharp increase in endothelial dysfunction by injuring epithelium, impairing epithelial vasodilation, and triggering inflammation. Powerfully addictive, cigarette smoking or low-level exposure via secondhand smoke leads to inhalation of toxic chemicals burned during combustion, resulting in DNA damage, inflammation, and oxidative stress. Smoking or exposure to smoke during reproductive years can affect fertility and conception and impact fetal and child development. Tobacco smoke exposure is associated with chromosomal damage or DNA damage resulting in reduced sperm quality, possibly leading to birth defects or early fetal demise. Smoking may also be related to inflammation in the mother as well as decreased nutrient absorption, decreased nutrient uptake, and reduced levels of necessary embryonic tissue nutrients, such as multivitamins and folate. In addition, evidence is consistent that carbon monoxide from smoking leads to lower birth weights and may be linked to cognitive and neurobehavioral deficits in the infant/child.

Residual nicotine and other chemicals left from smoking, known as thirdhand smoke, can react with indoor pollutants to create a toxic mix of cancer-causing compounds. These compounds pose risk to non-smokers and young children. A relatively new concept, the residuals from thirdhand smoke, cannot be removed easily from fabrics and surfaces or from airing out a room or restricting smoking to one location. Inhaling, touching, or swallowing items exposed to thirdhand smoke may place non-smokers and children at risk of smoking-related diseases. This can be especially problematic for infants and young children who have a tendency to put things in their mouths. [22, 23]

33.4.3 Alcohol

According to the Centers for Disease Control and Prevention, alcohol is responsible for 88,000 deaths in the United States each year and is identified as single condition for 25 diseases and chronic conditions in the *International Classification of Disease* (ICD)-10 manual. Alcohol has been a part of human culture since history was first recorded. It has been noted to have both beneficial and detrimental effects on health, depending on the amount consumed. However, long-term excessive intake has been linked to tumors, neuropsychiatric conditions, and many cardiovascular and digestive diseases, while short-term health risks include violence, injury, risky sexual behavior, and risk of miscarriage or preterm birth. Excessive alcohol consumption has been identified as responsible for 1 in 10 deaths among working age adults ages 20–64 in 2010 and involves binge drinking (for women, 4 or more drinks during a single occasion and 5 for men), heavy drinking (8 or more drinks per week for women and 15 or more for men), and any drinking by pregnant women or people younger than age 21 [24–27].

Some people use alcohol to reduce stress or believe it is a mood elevator. Social influences and norms can also prompt a person to drink, and, in some instances, too much. Low levels of parental involvement and support have been shown to increase the likelihood of adolescent alcohol use and other problem behaviors, including smoking. A family history of alcoholism has been noted in the development of alcoholism, and studies have clearly demonstrated that alcoholism is a genetically complex disease, influenced by multiple genes interacting with each other and with environmental factors to cause disease [24–27].

33.4.4 Sleep

Insufficient sleep alters the endocrine regulation of hunger, appetite, and energy expenditure. In the short term, lack of sleep inhibits leptin production, suggesting a potential mech-

anism for the early development of obesity related to increased fat mass [27, 28]. Sleep deprivation, shift work, and exposure to bright light at night can have an impact on the body's circadian rhythm and increase the probability of developing obesity. A prospective cohort study of 8234 children aged 7 years and a subsample of 909 children (children in focus) with data on additional early growth-related risk factors for obesity in Great Britain revealed a relationship between lack of sleep and obesity. Amount of sleep in children at 30 months of age was independently correlated with obesity at 7 years of age. Those children with the lowest amount of sleep (<10.5 hours and 10.5–10.9 hours) before age 7 were more likely to be obese than those recording 12 hours of sleep or more [29].

Obesity, in and of itself, is a risk factor for developing sleep apnea, which can further exacerbate chronic illness. The presence of sleep apnea in obese individuals is estimated to be up to 45% of subjects observed. A review of six large studies conducted worldwide suggests that 25% of individuals with a BMI between 25 kg/m^2 and 28 kg/m^2 have at least some mild sleep apnea. Independent of obesity, several cardiometabolic abnormalities have been identified in persons with sleep apnea, including glucose intolerance and insulin resistance, both of which are precursors to diabetes and cardiovascular disease. In addition, persons with obstructive sleep apnea, have exhibited a heightend systemic inflammatory state as indicated by increased cytokines, serum amyloid- A production and in some, elevations in C-reactive protein [28].

33.4.5 Social Determinants

The Commission on Social Determinants of Health defines social determinants of health as economic and social conditions that influence the health of people and communities. Money, power, and resources that people have, which are often influenced by policy choices, form these environments [30]. The factors determining the social determinants of health are related to health outcomes and include:

- Early childhood development
- Education level
- Employment and retaining a job
- Type of work a person does
- Food security
- Access to healthcare and quality of service
- Housing, including neighborhood quality and safety
- How much money a person earns
- Discrimination and social support (CDC, Social Determinants of Health)

They are the conditions in which individuals are born, grow, live, work, and age. Notterman (2015) refers to the social determinants of health as any nonmedical factor directly influencing health, such as values, attitudes, knowledge, and behavior [10]. Family, neighborhood, and social network context are external sources of influence. Social disadvantage, risk exposure, and social inequalities are recognized as having causal roles impacting health across the lifespan [9].

Bharmal et al. have proposed main categories of upstream factors that provide a better understanding of how these macro factors lead to poor health and inequities. Greater social disadvantage appears to be dose-responsive and is associated with poorer health. This social disadvantage approach is similar to, but elaborates on, those defined by the Commission on Social Determinants of Health:

1. Neighborhood conditions that can influence health through physical conditions such as air, playgrounds, and safety.
2. Working conditions with the ability to influence physical, social, and psychosocial aspects of health from injury, sedentariness, obesity and obesity-related chronic diseases, ventilation and air quality, imbalance of work efforts and rewards, and support among and of co-workers.
3. Education, which has been linked to increased knowledge, resulting in better health and healthy behaviors. It shapes employment opportunities that determine economic resources influencing health, and it influences health through psychological and social factors with a perception of greater control, higher social status, and increased social support.
4. Attainment of income and wealth while income inequality is linked with poor health due to social erosion and lack of social cohesion.
5. Ethnicity and racism affects individual opportunities based on race or ethnicity and perpetuates social disadvantage in segregated neighborhoods, unsafe housing, and low quality/poor educational opportunities.
6. Stress, as described above, may also be a causal factor of chronic disease through accumulated injury from stressful socioeconomic and environmental situations that trigger the release of cortisol, cytokines, and other substances that can damage the immune system, vital organs, and physiological systems that lead to more rapid onset – or progression to – chronic diseases, such as cardiovascular disease [9].

In addition to the social disadvantage theory, Bharmal also describes a life course approach to health that explores three life periods that are vulnerable to the effects of the risk and duration of exposure to social determinants of health.

1. Adverse health effects of early childhood experiences that are related to social disadvantage that affect children's cognitive, behavioral, and physical development, in turn affecting lifelong health.
2. Intergenerational transfer of advantage has been studied over at least two decades. Children of socially disadvantaged parents have limited educational choices and are less healthy, which translates into decreased advantage for good health and social advantage as adults. Research on gene and environment interactions proposes that intergenerational transmission of social advantage may be partly explained by changes in gene expression that are passed on to future generations.

3. In animal studies, a potential causal link of epigenetics suggests that social status can regulate the expression of genes that control the immune system. Perceived stress, occupational status, educational achievement, work schedules, and intimate partner violence have been linked with telomere shortening, resulting in cellular aging [9].

33.4.6 Physical Activity

Lifestyle shifts, including changes in access to healthcare, migration from more rural to urban areas, transportation accessibility, frequent job changes, access to more electronic devices including television, concern regarding safety in communities, and chronic disease are becoming more prominent in younger individuals, leaving them encumbered with poor health for the rest of their lives. These shifts have resulted in the prevalence of physical inactivity, a change that has been identified as being partly responsible for the earlier onset of chronic disease. People are less physically active today than they have been in past generations, with the number of daily steps taken approximately 50–70% less since industrialization and the introduction of powered machinery [31].

A sedentary lifestyle over years can lead to primary decrease in functionality, obesity, cardiovascular disease, type 2 diabetes, and premature death. Furthermore, individuals with a chronic disease are more likely to become less physically active, if they were not already, which leads to deconditioning and further decreases in the ability to perform physical activity. If this cycle is not halted, the likelihood for suboptimal quality of life and long-term poor health increases significantly.

In order for people to enjoy health benefits, WHO recommends they get at least 600 MET minutes (the physiological measure expressing the energy cost of physical activities) of total activity a week. Moderate-intensity activity such as brisk walking 150 minutes/week or 75 minutes of vigorous physical activity such as running meets these guidelines. A review of literature citing the association between physical activity and the risk of breast cancer, colon cancer, diabetes, ischemic heart disease, and ischemic stroke was completed by Kyu et al., in order to quantify the dose-response association between disease risk and physical activity. They concluded that people who achieved total physical activity levels several times the WHO recommendations experienced a significant reduction in the risk of the five diseases. Most health gains were observed at levels of 3000–4000 MET minutes/week [32].

With the exception of genetic causes, cardiovascular disease is highly correlated to physical inactivity. Daily physical activity reduces the risk of cardiovascular disease, and it improves functional capacity. Diabetes affects more than 24 million Americans, with another 60% having prediabetes and at greater risk for developing type 2 diabetes. An increase in physical inactivity has been linked to the rising rates of type 2 diabetes with increased blood lipids, blood pressure, and glucose intolerance. Obesity, linked to many chronic diseases including heart disease, diabetes, osteoarthritis, and cancer, is directly linked to physical inactivity. When excess energy (calories) is consumed and not expended, the surplus is stored as adipose tissue. Daily physical activity aids in weight loss, balancing the intake output equation, and in improvements of functional capacity. Physical inactivity has also been associated with certain types of cancer, while epidemiological studies show that increased physical activity is associated with a decreased risk of breast, colon, and prostate cancers [33].

33.4.7 Dietary Patterns

Changes in the way people eat and live are increasingly impacting the health and development of chronic disease. Diet-related chronic diseases have increased as the American diet and lifestyle has changed. A nutritional transition is occurring, whereby traditional diets are being replaced by diets higher in processed foods, animal fats, and sugar. Rising incomes have increased the demand for, and prestige of, large amounts of animal proteins, as well as generous sized meals. This transition, combined with physical inactivity, is increasing the burden of chronic disease by promoting overconsumption and underexercising (see ▶ Chap. 2).

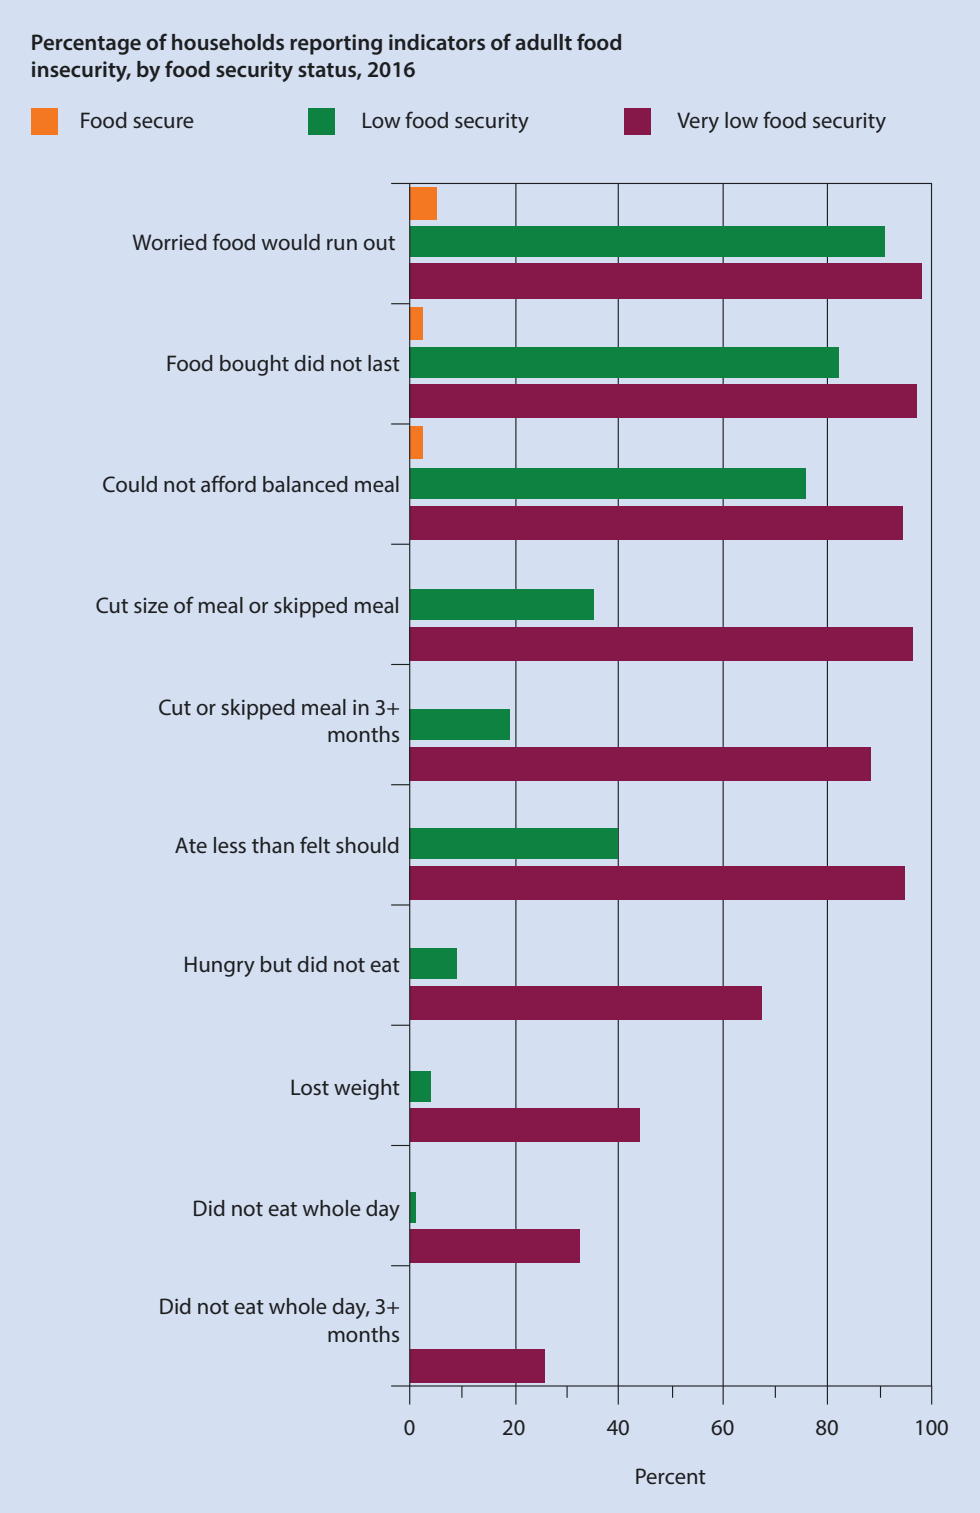
The standard American diet (SAD) is one high in processed foods, fat, sugar, and animal products and is consumed by a majority of the population. It contains a low amount of fruit and vegetables, which is linked to a lower intake of nutrient-dense foods that contain phytonutrients, antioxidants, fiber, and other health-conferring properties. This shift in diet began after World War II and rapidly escalated with convenience foods, fast foods, and sugar-containing beverages, being the norm for families who once relied on a stay-at-home mom to prepare meals. Now working mothers with limited time and a hungry family find they must rely on options that are quick and filling.

A traditional diet, once the "norm," is one centered on plant-based foods with small amounts of animal proteins, with sweets and desserts reserved for special occasions. These plant-based foods maximize nutrients, while the SAD diet minimizes them. Traditional diets are also inspired by rich cultural and historical cuisines around the globe. Unfortunately, many of the healthier traditional diets are now threatened by exposure to Western-style foods with fast food and convenience foods permeating all corners of the globe. Eating a traditional diet can bestow benefits that are health-promoting. These diets include the diet popular in healthcare – the Mediterranean diet with its emphasis on plant-based foods, legumes, healthy fats, low fat dairy, eggs and poultry in small amounts, fish as the predominant source of protein, and red meat and sweets once a week or less. Other less well-known or practiced traditional diets include the African Heritage diet, Latin American diet, Asian diet, and more widely seen and accepted vegetarian and vegan diets. Of course, the foods and the preparation techniques of these diets can and have been changed to meet the American taste, but if eaten as intended, they can and will confer health benefits on the consumer.

33.5 Patterns Difficult to Control on an Individual Basis

33.5.1 Food Insecurity

According to the United States Department of Agriculture (USDA), "Food security means access by all people at all times to enough food for and active, healthy lifestyle." Food insecurity, on the other hand, is defined "as a lack of consistent access to enough food for an active and healthy life and or a household-level economic and social condition of limited or uncertain access to adequate food." It is further defined as low or very low food security (Fig. 33.1). Both low and very low food security households with children reported similar patterns of lack of food or uncertain access to it. According to the USDA, "The defining characteristic of



Percentage of households reporting indicators of adullt food insecurity, by food security status, 2016
Food secure
Low food security
Very low food security
Worried food would run out
Food bought did not last
Could not afford balanced meal
Cut size of meal or skipped meal
Cut or skipped meal in 3+ months
Ate less than felt should
Hungry but did not eat
Lost weight
Did not eat whole day
Did not eat whole day, 3+ months

Percent

Fig. 33.1 Percentage of households reporting indicators of adult food insecurity, by food security status, 2016. (Source: USDA, Economic Research Service, using data from the December 2016 Current Population Survey Food Security Supplement)

very low food security is that, at times during the year, the food intake of household members is reduced and their normal eating patterns are disrupted because the household lacks money and other resources for food [34]."

In 2015, some 42.2 million Americans lived in 15.8 million food-insecure households, with about 6.3 million of these people experiencing very low food security. Households with children reported food insecurity at a significantly higher rate than those without children and especially so in households headed by single mothers [35]. Data from several studies have demonstrated that food insufficiency is associated with poor dietary intake, inadequate micronutrient intake, and poor diet quality. Over time, these factors can contribute to the development of chronic disease including osteoporosis, sarcopenia, and anemia. Analysis of data from the National Health and Nutrition Examination Survey (NHANES) showed that of the 15,199 persons, approximately 1256 reported some level of food insecurity and experienced 1 of 3 chronic diseases – diabetes, hypertension, or chronic kidney disease. In the review of this data, food-insecure individuals were more likely to have diabetes [36]. Food-insecure adults with diabetes were observed to have poorer glycemic control than food-secure individuals. They also have a higher prevalence of metabolic syndrome and have diets of lower quality that contribute to risk of cardiometabolic disease. In addition, food insecurity was associated with several individual chronic disease risk factors including smoking, higher concentrations of HgBA1c, higher levels of C-reactive protein, and greater incidence of obesity among women. It has been suggested that financially strapped families may purchase cheap energy-dense foods that are high in calories and highly processed [37].

33.5.2 Environmental Toxins

The environmentally based contributors to chronic disease risk are, although poorly understood, known to have a cumulative and dose-responsive effect. Most Americans have detectable levels of an extensive assortment of environmental chemicals in their bodies, including many with known endocrine-disrupting, neurotoxic, and carcinogenic activities. In animal models, these are biologically and toxicologically relevant to the development of chronic diseases such as cardiovascular disease, diabetes, hypertension, obesity, and cancer [38].

Among environmental hazards are air pollution, including smoking and occupational exposure, polycyclic aromatic hydrocarbons, heavy metals, and bioaerosols linked to chronic disease through epigenetic processes, including gene methylation and histone modification. Although epigenetic modification and transgenerational inheritance of disease risk have been demonstrated in animals, definitive evidence for heritable environmentally induced epigenetic changes in humans is limited. However, there are epidemiologic studies that establish a relationship between maternal and grandmaternal smoking and the risk for asthma in children [4].

Endocrine-disrupting chemicals (EDC), widely present in the environment, are natural or synthetic compounds which, through environmental or inappropriate developmental exposures, alter the hormonal and homeostatic systems that enable the body to communicate with and respond to the environment. The most commonly studied EDCs are bisphenol A (BPA), phthalates, atrazine (ATR), polychlorinated biphenyls (PCB) and polybrominated diphenyl ethers, and DDT and DDE. BPA has long been used in a wide variety of manufacturing, food packaging, toys, and other uses and is produced and used in larger amounts than any other chemical. Resins of BPA are found in foods and beverages regularly consumed. Phthalates and their esters are used as liquid plasticizers and found in everyday products such as plastics, coating, cosmetics, and medical tubing. Atrazine is an herbicide used for control of broadleaf grasses and has been the major herbicide used worldwide since 1959; it and its metabolites are common groundwater contaminants. p,p'-Dichlorodiphenyltrichloroethane (DDT) is an industrial and household synthetic insecticide. It was used extensively until 1972, when it was banned due to its effects on human health and the environment.

Dichlorodiphenyldichloroethylene (DDE) and dichlorodiphenyldichloroethane (DDD) are metabolites of DDT and have been linked to endocrine-related chronic diseases including endometrial, pancreatic and breast cancer, testicular tumors, and type 2 diabetes [38].

Toxins during gestation have been associated with adverse outcomes at birth for decades. Children exposed in utero to thalidomide were born with limb deformities, while those born to alcoholic mothers experience fetal alcohol syndrome. Insufficient folate in the maternal diet may result in spina bifida. Methyl mercury exposure has resulted in Minamata disease, and diethylstilbestrol (DES)-exposed children of both sexes may have multiple reproductive disorders, certain cancers, cryptorchidism, and other diseases. Increased disease risk is now being observed in the grandchildren of DES-treated women, as well as examples of disease in those children with transgenerational exposure to BPA, PCBs, pesticides, and other environmental toxins [38].

Air pollution, either outdoor or indoor, is known to contribute to respiratory diseases, cancers, cardiovascular disease, and adverse pregnancy outcomes. Air pollutants have been categorized into four different groups: (1) gaseous pollutants such as sulfur dioxide, carbon dioxide, ozone, or volatile organic compounds; (2) persistent organic pollutants including dioxin; (3) heavy metals such as lead and mercury; and (4) particulate matter.

All kinds of air pollution can affect the respiratory system, from itchy throat and bronchoconstriction to asthma, emphysema, and lung cancer. Carbon monoxide affects the organs that consume a lot of oxygen, such as the heart and brain, resulting in impaired concentration, slow reflexes, and confusion. Particulate matter has the ability to interfere with blood coagulation and lung inflammation and can lead to myocardial infarction or angina. Dioxin has been shown to result in ischemic heart disease and adverse effects on the nervous system by decreasing nerve conduction velocity and

impaired mental development in children. Heavy metals such as lead, mercury, and arsenic have been linked to neuropathies, due to neurotoxicity, resulting in memory disturbances, sleep disorders, anger, fatigue, and other problems. Heavy metals have been associated with kidney damage and disease and dioxin with liver cell damage. During pregnancy, pollutants can lead to spontaneous abortion, reduced fetal growth, and prematurity, while lead exposure is known to lead to congenital malformations and lesions on the developing brain, interfering with infant motor and cognitive functions. Dioxins are endocrine disruptors and affect the growth and development of the fetal nervous system [39].

33.5.3 Legislative Policy and Chronic Disease

33.5.3.1 Asbestos

It is well-known that exposure to asbestos results in chronic lung disease, including lung cancer, mesothelioma, and asbestosis or fibrosis of the lung. Although its use in products is limited, its effects will be felt well into the twenty-first century. Workers who are exposed to asbestos are five times more likely to develop lung-related diseases than nonsmokers not exposed, but the disease risk rises to 50 times more likely for those who smoke. Asbestos has been seen as the principal cause of occupational cancer in the United States and a significant cause of disease and disability from noncancer-related disease. Estimates indicate that the cumulative total number of asbestos-associated deaths in the United States may exceed 200,000 by the year 2030 [40–42].

In the 1970s, some uses of asbestos were banned or otherwise regulated, and its importation from other countries was dramatically reduced in light of growing evidence concerning its connections to serious health conditions. Continued research has demonstrated the adverse effects of asbestos, and, in 2002, the United States discontinued mining it. Still, asbestos remains in use in some products today and still exists in many old buildings. As of this writing, although lawmakers have attempted to introduce legislation banning asbestos use, measures to do so have failed. Thus, there is no comprehensive law governing its use in the United States [41].

33.5.3.2 Lead

Lead has been used since the beginning of time and continues to be found in man-made and natural products, so its complete elimination is virtually impossible. The use of lead in paint, gasoline, pipes, some construction materials, and cosmetics has been banned for a number of years. However, lead from gasoline emissions and other deposits from years ago remain in the soil and will not break down or go away. Lead is still in use in lead-acid batteries, ammunition, cable coverings, piping, in the manufacturing of brass and bronze, as bearing metal in machinery, and in sheet lead. Lead compounds are used in matches, some paints and ceramics, soldering and building materials, and photography and as catalysts to help chemical reactions [40, 43].

Lead poisoning in children has brought significant attention to the topic since the 1970s. Children exposed to lead, primarily from paint chips and dust in the environment, are at greater risk due to their developing brain and rapid uptake of nutrients. Children exposed to lead often exhibit cognitive issues, including behavioral and learning problems, stunted growth, and mental retardation. Studies looking at the relationship of lead to cancer are mixed; however lead levels in adults can lead to headaches, mood swings, and problems with memory and damage peripheral nerves and kidney and reproductive function [43].

33.5.3.3 Arsenic

Arsenic exposure can occur through such occupations as mining and smelting, the burning of arsenic-rich coal, and from drinking contaminated water. Arsenic can enter the water through soil or as a result of industrial waste contamination and burning of fossil fuels, through the use of agricultural pesticides and food additives, or through natural decay of minerals in weathered rocks and soils. Arsenic in drinking water is a concern throughout the world as it can cause morbidity and mortality from a number of diseases, including skin lesions, diabetes, peripheral neuropathy, gastrointestinal symptoms, high blood pressure, and cardiovascular disease [40]. The Environmental Protection Agency (EPA) updated arsenic standards in the early 2000s after considerable delay, and while levels have declined, it remains present. The most common source of arsenic in drinking water appears to be from private water wells, although contaminants may be present in larger municipalities where the main source of drinking water is from wells [44].

33.6 Tertiary Origins

Although not an *origin* of chronic disease, tertiary is more aptly defined as the management of the chronic disease and prevention of further complications, based on what is known about the individual. This approach is central to the expanding field of lifestyle medicine, whereby the clinician uses risk factor markers to assess for and identify chronic disease. Lifestyle medicine focuses on the prevention and treatment of chronic disease caused by lifestyle factors including physical inactivity, poor diet, tobacco use, and stress and psychosocial factors. Below is a table of chronic diseases with their risk factor markers, potential origins that may help in identifying the approach appropriate for the identified chronic disease (◘ Table 33.1).

Noncommunicable, chronic diseases have surpassed communicable and infectious diseases as the cause for morbidity and mortality worldwide. More than one third of Americans have been identified as obese, and diseases related to obesity – cancer, heart disease, type 2 diabetes, and stroke – are among the leading preventable causes of morbidity and death. New approaches to identify and treat these conditions are needed to reduce the incidence of these diseases and to prevent their continued explosion. Lifestyle medicine is

Table 33.1 Chronic diseases, risk factor markers, and their potential origins

Disease	Risk factor markers	Primary origin [45]	Secondary origin
Cardiometabolic			
Obesity	Weight		Diet
Diabetes Heart disease	Glucose HgB A1c Lipids Homocysteine Blood pressure	Type 1 diabetes – HLA-DQA1, HLA-DQB1, and HLA-DRB1 genes	Smoking Stress Psychosocial Inactivity
Cancer	Obesity	BRCA1	Diet
	Diabetes	BRACA2	Chemical exposure
	Inflammation	Multiple tumor markers	Smoking
Hormonal and endocrine			
Thyroid	Hyperthyroid Hypothyroid Low vitamin D		Iodine intake Drugs Infections Chemicals
Hashimoto's thyroiditis	TSH Antithyroid antibodies Free T-4 test	HLA genes CTLA-4 gene PTPN22 gene VDR gene Cytokine genes Female Postpartum Fetal microchimerism Human leukocyte antigen (HLA) complex	Change in sex hormones Excess iodine intake Viral infections Ionizing radiation
PCOS	Thyroid function tests Prolactin Free androgen index Fasting glucose Fasting insulin Elevated blood pressure Weight Miscarriage Dysmenorrhea Hirsutism Acne	Possible multiple genes with relationship to PCOS	Stress/anxiety Low socioeconomic status
Adrenal (Cushing disease)	Weight Blood pressure Moon face Cortisol levels	Does not have a clear pattern of inheritance Somatic genetic mutations	Prolonged stress and/or depression
Autoimmune			
Allergies and intolerances	Physical measures – NFPA IgE IgG	Ethnicity Genetic factors are yet unknown	Environmental smoke Diet/nutrition Sleep Air pollution
Celiac disease	Type 1 diabetes Weight loss Skin rash	Variants of the HLA-DQA1 and HLA-DQB1 genes Possibly changes in other genes	Diet
Rheumatoid arthritis	Red, swollen, warm joints Anemia	HLA complex Various genes Sex Age Family history	Smoking Obesity Environmental pollutants Viral/bacterial infections

Table 33.1 (continued)

Disease	Risk factor markers	Primary origin [45]	Secondary origin
Systemic lupus erythematosus	Joint pain Fatigue Weight loss	Immune function-related genes	Drugs Viral infections Diet Stress Chemical exposures Sunlight
Gastrointestinal			
Inflammatory bowel disease/ulcerative colitis	Weight (loss) GI function	Variations in various genes related to protective function of intestine	Abnormal immune response to bacteria and toxins
Crohn's disease	Weight (loss) Anemia	Variations in the ATG16L1, IRGM, and NOD2 genes IL23R gene Variations in certain regions of chromosome 5 and chromosome 10	Cigarette smoking
Gastroesophageal reflux (GERD) Barrett's esophagus	Weight (obesity) Non-cardiac chest pain Dental erosion Hiatal hernia	Polygenic basis overlapping with Barrett's esophagus, but incompletely understood [46]	Alcohol Large meals Viral infections COPD
Ulcers	Weight (loss) Appetite loss	Many individuals with peptic ulcers have close relatives with ulcers, suggesting that genetic factors may be involved but has yet to be fully elucidated	*H. pylori* infection Gastritis Aspirin use Stress/severe illness Tobacco use Alcohol Stress
Developmental			
Attention deficit hyperactivity disorder (ADHD)/ attention deficit disorder (ADD)	Behavioral problems	Research suggests there may be a genetic component as it appears to run in families	Exposure to lead Smoking and alcohol use during pregnancy
Autism spectrum disorder	Impaired social interaction Poor communication skills Repetitive behavior	It is believed that 50% of the risk of ASD is due to genetic variation, but exact genes are yet positively identified [47]	Drugs taken during pregnancy Environmental toxins Alcohol
Neurological			
Parkinson's disease	Tremor Weight (loss)	Mutations in LRRK2, PARK2, PARK7, PINK1, or SNCA genes. Effect of changes not fully understood	Free radical production
Alzheimer's disease	Memory loss Weight (loss) Malnutrition	Gene mutation passed from parent to child – APP, PSEN1, or PSEN2 genes	Poor diet (lack of folic acid, phytonutrients, naturally occurring nitrates, b vitamins) in middle age
Amyotrophic lateral sclerosis (ALS)	Dysphagia Muscle weakness, twitching, and cramping	Mutations in the C9orf72, SOD1, TARDBP, and FUS genes	Secondary origins do not appear to affect the development of ALS
Multiple sclerosis (MS)	Muscle weakness Tremors Difficulty walking Vision difficulties	Variations in numerous genes are thought to cause MS – HLA-DRB1, IL7R	Vitamin D intake Smoking Exposure to Epstein-Barr virus
Muscular dystrophies (Duchenne and Becker)	Progressive muscle weakness Muscle wasting	Mutations in the DMD X-linked recessive pattern carried by the mother	Secondary origins do not appear to affect the development of muscular dystrophies

becoming the recommended approach to preventing and treating chronic disease. This approach considers lifestyle intervention including physical activity, nutrition, stress reduction, and avoidance of excess alcohol and smoking as the preferred interventions. Although a challenge, given the current state of health worldwide, this approach, rather than a curative approach, is the one with the most ability to impact health over the long term.

34.1 Introduction

Chronobiology is the study of how biological clocks control and regulate virtually every function of life. Most living organisms, including humans, have an endogenous biological clock that operates on a near 24-hour cycle, in concert with Earth's daily rotation and the lunar cycles. This is called the circadian rhythm (from the Latin "circa diem," which means "approximately a day"). This intrinsic clock regulates a wide variety of functions, including sleep, arousal, feeding, and a myriad of metabolic processes. Indeed, it appears that nearly all biological mechanisms are regulated by the circadian clock system, including blood pressure, body temperature, cell division, immune function, digestion, and hormone secretion [1].

In humans, the master biological clock is located in the suprachiasmatic nucleus (SCN) within the anterior hypothalamus of the brain. The SCN receives photic input from the retina each day, which serves to reset the clock. The master clock then coordinates the peripheral clocks which are present in nearly all cells of the body, by way of a common set of clock genes that work in various negative feedback loops to create the circadian oscillations that regulate metabolism [1–3]. Functional genomics have established that these circadian clocks govern a large portion of the human genome.

Though circadian rhythms are endogenous in nature and regulated by the clock genes, they can be entrained or adjusted by zeitgebers (from the German, "time giver"), which are external cues from the environment. Zeitgebers include light, temperature, redox cycles, diet, exercise, and social contacts [4, 5]. Disruptions in the circadian coordination, whether environmental or genetic, can cause metabolic imbalances, leading to sleep issues, which may eventually affect the nervous, endocrine, cardiovascular, and immune systems. This can result in dyslipidemia, obesity, hypertension, inflammation, and mental health disorders [6]. Growing evidence also shows support for the idea that circadian disruption from shift work, chronic jet lag, or artificial light exposure at night may be risk factors for the development of cancer [7–9].

Circadian rhythm sleep disorders (CRSDs) or circadian sleep disorders are clinically diagnosed disorders that arise from abnormalities in the length, timing, or alignment to the day-night cycle. These include delayed sleep phase syndrome (DSPS), advanced sleep phase syndrome (ASPS), non-24-hour sleep-wake disorder (Non-24), irregular sleep-wake disorder (ISWD), shift work disorder, and jet lag disorder [10].

The gold-standard measures of circadian rhythm in humans have been core body temperature and salivary or plasma melatonin levels [4]. The SCN regulates the secretion of the hormone melatonin (N-acetyl-5-methoxytryptamine) by the pineal gland in response to the environmental light-dark cycle, inducing sleep. Abnormal oscillations in melatonin secretion can affect sleep patterns [11]. Bright light exposure and melatonin therapy have been shown to be effective treatments for circadian rhythm sleep disorders [12, 13].

The circadian rhythm is tightly connected to energy homeostasis and is affected by the timing of meals, as well as food composition and components. The clocks control energy metabolism, and the metabolic states, in return, can influence the circadian clocks. In many countries where meal timing and sleep habits are not in tune with the natural circadian rhythm, metabolic disease can arise [14]. The principles of chrononutrition, which studies the relationship between the circadian system and metabolism, have been shown to improve human weight loss and will likely benefit people who suffer from metabolic disease, as well as the general public [15].

34.2 Background of Scientific Relevance to Metabolism and Nutrition Status

As the saying goes, "You are what you eat," however, research indicates that we may need to add a companion axiom that states, "You are *when* you eat," as well. Food has been shown to be a strong driver of circadian rhythms, and a disruption in metabolism can occur if food consumption is not in phase with the light-dark cycle [5]. The term "chrononutrition" refers to the timing of food ingestion in coordination with the daily circadian rhythm. Time-specific food intake has been shown to have distinct consequences on physiology, and the circadian clock system provides a critical connection between nutrition and an organism's homeostasis [16]. Meal timing can affect the sleep-wake cycle, core body temperature, performance, alertness, and hormone levels, and it appears to be connected to obesity and metabolic pathologies [16].

In addition to the timing, the type and quality of macronutrients and micronutrients have the capability of functioning as zeitgebers by modulating clock proteins or nuclear receptors. The use of targeted nutrients based on SNPs (single nucleotide polymorphisms) in human clock genes, as well as a person's specific chronotype, has the potential for clinical utilization [5]. Nutrients can either disrupt or restore the synchronization between the peripheral clocks and the suprachiasmatic nucleus (SCN), also known as the central pacemaker in the brain.

The SCN is a network of neurons. It is a wing-shaped structure located within the hypothalamus gland that sits directly above the optic chiasm. This neural network consists of thousands of neurons, and it sends out signals that keep the rest of the body on a near 24-hour schedule.

The role of the microbiome is being explored for its role in circadian rhythm. A large portion of the body's microbiota is located in the gastrointestinal tract, a site that has been shown to have a powerful circadian clock. The microbiota participates in the daily cycles of digestion, and changes in its levels and composition can have an impact on the system-wide cyclic homeostasis of the body [16]. An appreciation of the circadian system has many implications for nutritional science and may ultimately help reduce the burden of chronic disease [17].

34.3 Central and Peripheral Circadian Clocks

Even without external cues from the environment, humans maintain a sleep-wake rhythm that is very close to 24 hours. In mammals, the central circadian clock that regulates this rhythm is the SCN. This master pacemaker regulates rhythms such as the sleep-wake cycle, the autonomic nervous system, body temperature, gene expression, and hormone secretion, including melatonin [17]. There is also evidence that the cell cycle is regulated via the day-night cycle, and numerous studies have shown that cell division is governed by a circadian variation in mammalian tissues, including the epithelia of the tongue, skin, oral mucosa, intestine, esophagus, stomach, duodenum, jejunum, rectum, as well as the bone marrow, and pancreas [3].

However, without time cues, the internal clock's period is actually about 24.2 hours, so it must be reset or entrained every day to the 24-hour day, to keep the organism in sync with the external world [17]. The SCN is entrained by light cues that enter the retina. The retina transfers information about light and darkness to the SCN, which then synchronizes a phase of rhythms with the external environment. This is orchestrated through a monosynaptic pathway from photosensitive cells in the retina that take photic input to the SCN. Then, by way of a multisynaptic pathway, information is transferred from the SCN to the pineal gland. The pineal gland synthesizes melatonin, a neurotransmitter-like substance that regulates circadian rhythms and sleeping patterns.

The central circadian clock also sends signals to peripheral clocks throughout the body. The peripheral clocks, or local clocks, are found in every cell, tissue, and organ [2, 3]. While the central clock is entrained by light, the peripheral clocks are entrained by feeding cues and dominate local metabolic rhythms including glucose, lipid homeostasis, and hormonal secretion. Nutrients and meal timing can affect the clock system. Thus, a current view for the adaptive significance of circadian clocks is their basic role in coordinating metabolism [18] (Fig. 34.1).

The master circadian clock is located in the suprachiasmatic nucleus (SCN) in the hypothalamus. This master clock is entrained to the 24-hour day cycle by light which enters the retina, and it dominates activity rhythms. The central circadian clock sends signals to peripheral clocks located in cells throughout the body. The peripheral clocks are entrained by feeding cues that dominate local metabolic rhythms. Both nutrients and meal timing can affect the clock system. Chrononutrition has two facets: (1) nutrients and substances, for example, caffeine, can alter the periodicity of the clock, and high-fat diets can affect the rhythm of lipogenesis, circulating lipids, and feeding behavior and (2) meal-timing can affect the clock system, for example, skipping breakfast or nocturnal eating can increase the risk of obesity, whereas regular or time-restricted eating can synchronize the clock system and offset metabolic disorders.

Synchronicity between the central and peripheral clocks appears to be important for metabolic health. It is shown that workers on the night shift or a rotating schedule have a greater risk for type 2 diabetes, obesity, and cardiovascular disease. If the light-entrainable pacemaker of the SCN is out of sync with the food-entrainable oscillators of the peripheral tissues, then there may be a disruption in the energy balance [5].

34.4 Circadian Rhythm and Disruption of the Sleep-Wake Cycle

Identifying circadian rhythm sleep disorders or functional versions of these disorders can be an important part of nutritional management. Medical care often overlooks functional sleep disorders and is not well-equipped to support sleep disorders non-pharmacologically.

Initial assessment can identify clues to the functional or pathologic state. Either on intake documents or initial interview, questions regarding diurnal preference (is the client a "night owl" or "morning lark"?) and whether or not they nap may be important regardless of the presenting complaint or health goal. Excessive daytime sleepiness and sleep deprivation are two common complaints in nutrition practice. Not only do these result in metabolic consequences but also poor decision-making as it pertains to healthy choices.

34.5 Types of Circadian Rhythm Sleep Disorders (CRSDs)

As a practical note when speaking about circadian rhythm, the term *delayed* is used to mean a later-than-usual onset of sleep. If normal onset of sleep is 10 p.m., then a delayed onset may mean an 11 p.m. or later sleep onset. The term *advanced* suggests the opposite and is used to mean an earlier-than-usual onset of sleep. This is important when evaluating therapeutics and methods that shift the circadian pattern and is relevant in CRSD nomenclature.

Delayed Sleep Phase Syndrome (DSPS) is thought to be the most common and similarly most understood CRSD. Typically, the delay is 3–6 hours. These clients are often awake until 2–6 a.m. and wake up between 10 a.m. and 1 p.m. or at least would if allowed. When a conventional wake time in those with DSPS is enforced, they often suffer from sleep deprivation [19]. Prevalence of DSPS in those with chronic insomnia is 5–10% but only 0.13–0.17% of the general population [20–22]. Polymorphisms in circadian rhythm genes, such as Human Per3 (hPer3), arylalkylamine N-acetyltransferase, HLA, and Clock, may play a role is DSPS [23–27].

Advanced Sleep Phase Syndrome (ASPS) can be clinically overlooked as a CRSD. Individuals with ASPS wake up early without much effort. Following their circadian pattern, they may choose sleep onset at 6–9 p.m. However, social pressures may delay their preferred bedtime and cause chronic sleep deprivation. Advancement in the phase of sleep-wake cycle is commonly seen with aging [28]. Prevalence is thought to be exceedingly rare [22]. Polymorphisms in circadian clock gene hPer2 have been identified [29].

Non-24-Hour Sleep Pattern is a CRSD that is primarily reported in blind individuals with no light perception. Delays or advances may result since the SCN does not respond to dark-light cycles. Up to 70% of blind individuals complain of chronic sleep disruption [30].

Irregular Sleep-Wake Pattern as a CRSD includes those with poor sleep hygiene or those who voluntarily have irregular cycles. Shift work and jet lag are two examples of this. Not all shift workers have sleep difficulty as the ability to cope with shifting circadian patterns varies between individuals [31]. Similarly, not all travelers suffer from jet lag. Eastward travel is often more problematic than westward travel. Irregular sleep-wake pattern also can occur in those with developmental conditions, brain injury, and dementia and those in institutional care [32–35].

Sleep Apnea is not recognized as a circadian rhythm sleep disorder per se. However, it can dramatically affect circadian patterns, may be affected by diurnal patterns, is a common sleep disorder, and can be modified, in part, by nutritional interventions. Poor sleep quality causes daytime sleepiness and affects both wake timing and normal somnolence. Sleep apnea severity is described by the average number of respiratory events per hour of sleep (frequency), but also the duration of each event can be monitored. At a circadian phase corresponding to early morning, apnea durations are longest and frequency was low. In the late afternoon and early evening, event durations are shortest and frequency is high [36]. This may be due to the concept that respiratory plasticity or neuronal control of respiration is modulated by a circadian rhythm [37]. Also, upper airway muscle activity, which helps maintain upper airway patency, is also modulated by a circadian rhythm [38, 39]. Prescribing a sleep schedule and possibly promoting daytime napping may be involved in managing sleep apnea as it pertains to breathing stability [37]. Addressing excess body weight and inflammation are key nutritional interventions to support individuals with sleep apnea [40, 41].

34.6 Treatment for Circadian Rhythm Sleep Disorders

34.6.1 Light, Melatonin, and Vitamin B12

Treatments are limited for circadian rhythm sleep disorders because of a lack of ability to assess circadian function in a practical and meaningful way, and there are limited randomized controlled clinical trials, especially in regard to functional alterations. In various combinations of dosing and timing, light, melatonin, and vitamin B12 routinely appear to support circadian rhythm.

Melatonin is not corrective and cannot be relied upon as a sole tool in the management of DSPS as treatment shows a wide variability among subjects [42–45]. Dosage trial and error is often required over the course of several months. The lowest effective dose is recommended.

Vitamin B12 likely acts to enhance the entraining light signal to the circadian pacemaker (SCN). Whether methylcobalamin is the right form is debatable. Cyanocobalamin, hydroxocobalamin, and adenosylcobalamin may be converted to methylcobalamin. If a clinician is tracking homocysteine as a functional marker, methylcobalamin would have to be used in order to note treatment effectiveness ◘ Table 34.1.

Table 34.1 Dosing light, melatonin, and vitamin B12 for disordered sleeping

Condition	Light	Melatonin	Vitamin B12
Delayed sleep phase syndrome	Early morning bright light (2500 lux) for 2 hours	Moderate dose (3–6 mg) between 5 p.m. and 7 p.m. for 1 month followed by moderate dose at 7:30 p.m. for two additional months	Dosed according to clinical need (1.5–4.5 mg methylcobalamin)
Advanced sleep phase syndrome	Early evening bright light (2500 lux) for 2 hours	Low dose (0.3–0.9) early morning	
Non-24-hour sleep pattern	If sighted or blind with light perception, bright light (2500 lux) for 2 hours	High dose (10 mg) before bed for entrainment Low dose (0.5 mg) at night	Dosed according to clinical need (1.5–4.5 mg methylcobalamin)
Irregular sleep-wake pattern shift work disorder	Bright light (1200–10,000 lux) for 3–6 hours during the night shift or 20 minutes per hour	Moderate–high dose (3–10 mg) at bedtime after night shift for 2–6 days	
Irregular sleep-wake pattern jet lag (eastbound)	Avoid bright light in the morning; get as much as possible in the afternoon	Moderate dose (2–5 mg) at bedtime	
Irregular sleep-wake pattern jet lag (westbound)	Stay awake while it is daylight at the destination; sleep when it gets dark		
Irregular sleep-wake pattern (other)	Early morning bright light (2500 lux) for 2 hours	Low–high dose (0.3–10 mg) before bed	Dosed according to clinical need (1.5–4.5 mg methylcobalamin)
Sleep apnea	Need determined by chronotype	Moderate dose (2–5 mg) at bedtime	

Some nutritional interventions may be applicable to virtually all aberrant circadian patterns. Assessment for the applicability in individual patients of these interventions may provide a useful clinical roadmap. Inflammatory signals have profound effects on circadian clocks. Essential fatty acid balance and natural substances that target NF-KappaB and AMPK (5′ adenosine monophosphate-activated protein kinase) can be considered [46, 47]. As examples, omega-3 fatty acids such as eicosapentaenoic and docosahexaenoic acids (EPA and DHA), turmeric, and berberine, respectively, can be considered. Red blood cell fatty acid analysis, clinically actionable markers of inflammation including C-reactive protein and erythrocyte sedimentation rate (ESR), and blood sugar dysregulation markers such as hemoglobin A1c, fasting glucose, and fasting insulin can be used to identify these opportunities for intervention. Supplements of and foods rich in magnesium and the other B vitamins beyond B12 can be included in the management of individuals with circadian rhythm sleep disorders [48, 49]. The type and dose of each require individualized clinical evaluation and a trial of therapy. Dietary management of circadian rhythm disorders may include the inclusion of phytonutrients such as polyphenol- and flavonoid-rich vegetables and spices [50, 51]. Additionally, nutrition professionals must consider macronutrient choices that support glycemic balance [52, 53].

34.7 Nutrition and the Circadian System

The circadian clock directs when we are active, when we sleep, and, to a great extent, when we eat. This system maintains the rhythm in the endocrine and metabolic pathways required for our body's homeostasis. A wide range of metabolic pathways are controlled by the clock system, whose daily fluctuations are affected by the food we ingest [54]. Today's modern lifestyle, which includes artificial lighting and ready-made, easy-to-access snacks, may place an evolutionary stress on our bodies that can impact our diet and health. The complex circadian system optimizes behavior and physiology according to the time of day and is organized with a central clock in the SCN primarily entrained by light. Patients are commonly exposed to less light during the day and more light at night because of artificial lighting. This further impairs the circadian system and disrupts sleep. Disturbed sleep thus results in widespread deleterious effects on metabolic health. As an example, sleep disruption promotes increased energy intake, reduced energy expenditure, insulin resistance in some individuals, and an increased propensity to make less healthy food choices.

The human biological clock can be disrupted or adjusted, depending on environmental factors, including not only the pattern of day and night, but the rhythmic intake of food [16].

34.7.1 The Circadian Clock System Prepares the Body for Feeding

The circadian clock system readies the body for daytime feeding. Gastrointestinal motility and gastric emptying peak in the morning, and animal studies have shown that the clock regulates the action of bile acids and nutrient transporters which optimize digestion [17]. In addition, the gut microbiota exhibit daily circadian oscillations, which are time-of-day specific in order to perform certain functions. The intestinal cells have a circadian clock that scientists are now investigating in order to discover its physiological pathway. The gut clock reacts to the rhythmic intake of food, and it has been shown that the microbiota participate in food processing and react with the intestinal clock [16]. Energy metabolism is enhanced by the gut microbes during the active phase, while detoxification occurs more often in the resting phase [17, 55]. There is a complex connection between the circadian rhythm and the microbiome, and a disruption in the clock system can have a disorganizing effect on the gut microbes [56]. This information lends itself to recommendations of avoiding high-fat meals in the evening and also ensuring micronutrient-rich evening meals to support detoxification during rest (Fig. 34.2).

The intestinal cells have a circadian clock that research is showing is connected to the central clock in the SCN. The gut clock responds to the rhythmic intake of food, and it has been demonstrated that the microbiota participate in food processing and react to the intestinal clock. The action is bidirectional, in that the gut clock needs the microbiota to function correctly, and the gut bacterial levels fluctuate according to the gut cycles. Thus, the circadian clock is an integral player between food and the intestinal system.

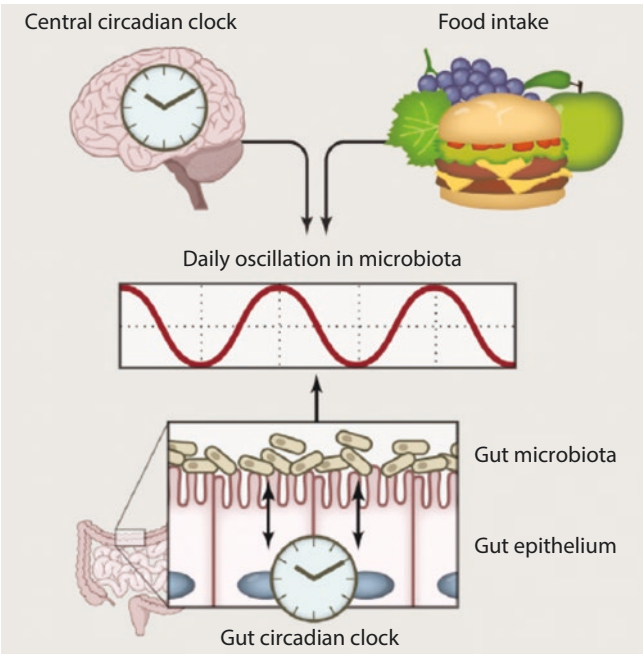

Fig. 34.2 The connection between the microbiota and the gut circadian clock. (Reprinted from Asher and Sassone-Corsi [16]. With Elsevier)

The circadian clock also controls rhythms in the blood concentrations of many nutrients, for example, glucose and lipids [57]. Due to the clock-controlled regulation of the gastrointestinal system, practitioners may want to consider the timing of nutritional testing. There has been some interesting research with rodent models and the timing of food intake and allergies. It was shown that exposure to food antigens during the resting phase produced more severe food allergy symptoms [58].

The circadian system regulates energy storage in the body's tissues. To a large extent, appetite is clock-controlled. There is a bimodal daily peak of insulin within the active phase, and diet-induced thermogenesis is rhythmically regulated and peaks in the morning. Hunger is typically lower in the morning and higher at night. This may be of importance when discussing obesity, since delayed bedtimes allow more time for food consumption when the appetite is higher. Some suggest that consuming a greater percentage of food in the morning may encourage a negative energy balance and a decrease in body mass [17, 59]. This works to the extent that a patient does, in fact, reduce portions in the evening rather than simply consuming more in the morning and allowing natural appetite and satiety to control excess eating at night. Encouraging self-awareness of a satiety index may be a central principle in medical nutrition therapy when these tools are used.

34.7.2 Coupling Between Metabolism and Clocks

The light-dark cycle entrains the central clock in the SCN and governs activity-related rhythms such as the sleep-wake cycle, core body temperature, the autonomic nervous system, and melatonin production, whereas the peripheral clocks, present in most tissues including the brain, are entrained by the feeding and fasting cycles. The peripheral clocks oversee local physiological processes such as glucose and lipid levels, hormone secretion, digestive functions, and the immune response [14, 60].

Recent studies have shown that the peripheral circadian oscillations respond differently to dietary cues than those of the SCN and that an irregular feeding schedule can cause a decoupling between the SCN and the peripheral system. A desynchronization or decoupling among the clocks is thought to result in the development of cancer, metabolic, and psychiatric disorders [14].

34.7.3 Eating Patterns: The Feeding/Fasting Cycle

The circadian system primes organisms to feed at specific times, and if feeding occurs outside the normal boundaries, negative health consequences may result [17, 61]. Studies in

both humans and animals suggest that the timing of meals may be related to diabetes, obesity, and impaired cognitive function via the peripheral clock network and metabolism [17, 61]. In humans, skipping meals, especially breakfast, has been shown to be associated with obesity and other metabolic issues. On the flip side, eating later at night can disrupt the rhythm of meal timing and sleep onset and has also been associated with weight gain. Though conclusive data is somewhat limited, there have been many studies on the effects of the fasting/feeding cycle on the circadian rhythm. Rodent studies show that fasting during the early "activity" phase (which for them is nighttime, since rodents are nocturnal) results in an increase in both body weight and hepatic lipid deposition. This early nocturnal fasting disrupts the peripheral clock system and results in de novo lipid synthesis and a tendency toward obesity. This is akin to skipping breakfast in humans [62].

There have been a number of studies that show the importance of eating a meal upon the beginning of the active phase to prevent obesity. Thus, one could make an argument for eating on a regular schedule, during the normal "active phase" (or light phase for humans) for proper peripheral clock management and optimal health [62]. Human studies have compared isocaloric weight-loss groups and have found there was a greater improvement in metabolic markers in the group given the larger breakfast and a smaller dinner, rather than vice versa. Other studies have found a correlation between earlier meal times and a decrease in serum lipid levels. Evidence also shows that the consumption of breakfast among adolescents is inversely associated with weight gain [63]. In addition, time-delayed eating, as in nighttime eating, is positively associated with an elevated body mass index (BMI) [14, 16]. In studies of both rats and humans, it was found that there was an affinity toward higher fat foods in the evening compared to morning. Though studies are not conclusive, this preference may indicate an association between late-night feeding and obesity [16].

34.8 Time-of-Day Restricted Feeding

The eating pattern of humans in modern societies typically consists of three meals and a few snacks every day. This is abnormal from an evolutionary perspective, where research shows hunter-gatherers eating intermittently. The body evolved to take up and store glucose (liver glycogen stores) and longer-lasting energy substrates, such as fatty acids in adipose tissue, and was designed for a diurnal rhythm of activity/rest and feeding/fasting. Modern lifestyle, with artificial light and erratic eating patterns, can upset our biological circadian system [64].

The timing of meals seems to be a significant zeitgeber for the oscillations in the peripheral clocks and could be seen as an important factor in regulating metabolism. Though the mechanisms by which an irregular feeding time affects the metabolism are not completely known, the evidence suggests that differential meal timing may alter the circadian cycle independent of lighting conditions. For the most part, the SCN clock is controlled by the light-dark cycle, whereas the peripheral clock rhythms are affected by feeding cycles. Time-of-day restricted feeding (TRF), where food availability is restricted to a smaller window during the day, has been shown to entrain the circadian rhythm in peripheral tissues without disrupting the clock rhythm of the SCN [62, 65]. The effect of restricted feeding is not the same as caloric restriction, which can affect the phase of circadian rhythms in the central pacemaker [5].

A number of studies show the beneficial effects of restricting food intake to a discrete window of time within the daily active cycle (daylight for humans). There have been several human epidemiological studies that exhibited a correlation between eating pattern and obesity. When food is restricted to a smaller time frame within the active period, increase in glucose tolerance, reduction in insulin resistance, and decrease in serum lipid levels have been shown. This has implications for reducing the risk of developing obesity [16, 66] (Fig. 34.3).

There is a wide body of evidence that shows that when food is restricted to a discrete window of time within the daily cycle, various metabolic processes are improved. When food is restricted to a smaller time frame within the active period, an increase in glucose tolerance, a reduction in insulin resistance, and a decrease in serum lipid levels have been shown. This has implications for reducing the risk of developing obesity.

In a study of overweight and obese women, those who consumed a larger percentage of daily calories earlier in the day lost more weight than those eating later in the day [67]. These findings are consistent with others that show that earlier lunch consumption is associated with greater weight loss after 20 weeks [17].

Restricting the delivery of nutrients in a rhythmic fashion may help to reset the peripheral clocks, which could potentially have a positive impact on the immune system. Some

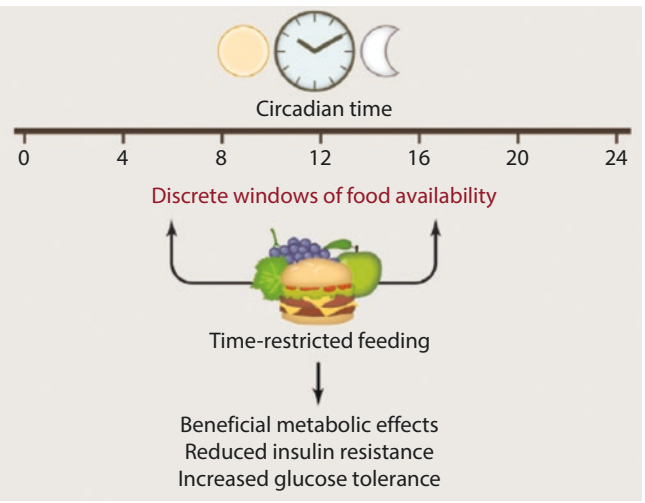

Fig. 34.3 The benefits of time-of-day restricted feeding (TRF). (Reprinted from Asher and Sassone-Corsi [16]. With Elsevier)

emerging research with both human and animal models shows improved health with intermittent energy restriction of as little as 16 hours (an 8-hour eating window). Here there is a shift to fat metabolism and ketone production, which can stimulate adaptive cellular stress response and repair molecular damage [64]. Circadian dysregulation can induce adverse health effects as well as hamper recovery. When dealing with ill patients in the ICU or those who are on enteral feeding, restoring their day-night cycle might help realign their biological rhythms during the recovery phase to improve outcomes [2].

Practitioners who develop nutritional plans for clients should not ignore the impact of the circadian rhythm on nutrition and health. The timing of meals has shown to affect body weight and the risk of obesity in humans [14, 68, 69]. Though not conclusive, it appears late meals and skipping breakfast encourage a gain in body weight and propensity toward obesity. Eating a larger breakfast and a smaller dinner may lead to better markers for fasting glucose, insulin, ghrelin, as well as improved mean hunger and satiety scores [14, 67]. Early mealtimes are also shown to reduce triglycerides and LDL levels in serum [65]. In addition, restricting the consumption of food to a smaller window during the active period may be beneficial to health [64].

Intermittent fasting (IF) is popular in the health and fitness field today. Practitioners often recommend a 12- to 16-hour fast, and many studies show a positive effect on weight loss [70–72]. However, breakfast is the meal most often skipped. Though positive weight loss may occur when breakfast is removed, evidence indicates that for overall health and weight management, it is better to eat breakfast [63, 73]. This is keeping with the idea that it is more advantageous to consume one's daily calories within the active (daylight) cycle [16]. Recent evidence demonstrates that when the first meal of the day is missed, neuroendocrine parameters may be negatively affected. In one study, levels of testosterone and IGF-1 were shown to be reduced, as was leptin [74]. Another study in men found that omitting breakfast led to an increased risk of type 2 diabetes [73]. It is worth speculating if perhaps the benefits of intermittent fasting could be achieved without the deleterious effects if the fasting window began in the early evening and breakfast was consumed on a regular basis.

34.9 Circadian Clock Genes

Within the neurons of the SCN, there are a number of genes that are activated or inhibited in a regular pattern over the course of a day. The fluctuations act as molecular gears of the biological clock which regulates the 24-hour cycle. These molecular oscillations work in a negative feedback fashion, whereby the protein product of a gene turns off production of more protein.

At the core of the molecular network are transcription factors that drive expression and regulate the biological function of the master circadian genes, *CLOCK* and BMAL1. The transcription of a large number of clock-controlled genes also directs the transcription of their own repressors, period (PER) and cryptochrome (CRY), which create a self-regulated feedback loop. During daytime, the *per* and *cry* genes create the PER and CRY repressors, which accumulate over the day. This eventually inhibits the CLOCK-BMAL1-driven transcription of *per* and *cry*. Then the degradation of PER and CRY allows the CLOCK-BMAL1 transcription to proceed once again. This creates the cycling in the circadian gene expression [16, 75]. Additional clock genes or clock-controlled genes, such as Rev-erbα/ß, Rorα/ß, Dpb, Dec1/2, CK1ε/δ, and NPAS2, also work to sustain mammalian circadian clocks [14] (Fig. 34.4).

CLOCK and BMAL1 are transcriptional activators that dimerize to stimulate the expression of many clock-controlled genes (CCGs) with E-box promoter elements in their promoters. CLOCK:BMAL1 also stimulate the expression of the Period (Per) and Cryptochromes (Cry) gene families. PER and CRY protein levels become elevated during the night. They dimerize and translocate to the nucleus to repress CLOCK:BMAL1-mediated transcription. PERs and CRYs undergo a number of posttranslational modifications that cause their degradation, which then allows them to start a

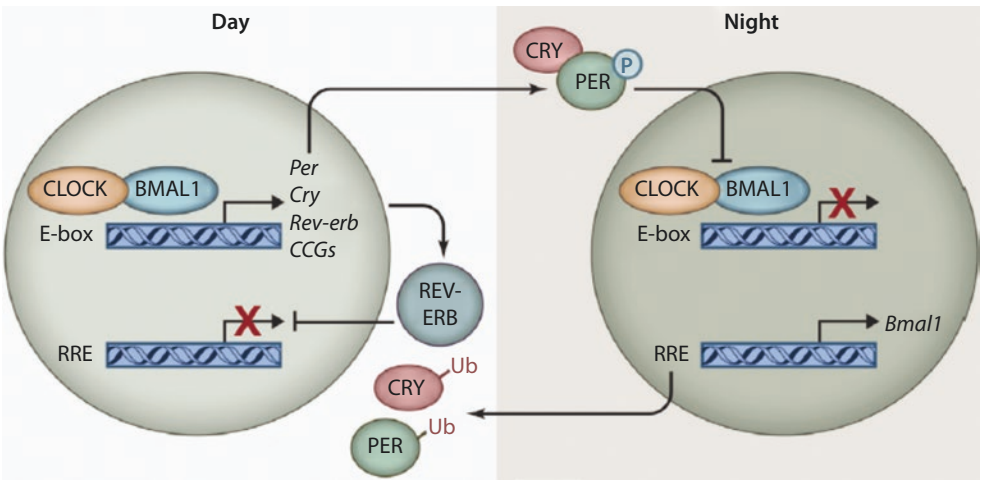

Fig. 34.4 The molecular organization of the circadian clock. (Reprinted from Asher and Sassone-Corsi [16]. With Elsevier)

new circadian cycle. Another loop involves the proteins REV-ERBa/b, whose levels increase during the day and bind to specific responsive promoter elements (RRE), inhibiting Bmal1 transcription. At night, REV-ERBa protein levels decrease, allowing Bmal1 transcription to take place. These regulatory loops operate in most cells and control a large percentage of the human genome.

Disruption in the feeding/fasting cycle can impact the circadian clock genes. In mice, early nocturnal fasting (which correlates with skipping breakfast in humans) alters lipid metabolism and the peripheral clocks. It increases caloric intake and alters lipogenesis at the levels of transcriptional and metabolic cycling, changing the expression of clock genes such as *CLOCK*, *BMAL1*, *Cry1*, and *Per2* [62]. Single nucleotide polymorphisms (SNPs) in CLOCK have been associated with non-alcoholic steatohepatitis, metabolic syndrome, small dense low-density lipoprotein levels, obesity, and diabetes. One of the most studied associations is that of obesity. So far, eight common CLOCK SNPs have been associated with obesity, and three of them are linked with energy intakes [17, 76].

Disruption of the molecular clock can produce metabolic disturbances, a fact which is supported by some observational studies [7, 9, 57]. Nutritional interventions, such as caloric restriction, may hold promise in mediating some beneficial effects [17]. Rodent models suggest that a calorie-restricted diet reprograms the circadian clocks both transcriptionally and posttranscriptionally. It appears that the transcription factor BMAL1 is important for the reprogramming of the clock [77].

Further study of clock genes and their alterations will expand our knowledge of the molecular workings of the circadian clock that could lead to potential therapies for treating metabolic, sleep, and neuropsychiatric disorders. Of particular interest is identifying the at-risk CLOCK genotypes, who may be more susceptible to overeating and gaining weight when they experience shorter sleep time [76].

34.10 Pathophysiology Mechanisms and Relevance to Chronic Disease Risk

34.10.1 Metabolism and Obesity

A large body of evidence shows that cellular metabolism is intimately interconnected with the circadian clock [16, 64, 78]. Some say it may be due to an evolutionary advantage that separates the anabolic and catabolic reactions of the body during different times of the day, such as gluconeogenesis and glycolysis. This way, the metabolic cycles are aligned to the sleep-wake cycle. The circadian clock mechanism influences homeostasis over a wide range of processes including glucose and lipid metabolism, body temperature, endocrine hormone secretion, and cardiovascular health [64].

Numerous studies have focused on the connection between the scheduling of meals and such pathologies as obesity and diabetes [60, 62, 63]. It can be conjectured that "optimal" feeding schedules may also provide health benefits beyond these conditions, such as preventing morbidity and reducing mortality in relation to other pathologies such as aging [16].

There is a daily cyclic control over glucose metabolism [64, 79]. Glucose tolerance and the action of insulin vary throughout the day. Glucose tolerance is reduced in the evening, as opposed to the morning hours, because insulin secretion is lower, and insulin sensitivity is diminished during the nighttime. Glucose levels peak right before the "active period" or daytime hours [64]. Insulin sensitivity has a bimodal peak during the daytime phase, and appetite is actually lowest in the morning [17, 59, 79]. Thermogenesis also has a circadian rhythm that is induced by the diet and peaks in the morning. Nutrition professionals may want to recommend a larger percentage of dietary energy during the early hours of the active phase. This will encourage a negative energy balance, which is the principle determining factor of reducing body mass [17, 80].

Poor-quality sleep and reduced sleep duration are linked with impairment of glucose tolerance, along with reduced insulin response following a glucose challenge. Studies with shift workers have revealed that, with a disruption in the light-dark cycle, the risks of metabolic dysfunction, cardiovascular disease, stroke, obesity, and cancer all increase. Evidence also shows a rise in BMI when there is a discrepancy between the natural circadian clock and one's social clock. In a compelling clinical study, volunteers were put on a cycle that was shifted 12 hours from their normal sleep-wake cycle. The subjects exhibited increased glucose, decreased leptin, and elevated blood pressure. Their postprandial glucose response was similar to a prediabetic patient [64, 79].

In mouse studies, feeding at the incorrect time in the light-dark cycle can elevate the obesogenic effects of a high-calorie diet, due to the desynchronization of the hormonal and molecular rhythms in maintaining energy balance [64, 81]. While feeding a high-fat diet during the rest phase leads to weight gain, restricting feeding to the active phase leads to an improvement in obesity and metabolic disorders.

Directing therapy toward weight loss in obese and overweight patients may improve sleep, such as is the case with sleep apnea [40]. The potential positive effects of normalizing body composition include improved glucose tolerance, normalized lipid markers and reduced blood pressure, reduced inflammation, and reduced stress to the circadian system. Obesity and related metabolic sequelae, including cardiovascular disease, accelerated aging, diabetes, cancer, and neurodegenerative diseases, are conditions of increased oxidative stress. It has been proposed that oxidative stress and circadian rhythm be supported simultaneously when one or both clinical challenges are identified [82].

34.10.2 Cancer

In human and rodent studies, abnormal circadian rhythms have been associated with a greater risk of both the development and progression of cancer. A disruption in the light-

dark cycle can result in poorer outcomes for cancer patients. Faster tumor growth and shorter survival times are seen when the rhythm is unbalanced. Shift work, with the attendant disruption of the natural circadian rhythm, is a significant and independent risk factor for the development of a variety of cancers. Studies in women with breast cancer show that those whose cortisol rhythms were off due to circadian disruption had a poorer survival rate [7]. It is believed that the prolonged disturbance of the circadian clock system may lead not only to cancers of the breast and prostate but to other types of cancers, such as ovarian, kidney, brain, colorectal, lung, head and neck, pancreatic, and hematological cancers [9].

Interventions that target the circadian timing system hold promise for potential therapies that may help improve the quality of life and survival in cancer patients [9]. In addition, the altered expression of various clock genes may be an important mechanism contributing to the progression of cancer and is an area of further research interest. Practitioners can work with their cancer patients to regulate the timing of meals in concert with the natural circadian rhythm. An organized feeding routine within the normal rhythm of the light-dark cycle will help maintain homeostasis, which may lead to more favorable outcomes.

34.10.3 Diabetes

Evidence is accumulating that inadequate sleep may be a risk factor for type 2 diabetes. Short duration of stage 3 and 4 NREM (non-rapid eye movement) sleep has been shown to increase insulin resistance. In clinical studies, decreased glucose tolerance was observed in adults after several nights of sleeping only 4–5 hours per night. These preliminary findings indicate that there may be a relationship between the time spent in slow-wave, deep sleep, and the circadian rhythm of glucose metabolism [83].

Studies involving circadian clock genes suggest a role for the clock proteins in diabetes. In animal models, circadian desynchronization results in a faster onset of type 1 diabetes. In this case, the overexpression of human islet amyloid polypeptide leads to pancreatic beta-cell failure. Other rodent studies show that when the SCN is ablated, the circadian rhythm of glucose uptake is lost, leading to hepatic insulin resistance [84–86].

Other investigations show that constant light exposure disrupts the circadian rhythmicity, resulting in insulin resistance [84, 87]. Melatonin is regulated by the light-dark cycle, and evidence for its role in diabetes comes from research that identified a SNP near the melatonin receptor 1B gene. This gene encodes the melatonin 2 receptor, which is linked with increased fasting glucose and a greater incidence of type 2 diabetes in white Europeans and Asians [84, 88, 89]. Melatonin is secreted in a diurnal fashion and influences insulin secretion. The circadian secretion of insulin from the pancreas is also clock-driven. Evidence suggests a connection between melatonin and the control of glucose-stimulated insulin secretion. The dysregulation of the circadian secretion of melatonin may be a key to the development of type 2 diabetes [84, 90].

In humans, a study demonstrated that two SNPs in the clock gene, BMAL1, led to a greater risk of gestational diabetes mellitus in women. Other recent work has illustrated a role for Cry1 and Cry2 in diabetes. In addition, there is ongoing research exploring the use of Cry1/2 agonists to treat the disease. Continued exploration into the physiological significance of the gene interactions may lead to therapies that successfully target the circadian clock for the treatment of diabetes and other metabolic disorders [84].

34.10.4 Cardiovascular Issues

Sleeping for less than 7 hours per night is associated with a higher risk of cardiovascular disease and poor cardiovascular health outcomes, such as hypertension, hypercholesterolemia, myocardial infarction, and cerebrovascular events [83]. Several studies in both rodents and humans have shown the importance of the circadian clock in cardiovascular disease, due to different cardiovascular phenotypes associated with circadian disruption or desynchronization [84, 91–93]. The desynchronizing of the clock system is often caused by rotating shift work or chronic jet lag [84]. There is mounting evidence that shows the importance of maintaining healthy circadian function for cardiovascular health. An area of active investigation is the regulation of blood pressure. Circadian clock proteins regulate the "dipping" of blood pressure at night (by about 10%) and its rise in the morning. The mechanism is unknown, but many people with hypertension, type 2 diabetes, and chronic kidney disease do not experience this effect. It is likely that a combination of sympathetic nervous system activity, hormone signaling, nitric oxide, and sodium reabsorption together contributes to the circadian control of blood pressure [84].

As with blood pressure, heart rate decreases at night and rises during the day. The exact mechanism for the circadian control of the heart rate is not yet fully understood, but peroxisome proliferator-activated receptor-gamma has been suggested, by way of an unknown pathway involving BMAL1 in the endothelium. It has been demonstrated that the circadian clock controls numerous intracellular calcium channels that are important for heart rate regulation. Myocardial repolarization also appears to be controlled by circadian rhythm [84].

The incidence of heart attack and stroke peaks in the morning, attributing to the rise in blood pressure and heart rate occurring at that time. Human studies show that infarct size and myocardial injury both display circadian oscillations, with the highest damage early in the day [84]. Cardiac remodeling occurs during sleep, and a desynchronization leads to an increased risk of cardiovascular events. Studies with shift workers who have rotating schedules show an increased risk for cardiac issues [94–98]. Those who suffer from chronic jet lag may have similar risks due to desynchronization. Therefore, it is important to maintain a healthy circadian rhythm for cardiovascular health [84].

34.10.5 Renal Function

Many processes in the kidney follow a circadian rhythm including renal blood flow, glomerular filtration rate, as well as potassium and sodium excretion. The clock gene, Per1, is involved with the epithelial sodium channel (ENaC) in the renal collecting duct, which is a key mediator of sodium reabsorption and blood volume control by the kidney. Per1 also regulates multiple genes involved in sodium reabsorption [99]. In one human study, it was found that Per1 was upregulated 1.7-fold in the renal medulla of kidneys in patients with hypertension, compared with normotensive controls [100]. Thus, it is suggested that Per1 may play a role in blood pressure control in humans.

34.10.6 Endocrine System

The circadian clock is a key regulator of the endocrine system, and conversely, the endocrine system plays a role in the synchronization and regulation of the peripheral circadian clocks. A mutual physiologic interaction between the circadian clock system and the hypothalamic-pituitary-adrenal axis (HPA axis) is orchestrated by the Clock/Bmal1 transcription factors, along with the glucocorticoids and glucocorticoid receptors. This serves to manage the adaptations not only to the day-night cycles but to the variety of stress stimuli the body is exposed to on a daily basis. The circadian clock system and the body's stress response system are both crucial for survival, and they communicate with each other on many levels to constantly adjust the various physiological activities. Dysregulation in either system may lead to similar pathologies [101].

The glucocorticoids, steroid hormones produced in the adrenal glands, are involved in reducing inflammation, and they play a part in stress response, metabolism, and the function of the neurological and cardiovascular systems. Glucocorticoids are thought to synchronize the circadian clock, as studies demonstrate that they can entrain the peripheral circadian oscillators [102]. Glucocorticoid levels are tightly regulated, and they express a daily rhythm, with their highest levels occurring in the early morning and their lowest in the late evening (in diurnal animals). The SCN, under the control of daily light input, regulates the rhythmic secretion of glucocorticoids from the adrenal glands by influencing the activity of the HPA axis. The glucocorticoids, in turn, phase-delay the peripheral clocks via the clock genes. This process is important for the body's adaptation and response to stress. A regulatory feedback loop is enacted by the peripheral clocks through the interaction of Clock/Bmal1 and the glucocorticoid receptors of the central clock on the HPA axis [101].

Numerous in vitro studies show that synthetic glucocorticoids can synchronize cell cultures via the circadian gene expression. In animal models, the administration of hydrocortisone synchronized circadian gene expression in the lung, pineal gland, salivary gland, cornea, and liver [102–104].

34.10.7 Immune System

The circadian system is an important component of the hypothalamic-immune communication. Disruption of this rhythmic process has been linked to immune dysregulation, and studies show that the circadian clock genes are involved in the immune response. Interactions between the HPA axis and the circadian clock system are seen in the regulation of immune function. The circadian oscillation of numerous cytokines has been observed in humans, including interleukin-1 beta (IL-1beta), IL-6, interferon (IFN)-gamma, and TNF-alpha in T- and B-lymphocytes and natural killer cells. In animal models, those with clock gene mutations display dysfunctional immune systems, including disrupted circadian rhythm in leukocytes and cytokine production, altered response to lipopolysaccharide (LPS)-induced endotoxic shock, and the defective development of B-lymphocytes [101]. Activation of the HPA axis and the resulting release of glucocorticoids strongly influence immune activity and the inflammatory response [101].

Sleep deprivation can evoke an acute stress response within an organism, and sleep loss can be a risk factor for impaired immune function. A number of studies have indicated that under normal sleep-wake and lighting conditions, circulating blood cell populations follow a diurnal rhythm. If sleep-deprived, however, granulocyte levels and their rhythmicity are disrupted, and these changes reflect the body's immediate immune response when exposed to a stressor [105]. In a rodent model of chronic jet lag, research demonstrated that natural killer cell activity is compromised [84, 106].

34.10.8 Reproductive System

Recent studies have added to the knowledge of molecular circadian rhythm activity in the reproductive system. Most of the work has explored the role of the central clock system in the female reproductive cycle; however, newer work has also revealed the existence of a testicular clock [84]. Daily and seasonal environmental signals impact fertility through the clock system, as it coordinates the various processes involved in sex hormone production, ovulation, spermatogenesis, mating, embryo development, and childbirth [107, 108].

In females, the reproductive clock is involved in the neurons that express gonadotropin-releasing peptide hormone (GnRH). GnRH is responsible for releasing follicle-stimulating hormone and luteinizing hormone from the anterior pituitary gland. GnRH displays a circadian pattern. The central SCN clock appears to have control over the peripheral ovarian clock. Animal models show the oscillation of clock genes in the ovaries, and those with mutations in BMAL1 and CLOCK show decreased fertility. It is interesting to note that the existence of the circadian clock in the placenta has been found; however, the significance remains to be seen [84].

Circadian clock gene expression has been discovered in the male reproductive system, and it is demonstrated that the

proteins CLOCK and BMAL1 are involved in the development and physiology of the chromatoid body in the male germ cells, which are crucial to spermatogenesis [107]. In rodent studies, BMAL1 was shown to be necessary for fertility and proper testosterone production. Other animal models show that clock gene mutations influence reproductive function [107, 109, 110].

34.10.9 Sleep Hygiene

The concept of proper sleep hygiene is currently attracting a good deal of attention in the health field. Many professionals recommend consistent daily rituals, including an ideal bedtime environment that pays attention to all the senses.

Human circadian rhythms were entrained by the light-dark pattern of the solar day. Since the development of electric lights, exposure to nighttime lighting makes it more difficult for the body to synchronize biological processes [111]. The natural effect of darkness on the initiation and maintenance of sleep may be disrupted by the bright lights from modern media displays, such as phones, tablets, televisions, and computers. Both bright lights and stimulating content curb the natural decrease in body temperature and heart rate, thereby affecting the inclination to sleep. Research shows exposure to bright light at night can decrease melatonin production and circumvent the physiologic sleep processes [83]. Lowering lights at night, turning off displays, and sleeping in a darkened room can encourage the natural sleep cycle [83].

The brain processes sounds even while the body sleeps. Some sounds can be disruptive, but some may be soothing and may help induce sleep [83]. Earplugs can help protect from disruptive noise, while on the other hand, a sound machine producing soothing nature sounds like a waterfall may help some people fall asleep more quickly [112].

Aromatherapy offers a safe, cost-effective intervention that can aid in decreasing some of the negative impacts of lack of sleep. Natural essential oils that contain sedative or hypnotic properties are encouraging as a sleep therapy. Numerous studies, including some randomized controlled trials, have shown that essential oils, especially lavender, can improve sleep issues [113–116]. Exercise is a healthy activity that can reduce the risk of cardiovascular disease and other chronic issues. The National Sleep Foundation states that exercise is a non-pharmacological intervention that can improve the quality of sleep. However, the timing of exercise may affect sleep quality. Studies have shown that moderate aerobic exercise in the morning, as opposed to later in the evening, results in longer periods of deep sleep and shorter sleep-onset latency. In addition, morning exercise is demonstrated to optimize blood pressure changes that lead to an improvement in sleep architecture [117]. Information is lacking regarding the timing of meals and sleep quality, except that, as discussed in an earlier section, later bedtimes result in an increased food intake during the late-night hours. Current studies are finding that sleep restriction may lead to greater desire and consumption of palatable food through the endocannabinoid receptor system [118]. Though the study of incorporating sleep hygiene into weight loss programs is in its infancy, research has demonstrated better weight management when a sleep component is added [119–121]. This may provide some insight to nutritionists and health professionals who are helping patients with weight issues [83].

There is growing consideration that keeping in tune with the body's natural circadian rhythm is advantageous for health. Developing a regular daily routine that includes optimal meal timing, exercise, and sleep habits may contribute to proper weight management and ward off chronic disease.

34.11 Toxin-Related Influences

Caffeine, while the most common drug used to combat daytime sleepiness, disrupts circadian rhythm. In fact, caffeine can shift sleep onset forward by as much as 45–60 minutes even when consumed 6 hours prior to a scheduled sleep time. Later consumption can have even more profound effects on sleep time [122]. Those with circadian pattern concerns should be counseled to reduce or eliminate caffeine or, at minimum, limit use to only early in the day. While medical and nutrition professionals may take this information for granted, consumption statistics suggest that patients are using caffeine at all times of the day. A population-based study of adults estimated that 90% of individuals consume caffeine in the afternoon between noon and 6 p.m. and 68.5% of people consume caffeine in the evening between 6 p.m. and midnight [123]. Forward shifts of sleep time and artificial waking times can further lead to reliance upon caffeine. The effects of caffeine are quickly adapted to thus further increasing the dose required for a cognitive benefit [124, 125].

Of particular interest in circadian patterns is the influence of heavy metals, such as cadmium. Cadmium changes the expression of various circadian rhythm-related genes, including Bmal1, Per1, Per2, Cry1, and Cry2, and disrupts virtually every hormone secreted by the pituitary gland in animal models, even at low doses via drinking water. Melatonin has been shown to reduce these toxic effects including disruption of prolactin, luteinizing hormone, thyroid stimulating hormone, and corticosterone [126]. Melatonin's protective effect may be derived from supplemental use or from endogenous production. However, if endogenous melatonin is shunted toward cadmium amelioration, less is available for other functions, in particular its key role in circadian control. Melatonin serves as a suicidal antioxidant and is not recycled by additional antioxidants as is the case with vitamins C and E, coenzyme Q10, and others.

34.12 Key Lifestyle Influences

Alcohol affects circadian patterns with both acute and chronic use [127]. Ethanol impairs sleep, and sleep problems often contribute to relapse drinking [128–132]. In one study,

healthy subjects who consumed a significant amount of alcohol over the course of a day did not see changes in cortisol levels but did see increases in testosterone [133]. In a similar binge replication study, alcohol dramatically decreased nocturnal thyroid stimulating hormone (TSH) secretion [134].

If cessation is suggested, a significant time period of 1 week or more should be used to determine the effectiveness of cessation on circadian patterns since alcohol withdrawal can have its own set of repercussions to diurnal chemical secretion and its effects. Of particular interest is that when alcoholics abstain from alcohol, a delay in the nocturnal rise of melatonin occurs [135]. Thus, during cessation, supplemental melatonin may support sleep and reduce the propensity for relapse that often occurs as subjects rely on alcohol as a sleep aid. In non-addicted individuals, alcohol also shows a suppression of melatonin secretion in a dose-dependent manner [136].

This is not the only place in the scientific literature where melatonin and alcohol intersect. Of specific interests to nutrition professionals, melatonin may counteract some of the effects that alcohol has on duodenal paracellular permeability [137]. Intestinal hyperpermeability, while not exclusively related to circadian patterns, is implicated in a variety of chronic health conditions. Alcohol consumption appears to decrease endogenous daytime glutamate signaling to the SCN, which may or may not be a clinically actionable mechanism [127]. Brain-derived neurotrophic factor (BDNF) can be increased via a Mediterranean-style diet [138], physical activity [139], intermittent fasting [140], and caloric restriction [141, 142]. Per2 abnormalities may predispose individuals to alcohol dependence [143]. Of interest for preventative models of care, those with abnormal circadian patterns may be good candidates for screening and preventative counseling for alcohol or other drug use and abuse.

Nutrition professionals should fully investigate alcohol consumption patterns among those with known circadian and/or sleep challenges and thyroid disorders. Those with gastrointestinal disorders may additionally benefit from such investigation. Some patients will benefit from abstinence even in the absence of addiction.

34.13 Chronotypes and Personalized Nutrition

With today's interest in personalized nutrition, understanding an individual's chronotype may be helpful in developing a personal diet and lifestyle plan. A person is classified by chronotype according to preference for when to sleep and when to be active. If laboratory investigations of an individual's internal time clock are not practical, a questionnaire may be used to estimate chronotype. These include the Morningness-Eveningness Questionnaire and the Munich Chronotype Questionnaire Test [144, 145]. If a person's chronotype influences physiological processes, then it may be important to consider chronotype when developing a nutritional plan. Recent studies are beginning to explore the role of clock gene SNPs in response to diet. Knowledge of gene variants in the circadian clock system may help practitioners design successful personalized nutrition [17].

34.14 Conclusion

Circadian rhythm disorders and disruptions in sleep habits may be overlooked or dismissed in clinical practice. The evidence of detrimental effects on metabolic function and dietary choices are accumulating. Emphasis on supporting circadian system function and addressing sleep disruption may significantly enhance health and productivity for many individuals.

Biochemical assessment of individuals who may have circadian rhythm dysfunction includes evaluation of the HPA axis via saliva or urinary parameters; inflammation markers such as C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR); DHEA-S; glycemic handling markers, including hemoglobin A1c, fasting glucose, and insulin; and B-vitamin status as estimated by homocysteine, methylmalonic acid, and a complete blood count. Advanced biochemical assessment may include heavy metal testing, such as a provoked urinary sample or urinary porphyrins, genetic analysis, and red blood cell fatty acids. Markers for gastrointestinal microbiotic dysbiosis and antioxidant status may further inform treatment strategies and promote treatment adherence.

Included in an interview in such a case should be the exploration of the regularity or irregularity of sleep and wake times, as well as sleep hygiene, including bedtime routine, light and sound exposures, electromagnetic frequency (EMF) exposure [146, 147], coping mechanisms, and stress influences, such as the Holmes and Rahe Personal Stress Inventory. Dietary intake assessment should include timing of meals to determine the normal eating window. Clinical assessment may include stress, depression and anxiety screening questionnaires, and sleep questionnaires such as the Pittsburgh Sleep Quality Index (PSQI).

Integrative physicians and nutrition professionals wishing to optimize the circadian system may consider emphasizing eating upon arising, minimizing the eating window on a daily basis to 8–12 hours, cautioning against high-fat evening meals, prudent use of melatonin and vitamin B12 as needed, and moderation or abstinence of alcohol and caffeine, especially in the last 6–8 hours before bed. Antioxidant- and mineral-rich foods should be promoted, and supplemental use of bioavailable turmeric, berberine, and other botanicals may offer additional support given the outcomes of inflammatory and glycemic markers.

Increasing genetic and genomic screening may further inform clinicians how aggressive these and other interventions should be. Chrononutrition is still a promising yet underdeveloped science and clinical practice. Best practices are still evolving, and further intervention strategies await.

Satisfactory chronic disease care on the whole is an unmet medical need. While there are numerous contributing factors

to chronic disease, the elements of sleep, circadian rhythm, and the stress response (HPA axis dysregulation) form a triad of independent, yet intimately related, components [148]. Each of these aspects can disrupt the other, and they may be impossible to treat independently. HPA axis dysregulation can cause circadian rhythm imbalances and/or sleep disruption. Circadian rhythm imbalances can cause sleep disruption and/or HPA axis dysregulation. Sleep disruption can cause HPA axis dysregulation and/or circadian rhythm imbalances. If a patient is being treated for a chronic disease, sleep quality and quantity should be evaluated from both a current and a historical perspective. Supporting a balanced and natural circadian rhythm is a favorable preventive medical approach to cancer, diabetes, cardiovascular disease, neurodegenerative conditions, and other chronic disease manifestations [149–154]. Considering that the natural circadian cycle with nutritional and lifestyle approaches does not necessarily fall under the role of any specific medical specialty, nutritional professionals, integrative medicine practitioners, and those in primary care can screen for and identify interruptions in circadian patterns and poor sleep as key health determinants as well as a component of chronic disease management.

The circadian clock shows promise for the development of new therapies, both pharmacologic and nutritional, that address a variety of disorders. The day-night rhythm plays a key role in multiple physiological systems and may prove to be a target for diseases that involve multiple organ systems. Understanding the molecular interactions and exploring the adverse metabolic consequences of circadian misalignment will help formulate therapies for metabolic, behavioral, and immune diseases.

» Exercise is king. Nutrition is queen. Put them together and you've got a kingdom. –Jack LaLanne

35.1 Background

Inactivity and poor nutrition are major drivers of chronic disease risk, suffering, and early mortality. Physical inactivity is the fourth-leading risk factor for global mortality (6% of deaths), trailing only hypertension (13%), tobacco use (9%), and hyperglycemia (6%). Approximately 3.2 million annual deaths are linked to insufficient physical activity. In fact, inactivity is a greater mortality risk than being overweight or obese (5% of global mortality).

In 2008, 31 percent of adults worldwide – slightly more women than men – were considered inactive. In the American and European-Mediterranean populations, about half of the women and 40 percent of men were insufficiently active. Southeast Asia had the lowest percentages of inactive populations, with men at 15 percent and women at 19 percent [1].

As will be highlighted in this chapter, most health conditions can be improved with movement and exercise training (MET) or a combination of MET and other lifestyle medicine therapies. One challenge in the public health arena, preventive medicine, and disease-oriented medicine is how to inspire, educate, organize, and follow up on lifestyle medicine therapies. People will always look for quick fixes, but how do we educate, inspire, and motivate them to establish and maintain lifestyle habits that promote health instead of disease?

Inactivity, poor food choices, alcohol abuse, smoking, and poor stress management are commonly listed as drivers of chronic disease. The functional medicine model adds environmental toxins as another risk factor. The more we can identify and rectify these causes of chronic disease, the more momentum is created and the more success we will have with individual patients. As a result, we will see lower healthcare costs.

35.1.1 Integrating Nutrition and Movement

In the same way, one should not separate the soul and body and one should not separate movement and nutrition. They influence each other. You cannot treat nutrient deficiencies with exercise, and you cannot treat inactivity with nutrition. Both are needed all the time.

Administering the correct dosages of movement and exercise training (MET) will make everything else work better. Even dietary supplements like fish oil work better when combined with movement and exercise [2]. This 2014 study in *Neuropsychologia* showed a difference in cognitive function between patients who took omega-3 supplements and exercised. They also saw that the omega-6 to omega-3 ratio improved by adding exercise to omega-3 intake. This shows the positive potential of combining the intake of nutrients with movement and exercise. The transport, uptake, and function of nutrients with or without different levels of exercise and oxygenation of the cells may differ, according to the previous study.

The addition of consistent MET will complement and make other lifestyle habits or therapies more effective, whether they are stress management, dietary habits, supplement intake, or even use of pharmaceutical drugs. Our physiology depends on movement for basic and optimal function. Daily movement and exercise provide good circulation to facilitate normal physiological and biochemical functions.

People often underestimate the power of changing small habits, such as drinking a couple of glasses of water every morning, using public transportation, using a standing workplace, eating a salad every day, taking a daily walk, or just doing a little more daily stretching and activity. In the public health arena, larger populations making a few small, positive changes produce tremendous health effects, healthcare savings, and increased productivity. According to a study in Australia, walking and moving for 35 minutes per day has a positive effect on health and survival. The study showed people in the city of Melbourne alone had 272 fewer deaths per year, 903 fewer cases of chronic disease and a savings of $12.2 million when they used public transport instead of taking a car [3]. This and other studies show how everyday exercise and movement, even walking to the subway or to work every day, has a positive effect on health.

35.1.1.1 Movement and Detoxification

We are surrounded and affected by daily toxins. In the past 80 years, we have been subjected to more than 100,000 new chemicals [4]. At least 62,000 of these chemicals have shown to be transported by our cell membranes and enter our cells. Most of these are toxic to our cells and mitochondria, and they can affect and disturb our hormones. These chemicals are everywhere, in air, water, food, cosmetics, pharmaceuticals, personal care products, cleaning products, fuel, receipts, plastic bottles, and more.

Why is MET so important for detox? Exercise increases thyroid activity, whole-body metabolism, perspiration, lymphatic circulation, and bowel movement so that all these functions become more efficient in cleaning out waste.

- MET activates the lymphatic system and helps with filtration of toxins through the lymph nodes and contributes to a better cleanse of interstitial tissue fluid.
- MET increases sweating, which carries toxins from the inside of the body to the outside of the body, where it evaporated or wiped off by clothes, towels, etc. The more you move and sweat, the more you get rid of environmental toxins which relieve the kidneys and liver for the detoxification process.
- MET increases the activities of autophagosomes and the "cleaning process" that helps to break down and remove or recycle the old worn-out cell components. The same applies to "urban workers" in the brain which are primarily active at night thanks to the movements through the lymphatic system of the brain, the so-called glymphatic system (lymphatic system in glial cells). Activity during the daytime combined with a good night of sleep has shown to optimize this glymphatic cleaning process, that is so valuable for removing debris from the brain.

- Increased oxygenation of cells occurs by exercise and makes the combination of circulation and nourishment to the citric acid cycle help bind and displace toxins.
- The balance of redox status. Consistent moderate MET helps maintain a healthy redox balance. Both under-exercise and overtraining create problems with redox balance and an abundance of free radicals, accelerating the aging process and increasing the risk of developing chronic disease. Exercise induces increases in superoxide dismutase and other markers. MET and aerobic capacity are important factors in maintaining balance in redox status [5].

To further optimize the expelling of toxins through sweating, make sure you shower directly after you work out, and even better, shower and take a 15–30-minute post-workout sauna or hot bath.

35.1.1.2 Sitting Is the New Smoking

Over the last 10 years, many studies have concluded that excessive sitting is a major risk for mortality or chronic disease, independent from MET. Many people who have transitioned from a sitting work desk to a standing work desk can attest to that it is one of the easiest changes one can make to decrease the risk of mortality and chronic disease. A meta-analysis in 2015 concluded that sedentary time, primarily hours of sitting time, was independently associated with a greater risk for all-cause mortality [6]. Even if someone gets the widely recommended 30 minutes of daily exercise, being active in the remaining approximate 6500 waking minutes of the week makes a greater difference. An international mobile health (mHealth) program for studying obesity, inactivity, and sitting showed improvement when these people could stand and move more [7]. In fact, reduced sitting time may have a positive impact on psychological and physical health [8].

Sitting and watching TV is more dangerous than just sitting and working because watching TV is often associated with snacking on processed foods. Every hour of TV viewing after the age of 25 takes 22 minutes off a person's life [9, 10]. Sitting with one's upper back hunched forward also restricts the flow of oxygen and induces shallow breathing. Shallow breathing and stress breathing are common in modern societies. Deep breathing exercises contribute to increased oxygenation of the tissues, improvement in blood and lymphatic flow, and better digestive functions. Aerobic exercise improves the heart's blood-pumping capacity, as well as the capacity of the lungs. Both aerobic and anaerobic exercises have been shown to increase our capacity to better quench oxidative stress and improve redox balance [11]. Standing, walking, and MET with good posture increase the vital flow of oxygen to tissues. Transitioning to a standing desk is a simple change to decrease sedentary time. At a standing work desk, it is easier to move, fidget, stretch, and maintain good posture, all of which improve oxygenation to the tissues. Transition to better sitting positions at work is a good first step. Standing and working or walking and working are ideal (Fig. 35.1).

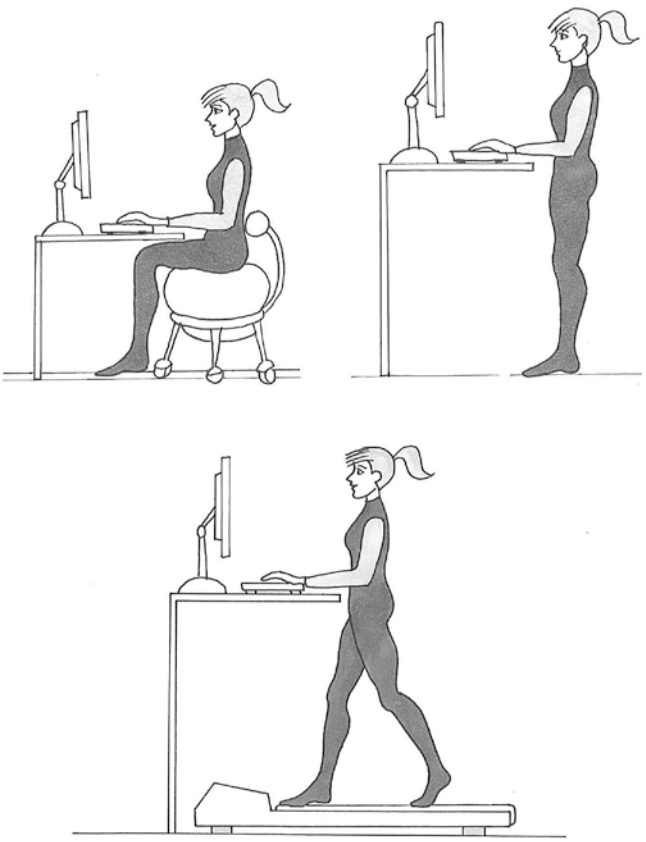

Fig. 35.1 Sitting upright, standing, and walking at workplace

35.2 Physiological Mechanisms Associated with Exercise and Nutrition

35.2.1 Oxygen Plays a Key Role

35.2.1.1 Oxygen, Nutrition, and Movement

We eat 4 pounds of food and drink 4 quarts of fluid a day, but in that same time, we take in 7.5 pounds of oxygen and produce waste from the burning of oxygen in biochemical reactions. About 3% of this oxygen intake ends up as free radicals due to by-products from energy production. These free radicals are complexed by our own production and even by the external reserve of antioxidants we ingest from foods, superfoods, and supplements.

There is a tendency for oxygen deprivation in the modern world, primarily because of our sedentary lifestyle. Boosting the production and transport of oxygen stimulates the synthesis and activity of white blood cells, resulting in a stronger immune system. Increasing oxygen levels may be the principal method to combat damage caused by aging and to discourage the growth of abundant number of anaerobic bacteria, yeast, and cancer cells. Production of energy and the use of oxygen are controlled tightly and influenced a great deal by MET. Oxygenation to muscle cells can increase nearly 15 times through intensive training as compared to a resting state, such as sitting. In a resting state, the body uses about 0.21 L of oxygen per minute, compared to the approximate 2.5 L/minute

rate from brisk walking and the 3.0 L/minute rate from running. The total cardiac output of blood in a resting state is approximately 5 L/minute, but that rapidly increases to about 25 L/minute when engaging in vigorous MET.

The heart must work against gravity to pump blood up to the brain, the body's largest consumer of oxygen. One of the main causes of mental deterioration with age is hardening arteries and high blood pressure, both of which result from decreased nitric oxide production/supply, oxidized lipids, chronic inflammation, autoimmunity, or other sources of endothelial dysfunction. Years of inactivity, especially coupled with poor nutrition habits, lead to endothelial dysfunction and a decreased oxygen supply to the brain. Thus, a major step in reducing mental deterioration over time may be consistently increasing the oxygen to the brain. In addition, exercise has been shown to increase brain plasticity through the increased production and expression of brain-derived neurotrophic factor (BDNF) [12].

Aerobic exercise increases the efficiency of the lungs in transporting oxygen into the blood and trains the heart to increase oxygen-rich blood to the body. Combining aerobic and resistance training lowers blood sugar levels and leads to a rise in the number of mitochondria in muscle tissue. Improved insulin sensitivity and glucose transport mean less glycation. Oxygen increases insulin sensitivity, particularly in muscle cells, efficiently transporting glucose as an easy fuel source for production of ATP energy for the muscles. A combination of aerobic and resistance exercise also increases the oxygen-carrying efficiency of hemoglobin and speeds up the general metabolism. It keeps the glucose, nutrients, and oxygen in the blood moving quickly through the system and saturating the body's tissues and cells.

Exercise training increases the transport and use of glucose in the cells and mitochondria by as much as 20 times. Inactivity contributes to insulin resistance by continually having too much glucose in the blood that must be transported by insulin into the cells or stored as glycogen or fat. Too much glucose creates an oxygen deprivation in which disease and pathogens can take root. Red blood cells contain hemoglobin molecules with an iron atom. A lack of red blood cell function means the body is deprived of oxygen. Hence, MET together with a low-glycemic, high-fiber, and mineral-rich diet build strong hemoglobin, increase blood flow, and ensure a highly oxygenated body. Proper oxygenation and adequate nutrient status ensure that all tissues are healthy. A copper and/or zinc deficiency increases glycation of hemoglobin and lowers the thyroid function, which is copper- and zinc-dependent [13].

35.2.1.2 Oxygen, ATP Production, and Nitric Oxide

A good example of the synergy of movement and nutrition is how all our cells produce adenosine triphosphate (ATP), our vital energy currency. To create ATP, the mitochondria must have access to oxygen. Hence, a major task for our respiratory and circulatory system is to deliver oxygen to the tissues so that our mitochondria can access it for energy. A basic prerequisite for health is a proper supply of nutrients and oxygen to our mitochondria for energy production and the disposal or recycling of waste products through aerophagia or biotransformation through, for example, the cytochrome p450 system. But this flow of life can easily be sabotaged, and one may become limited or incapacitated.

However, we can produce ATP energy units through the anaerobic system, which does not need oxygen. This system can produce energy for a short or limited time, but is not as effective as the aerobic system and creates excess lactic acid in the process. It may be viewed as a Plan B system for long-term energy production, but it is used as a Plan A system for sprint athletes and short interval exercise training.

Both physically fit and unfit people feel a burning pain when they do intense exercise that their body is unaccustomed to. A well-trained athlete, by contrast, is more efficient at converting excess lactic acid to glucose so the excess lactate content and the workout "burn" is reduced.

Good production of nitric oxide (NO) allows the endothelial tissue to be softer and more flexible. This enables more oxygen to reach the muscle cells for growth, function, and good ATP production. The enzyme nitric oxide synthase (NOS) produces nitric oxide by regulation of the protein caveolin. Nitric oxide (NO) is formed primarily in endothelial tissue.

Nitrate-rich vegetables and the body's production of nitric oxide and arginine are important precursors to form NO. Endothelial nitric oxide synthase (eNOS) keeps the cardiovascular system healthy. Arginine from food or supplements helps to synthesize eNOS, and citrulline keeps it circulating in the blood. Optimal NO production supports relaxed and healthier blood vessels, enabling better transport of oxygen to the cells. NO also has an anti-inflammatory effect and helps prevent blood clots [14]. Many endurance athletes drink beetroot juice or take nitrate-rich supplements to improve their performance through increased blood flow and oxygenation of muscle tissues.

Production of NO decreases with age, and most people eat few nitrate-rich plants, such as arugula, spinach, kale, pomegranate seeds, and beetroot. Furthermore, when we are out of balance, we can produce too much of a toxic form of NO called peroxynitrite. Peroxynitrite increases the risk of cardiovascular disease and diabetes, additionally poisons our mitochondria, and reduces the production of ATP [15]. Poor NO production, along with other factors like a slow metabolism, creates a poor blood circulation.

Box 35.1 Common Symptoms Associated with Poor Circulation

- Coldness in extremities, regardless of environment but worse when it is cold outside
- Headaches, including migraines
- Brain fog and poor concentration
- Varicose veins
- Swelling and water retention, especially in the ankles, neck region, and upper arms
- Fatigue
- Numbness in extremities that is not related to a pinched nerve

35.2.1.3 The Glymphatic System

A study published in a 2015 issue of *Nature* changed our understanding of anatomy and physiology by introducing a system of lymphatic vessels that circulate to the brain that had not been widely known or proven [16]. This study suggests we have underestimated the effects of the lymphatic system in health and disease, particularly brain health. The lymphatic system has been shown to play a major role in the immune system that influences neurological diseases. It has also been shown to be vital to brain health by increasing transport of oxygen and nutrients to the brain cells and by helping to carry away waste products that are a natural consequence of normal brain functioning. "In Alzheimer's, there are accumulations of big protein chunks in the brain," lead author Jonathan Kipnis said in a press release [17]. "We think they may be accumulating in the brain because they're not being efficiently removed by these vessels." In other words, increased lymphatic circulation and drainage by the glymphatic channels of the brain are important to brain health and prevention of cognitive impairment diseases. Old and new illustrations of the lymphatic system show a stark contrast of how limited our knowledge has been of the vast functions of the lymphatic-glymphatic system. The following pictures tell a thousand words (Fig. 35.2):

The new discovery emphasizes the importance of exercise and breathing in stimulating the flow of lymphatic and glymphatic fluids to and through the brain, increasing oxygenation of tissues and drainage of metabolic by-products.

There is no central pump for the lymphatic system. Lymphatic fluid is pumped through both movement and breathing. Diaphragm movement during deep breathing and physical activity are important stimuli for the lymphatic system. Adequate MET support a well-functioning lymph system. Massage, skin brushing, saunas, and other therapies also contribute to lymphatic flow. The lymphatic system's movement is so important to do abdominal breathing versus shallow chest breathing. Another reason is that abdominal breathing keeps you calmer and makes sure you spend more time during the day in the parasympathetic dominant state. This ensures that you are not in a sympathetic-dominant-stimulated state of stress for a long time.

Both abdominal breathing and increased circulation through exercise oxygenate muscle cells via the citric acid cycle. MET stimulates the movement of fluids in the lymphatic vessels and helps to transport waste from the cells. Evidence from the 2015 study in *Nature* suggests breathing and movement have a greater impact on brain health than previously thought. The reason this was overlooked is that the tiny lymphatic vessels are so intimately wrapped in the blood vessels, which move from the throat and sinuses through the brain. Drainage of waste by the glymphatic system works together with movement of the cranial spinal fluid. This extra movement of waste by the glymphatic system may partly explain why regular exercise has a protective effect against dementia and neurological diseases.

Poor lymphatic flow and blood perfusion due to inactivity contribute to crippled ATP energy production. The poor lymphatic flow hampers the filtering of waste products and extracellular debris. Restoring and ensuring healthy blood and lymphatic circulation through MET is key to all physiological, psychological, and biochemical functions.

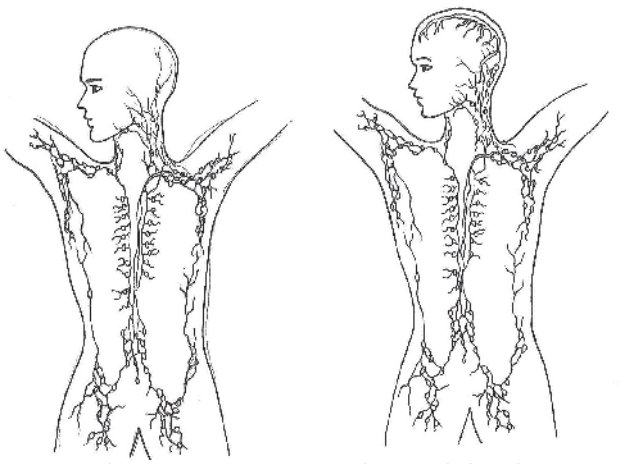

Fig. 35.2 Recent discovery in glymphatic anatomy and drainage

35.2.1.4 Pathophysiology Resulting from Lack of Oxygen and Energy

Nothing is more fundamental to life than respiration – the intake of oxygen and release of carbon dioxide. Healthy red blood cells (erythrocytes) absorb oxygen from the lungs for delivery to cellular tissues by a vast capillary network throughout the body. To support this process, the bone marrow produces a continuous supply of new blood cells, giving birth to two million new red blood cells every second. Each day, the body produces more than 200 billion new red blood cells, and at any given moment, there are more than 25 trillion blood cells in circulation.

Good blood circulation enriches the blood and cells with oxygen, transports nutrients throughout the body, helps manage waste production, improves muscle recovery, and accelerates healing. When circulation is compromised by aging, sitting too much, inactivity, disease, or other factors, the muscles may atrophy, and numbness and tingling can occur. Poor circulation increases the risk for serious health threats, including stroke, hypertension, and kidney failure.

Over time, consistent MET strengthens the vessels and the heart. One reward of consistent MET is a stronger heart and a lower pulse. A pulse below 62 beats per minute and a blood pressure under 120/80 are generally considered protective signs that decrease your risk for chronic disease, especially cardiovascular disease. Even your risk for psychological disturbances, substance abuse and violent behavior are reduced by MET, according to a 2016 Karolinska Institute study conducted on one million Swedish men [18].

A strong heart and healthy endothelial tissue contribute to excellent blood flow, requiring less work to transport

nutrients, carry away waste products and oxygenate the cells. Hypertension is still considered the largest risk factor for cardiovascular diseases and the combination of a healthy diet, an appropriate MET program and improved stress reduction may improve health and decrease mortality risk.

35.2.2 Nutrients Play a Key Role

35.2.2.1 Key Nutrient Patterns for Better Energy and Health

Macronutrients, carbohydrates, amino acids, or fats are needed for conversion into fuel for the citric acid cycle. Nutrients such as citric acid, malic acid, and fumaric acid are needed for the cycle to create energy, which will enter the final stage of energy production, oxidative phosphorylation. B vitamins and metabolites NAD and NADH are needed as cofactors in the citric acid cycle. Magnesium and coenzyme Q10 are important for oxidative phosphorylation to work. Antioxidants are needed in the body to take care of the free radicals produced as a waste product from the production of energy. Nitrates are needed for optimal production of nitric oxide, which provides optimum oxygenation to the cells. B vitamins and other nutrients may be needed to ensure that the methylation and other cellular functions work and keep our mitochondria, DNA, and RNA in balance. Oxygen is needed for the whole process of aerobic energy production to work at all.

For blood to be able to carry oxygen to the cells, it needs hemoglobin. In adult men, hemoglobin concentrations can range from 13.5 to 18 g/100 ml of blood. In adult women, the concentrations vary from 11.5 to 16.4 g. The following factors are among the most important reasons that affect the amount of hemoglobin in erythrocytes: nutrients such as iron, vitamin B12, folic acid, and the availability of nitrates, proteins, fatty acids, elevation, and oxygen supply. The most important factor, however, is movement and exercise. Well-trained elite athletes usually have very high hemoglobin levels and thus have an excellent transport of oxygen to the muscle cells.

Through the combination of MET and nutrition, as well as certain genetic and epigenetic factors, you reach optimal transport of oxygen to the muscle cells. With moderate to intense MET, you can produce at least 30 times as much ATP compared to a resting state. During intense exercise, such as sprint intensity training (SIT), you can use more than 1000 times more ATP than in the resting state. After 10–15 seconds, the normal ATP production takes place through anaerobic and aerobic combination, instead of only via anaerobic metabolism.

35.2.2.2 Nutrients for Oxygen Transport

Here are some of the ways that nutrients and oxygen work hand in hand:

- The B vitamins B12 and folate are necessary to produce red blood cells.
- Iron is important for the transport of nutrients and oxygen through healthy hemoglobin transport in the blood.
- Vitamin C is essential to the uptake and utilization of iron.
- Vitamin E helps transport oxygen to the blood cells.
- Vitamin K2 increases the oxygen-carrying capacity of the hemoglobin in red blood cells. Vitamin K2 and nitrates in foods, amino acids arginine, and citrulline and nitrates eaten in a plant-based diet through the intake of spinach, red beets, pomegranates, arugula, and other nitrate- and chlorophyll-rich greens all aid in the status of healthy endothelial cells. This increases blood flow and oxygen transport. Inactivity, lack of chlorophyll and minerals, lower oxygen levels in the air, and air pollution all contribute to low oxygen.
- Magnesium enhances the binding of oxygen to heme proteins and gives red blood cells the flexibility to enter tiny capillaries. Magnesium also stimulates the movement of oxygen atoms from the bloodstream to the cells and prevents blood vessels from constricting and platelets from sticking together. Calcium and magnesium aid in the transport of oxygen into the cell. Magnesium is also needed to shift calcium in and out of cells, thereby providing the correct pH for high-cellular oxygen. Magnesium-deficient individuals use more oxygen during physical activity, which in turn produces more free radicals.
- Antioxidants found in foods, phytochemicals, amino acids, vitamins, and minerals help the body use oxygen better and protect against damage by free radicals formed when excess oxygen is produced in intense exercise or overexertion. Copper, manganese, and zinc are used by the body to synthesize superoxide dismutase, a potent antioxidant enzyme. This is extremely important in the body's defense against oxidation and the accumulation of excess glycation, so-called aggregated glycation end products which contribute to systemic oxidative stress and disturb the proper function of proteins.

35.2.2.3 Nutrients for ATP Production

What can affect or limit ATP production? Energy production will gradually become less efficient with aging, especially after one is in their 40s. Infections, such as mycoplasma infections and Lyme disease, meningitis, heavy metal poisoning, and poisoning from chemicals or plastics, can all limit ATP energy production. Lack of oxygen and ATP-rich nutrients, such as, CoQ10, B2, NADH (niacin metabolite), B5, B6, and magnesium, may also limit energy production. The bases for protecting and optimizing the mitochondria are lifestyle factors, access to optimal amounts of oxygen, macro- and micro-nutrients and minimal exposure, and storage of environmental toxins.

It has been found that the coenzyme Q10, the active form of folate (5-methyltetrahydrofolate, 5-MTHF), grape seed extract, lipoic acid, melatonin, artichoke, the herb selfheal (*Prunella vulgaris*), and naturally occurring polyphenols and other phytochemicals present in beetroot, olives, olive oil, tomatoes, cocoa, ginkgo biloba, pomegranate, and hawthorn berries all contribute to normal NO production. These promote good circulation and oxygenation and also provide protection from the overproduction of peroxynitrite. Nutrition

for better absorption of oxygen can be found in nitrate-rich vegetables (e.g., arugula, kale, beets, etc.), arginine, citrulline, CoQ10, magnesium bisglycinate, B-complex vitamins, and vitamin E complex.

Box 35.2 Twelve Tips for Better Mitochondrial Health

1. Regular physical activity equivalent to at least 12,000 steps per day.
2. A plant-based diet with a low-glycemic index.
3. Avoid gluten and possibly other substances/foods that you may be allergic or oversensitive to.
4. Frequent mild detox and detox cures for a few weeks, several times a year.
5. Abdominal breathing and, if possible, treatment for the lymphatic system through massage, sacro-cranial treatment, dry brushing, saunas, and relaxing Epsom salt or herbal baths.
6. Extra intake of nitrates from arugula, spinach, beets, pomegranate, and supplements of nitrates from concentrated red beet juice or juice-concentrated powders or capsules.
7. Good sleep, staying calm, and using a stress management program as an everyday part of life.
8. Use clean-toxic-free products in terms of hygiene, cosmetics, food, etc. and gradually chelate accumulated heavy metals and chemicals in tissues by eating organic veggies, sprouts and regularly using spices such as tumeric, cayenne, cilantro, rosemary, oregano and basil. Regular use of green superfood powders such as chlorella, spirulina and wheat grass is a great way to gentle move out toxins from the body.
9. Mitochondrial-supportive supplements, such as CoQ10, ribose, L-carnitine, acetyl L-carnitine, resveratrol, vitamin B complex, magnesium, and lipoic acid.
10. Extra methylation supplements if necessary and if there are gene deviation (DNA testing) and elevated homocysteine levels above 8 from blood testing: Vitamin B6, B12, folic acid, choline, betaine, trimethylglycine, or SAMe supplementation will most likely improve homocystein levels and methylation functions.
11. Acupuncture for better energy.
12. Adaptogenic herbs: *Astragalus*, ashwaganda, eleuthrococcus root, arctic root, ginseng.

    The addition of nutrients, herbs, or low-dose aspirin that counteract blood viscosity. The most common blood thinning supplements are omega-3 fatty acids, garlic, gingko, and meadowsweet. These are especially valuable for elderly people, or those at cardiovascular risk.

35.2.2.4 Unique Considerations for Cardiometabolic Syndrome

Cardiometabolic syndrome is a term which recognizes the common development of cardiovascular diseases due to an etiology of the combination of insulin resistance, obesity, and inflammation. From a functional medicine perspective, we would add other contributing factors such as inactivity, nutritional imbalances, and toxicity.

Insulin resistance and glycemic control are influenced by many mechanisms. MET seems to be one of the most effective strategies in helping the body maintain healthy blood sugar. MET stimulates 5'-AMP-activated kinase that influences GLUT4 glucose transport of glucose inside the cell. Another way it helps is by influencing insulin pathways and modulating inflammation-signaling pathways. Modulation of these pathways is dose-dependent [19]. Aside from inactivity, other lifestyle factors reported to impact insulin resistance are xenoestrogens, obesity, stress, and dietary factors.

Even though one can approach the challenges of insulin resistance with weight reduction, biotransformation/detoxification of chemicals, caloric or dietary restrictions, or use of supplements such as chromium and cinnamon extract, MET or pharmaceutical therapies such as metformin, a more ideal approach is to use a combination of lifestyle therapies to affect improvement either before or in conjunction with food supplement or pharmaceutical support. A simple but consistent lifestyle support program has been shown to be very effective in affecting positive change. One 2002 study showed better improvement with lower costs compared to taking the pharmaceutical metformin [20].

A healthy and fit person can really enjoy a great level of aerobic fitness by doing 45–120 minutes of MET, but this dose is too much, of course, for one who is not well-trained, or for a person with pathology or strong risks for problems, such as those who are obese, take lots of medications, or have past or current cardiovascular diseases. A study conducted at Mayo Clinic in 2012 found that, for cardiovascular patients, the optimal dose is more likely to be 30 minutes a day of moderate training instead of the 60–90 minutes for the very fit. For these cardiovascular patients, too much oxidative stress is initiated with 60-minute moderate or vigorous MET. The strongest risks are at a sustained effort of vigorous exercise such as long interval training [21].

Box 35.3 Improvement of Cardiometabolic Markers

The following cardiometabolic markers have been shown to be improved by regular exercise training:

- Lipid, inflammation, and glucose profile:
  - Trigylceride (Tg)
  - HDL
  - LDL
  - Fasting glucose, glucose stress test
  - Fasting insulin, insulin stress test
  - HbA1C (long-term sugar management)
  - Hs CRP
  - Uric acid
  - Homocysteine
  - Fibrinogen
  - Lp_PLA2
- VAP advanced lipid profile:
  - Apo B, Apo A1 and or Apo B/A1 quota
  - VLDL 3
  - HDL 2
  - Lp (a)
  - GGT (oxidative stress/toxicity marker)

The level of intensity of aerobic training estimated to improve cardiorespiratory fitness has been 69% exertion of maximum heart rate (max HR). This is considered to be moderate training pace, where you can carry on a strained conversation, or a 6–7 out of 10 on the scale of exertion, a 13–15 on the Borg

scale of 1–20 of exertion. This level of exertion is also considered the minimal effective dose for improving cardiorespiratory fitness. It is also a rate where you are burning about 45% fat and 55% carbohydrates as fuel.

Box 35.4 Functional Medicine Causative or Contributing Factors

- Insulin resistance
- Toxicity
- Oxidative stress
- Inflammation
- Endothelial dysfunction, dyslipidemia
- Hormonal
- Genetic, epigenetic factors
- Dysimmunity, autoimmunity
- Energy, mitochondrial dysfunction
- Microbiome
- Structural
- Tissue Perfusion—blood and lymph and maintenance of muscle mass
- Emotional, mental, spiritual

In addition to the challenges of the pathophysiology of the combination of insulin resistance and cardiovascular irregularities or dysfunction, a functional medicine-trained nutritionist will also investigate other underlying processes, which may be important parts of the etiology or contribute to the problems. Most of these processes will be influenced by increases in various types of physical activity. I have even added tissue perfusion, increased cardio conditioning, and increased muscle mass as a solution to one of these functional medicine links in the causal chain of chronic disease. Regardless of the mechanisms and processes, people are most concerned about the length and quality of their lives. The bottom line is that MET gives you the most "bang for your buck." Better aerobic conditioning gives you not only a longer life but a better quality of life.

- Among other things, VO_2 max is correlated with both lowered morbidity and mortality [22].
- Chromosome telomere length, which is a predictor of health and longevity, is spared for those who have a better VO_2 max [23].
- Telomere length (mitochondrial mitogenesis) is increased by exercise [24].
- Epigenetic studies show that activity helps modify DNA signaling [25].

35.2.3 MET: Powerful Prevention and Treatment of Chronic Disease

Not only is MET vital for prevention of disease and rehabilitation of injuries; it is often very powerful for alleviating suffering, increasing quality of life, restoring function, and assisting in improving states of pathophysiology. The following are only a few of the many chronic disease states where MET has shown to be a valuable in conjunction with other treatments.

35.2.3.1 Types of MET

Integrated standing, movement, and exercise training (ISMET) is a vital part of a holistic and integrative lifestyle strategy to promote healthy aging and decrease the ravages of chronic disease. Standing, movement, and exercise training maintain or upgrade normal physiological and biochemical functions, thereby preventing breakdown of function and development of progressive pathology.

ISMET should be part of a holistic lifestyle prescription and support system like that which has been repeatedly implemented by Dr. Dean Ornish. In several of his studies, where movement and exercise training (MET), meditation, nutrition, supplementation, and psychosocial support are implemented as an integrative system, intensive lifestyle changes may affect the progression of prostate cancer [26]. Depending on the patient-doctor/lifestyle coach interaction, a comprehensive lifestyle program can be suggested and negotiated, with the proper support system, inspiration, and knowledge to implement the program. In integrative and functional medicine, the increasing model has shown that it takes a team or network of professionals or lay coaches to help the patient turn their life around and integrate new habits of health into their lives.

ISMET is as an important part of these regenerative changes and strategies as dietary changes or psychosocial changes. These types of integrated comprehensive programs have been shown to often be effective in various types of chronic disease [27].

Although setting a goal of walking the equivalent of more than 10,000 steps daily is admirable, and will improve your health or disease status, setting more specific goals for whole body training is even better. The integrative model I am recommending with the acronym, ISMET, involves improvements in the following areas:

1. More standing, less sitting, the 12–12 rule (12 hours sleeping and sitting, 12 hours standing, moving or exercising)
2. More habits of incidental movement
3. Walking and play, hobbies, and extra activities
4. Exercise training, both planned and spontaneous

The planned or habitual MET can be a combination of aerobic and anaerobic activities and can include a combination of dancing, playing, endurance training, interval training, strength/resistance training, and flexibility and balance training (i.e., yoga, stretching). If possible, spend some of this time in a natural environment, such as beaches or paths through wooded areas or near lakes. Nature deficit disorder, as identified in 2005 by the author Richard Louv in the book, *Last Child in the Woods*, emphasized the added bonus of health benefits and joy in playing, moving, and exercising in a natural environment.

Box 35.5 Good Tips for Starters, from Inactivity to Active Movers

Some good tips for those who are starting to exercise:

- Start slow and start small.
- Work out at a time of the day when you have more energy.

- Find activities that bring you joy or connection with people, your tribe.
- Be comfortable and use the right clothing, shoes, and gear.
- Reward yourself for successes and consistency.
- Make exercise a social activity with friends or community groups. Community exercise groups are effective. This has been demonstrated repeatedly in lifestyle support groups, such as those formed at Saddleback Church, called The Daniel Plan (▶ www.danielplan.com).
- Use apps, technology, and tracking devices to see improvements and for coaching.
- Keep gradually increasing the MET dose as your motivation and goals grow, but be careful, gain knowledge and experience before doing extreme sports. Extreme exercise, such as triathlon training and competition, can easily cause too much oxidative stress, gastrointestinal disruption, inflammation, injury, hormonal disturbances, anemia, eating disorders, osteopenia, etc.

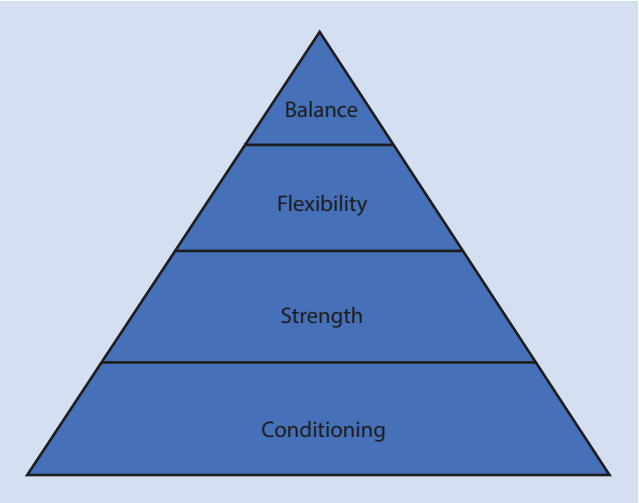

Fig. 35.3 MET pyramid

35.2.3.2 Key Exercise Patterns for Better Energy and Health

Traditional exercise trainings, such as yoga, tai chi, and qigong, have proven through centuries of use to be important for both the health and well-being of individuals and cultures. One of several thousand studies on these ancient practices shows increased quality of life for the elderly [28]. These practices not only involve movement but also concentration, balance, stretching, meditation, breathing, and stress management. These are an excellent complement to aerobic conditioning training, which is the base of the MET pyramid.

Box 35.6 ET Training Pyramid
Cardio or aerobic training is the base of the pyramid of training. It is important that everyone has a basic level or energy and endurance. The next three levels are maintaining the goals of having strength, flexibility, and balance. These levels provide great fitness focuses for goals to help prevent sarcopenia, accidents, falls, and development of chronic disease (Fig. 35.3).

Many people struggle with scheduling movement and MET into their daily lives; but by simply increasing your amount of incidental activities and planning regular MET sessions, you can enjoy more movement and health. All it takes are a few small changes of habit, like parking farther from work, taking public transportation, bicycling more, walking to nearby neighbors' homes or stores, walks and talks with colleagues or friends, taking the stairs regularly, more play with the kids or grandkids, walking somewhere in the building every hour at your workplace, and more house cleaning, yard work, or gardening. Such changes can add the equivalent of 2000–6000 steps per day. After a few weeks, it has become a lifestyle habit and you don't notice it. It is now on autopilot. This is especially important if you have an occupation, workplace, or home environment that is not conducive to movement.

Walking is a great place to start for an inactive person who wants to become active. One can always start low and go slow to avoid pain and injury. If one has a difficult time taking an extra 30–60-minute walk every morning or evening, taking 3–6 shorter walks will accomplish a similar result. Using a pedometer or step monitor is one of the easiest tracking tools for your health. Devices worn on the belt, wrist, or as a wristwatch can measure the amounts of steps the wearer takes per day. Minimal recommendations usually suggest 4000 steps of incidental activity and 3000 steps of walking, for a daily total of 7000. A 30-minute power walk will give you about 4000 steps.

According to many public health recommendations, you should create a habit where you spend at least 30 minutes a day walking 5 days per week to accumulate at least 15,000 weekly steps [29]. This recommendation, while modest, is deemed sufficient for creating better health and decreasing risks for chronic disease. A breakthrough book in this field, *Biomarkers*, was published in 1992 by Evans and Rosenberg at Tufts University. This book shows that even walking 30–60 minutes five times per week, when started by obese/overweight individuals, improves key biomarkers of health and disease. These improvements are easy to track and measure with blood tests, a tape measure and bio impedance calculations.

Exercise goals and types vary quite a bit depending on one's situation and personal wishes. To make progress with obesity, one most often needs to exercise more than those who are just looking for a minimal amount of exercise or steps for general health. Eating the right amounts and kinds of nutritious foods is also important.

As seen below, certain levels of movement and exercise training have positive effects on insulin resistance and metabolic resistance. However, consistency is the most important key. Even modest progress can be noticed when you are walking every day. The best form of exercise is that which you do consistently.

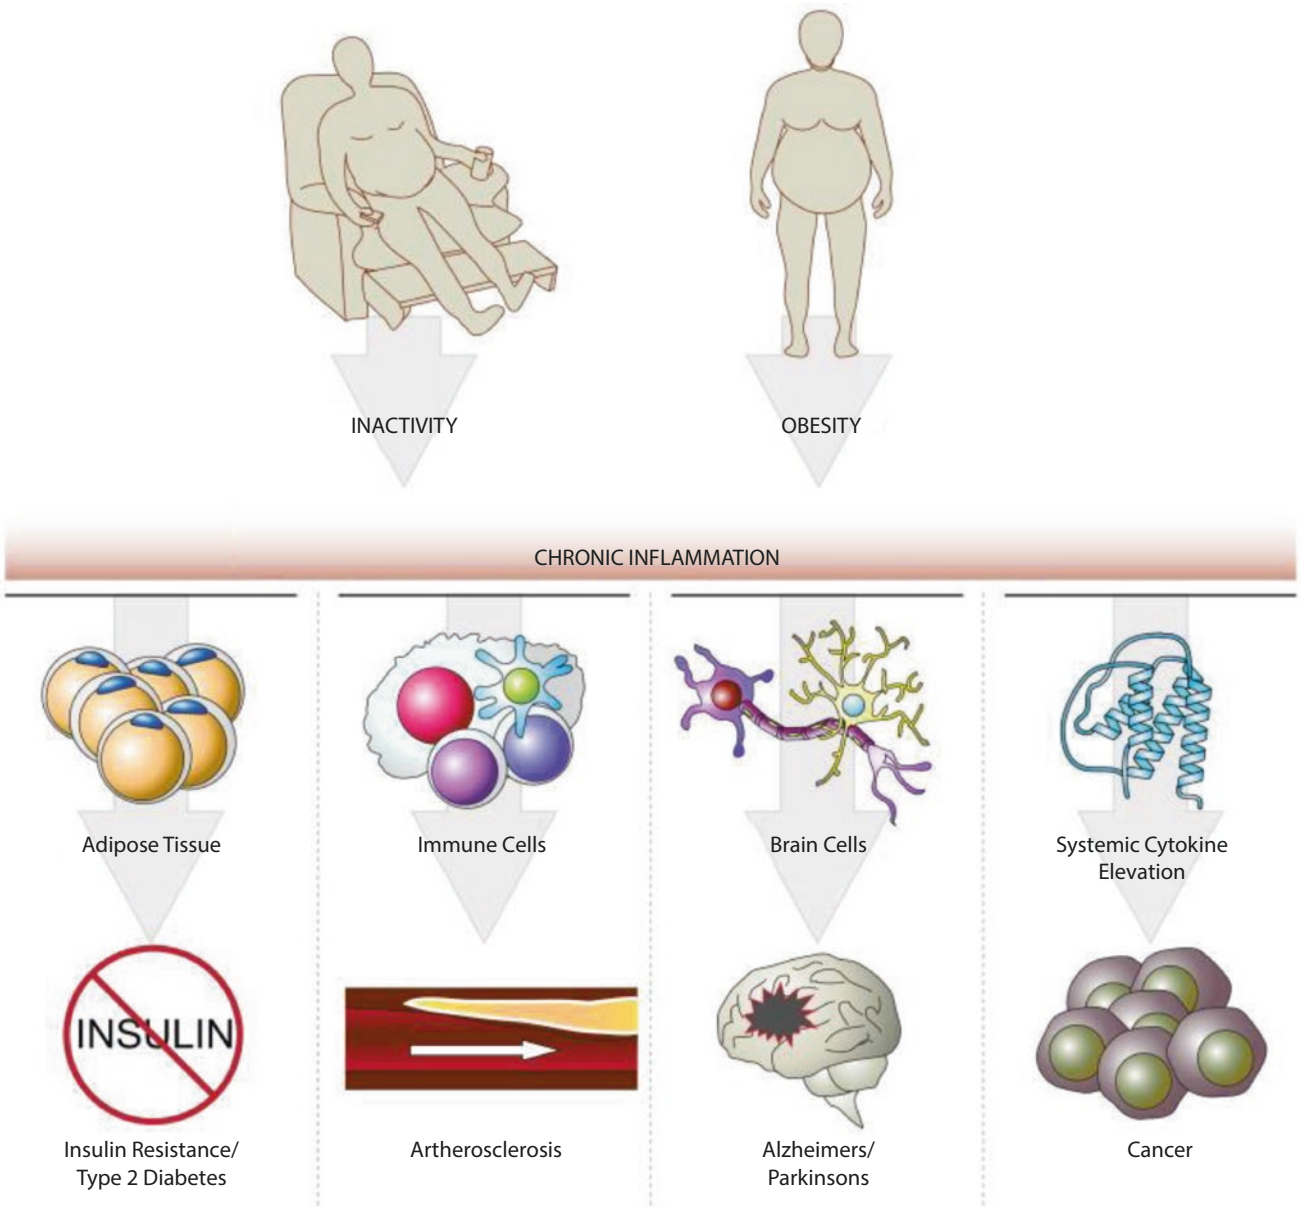

Fig. 35.4 The role of nutrition and exercise in the mechanisms of pathology or in pathophysiology. (Reprinted from Handschin and Spiegelman [39]. With permission from Springer Nature)

Box 35.7 Step Goals

The following is a guideline for amounts of steps to aim for each day, on average. This includes incidental activities, walking, play, and planned movement and exercise training (MET):

- Inactivity contributing to chronic disease (<5500 steps daily)
- Some improvements in immunity functions and health markers (>7000 steps daily)
- Metabolic syndrome/insulin resistance improvement (>8000 steps day)
- BMI-defined weight status improvement (>10,000 steps daily)
- Optimal daily steps matching our physiological needs and our historical past (>14,000 steps daily)

Taking 7000–10,000 steps per day from incidental activities, movement, and walks should be seen as the minimal amount of effort for combined daily movement and planned exercise time. If you do a moderate-to-intense gym workout, dancing, aerobics, or strength training, you can count that as 2000–4000 equivalent steps per half hour, depending on the level of intensity/challenge.

A more optimal number of steps per day would be 12,000–20,000 steps with combined, incidental movement, play, walks, and MET (planned movement and exercise training). The more natural and healthy cultures on the planet, the "Blue Zone" communities, have a daily average of 18,000–24,000 steps movement. This also reflects the

amount of movement many of our ancestors had many centuries ago. These goals should also be an excellent complement to the habit of sitting less.

My recommendation is the 12–12 rule. Out of your daily 24 hours, spend 12 of them sleeping and sitting, and spend the other 12 moving and standing. Moving more at work and home, exercising regularly and using a standing work desk are some measures that can help you reach the 12–12 balance for greater health. MET should be put in a context of good technique, body posture, and lots of standing during the day. I refer to this healthy habit as integrated standing, movement, and exercise training (ISMET).

Box 35.8 Get the Blood Flowing and Keep It Flowing

- More standing and less sitting. No more than 4 hours per day sitting, 7–8 hours of sleeping, and the rest of the time should be standing or moving. The 12–12 rule of ISMET.
- Movement improvement, incidental activity producing >6000 steps daily.
- Planned exercise at least 4 hours a week, whether at the gym, dance studio, in the outdoors, or at home looking and following a DVD/online workout program. For two to four sessions per week, transition from walking to power walking, Nordic walking (walking with poles), cardio workouts, running, biking, swimming, spin cycling, or cross training for a more strenuous workout.
- Fidget and move at a standing desk. Taking a break every hour for some walking, doing squats, stretching, yoga poses, or having a walk-and-talk meeting with a colleague.
- Lots of little movements and stretching throughout the day. Keeping all body parts moving every day. A good stretching program like yoga helps stimulate blood flow and balance to all parts of the body.
- Consuming more spices like cayenne, cardamom, ginger, garlic, rosemary, sage, and pepper to stimulate and assist in increased blood flow and perfusion of the tissues.

The best types of ISMET exercise programs are the ones you do consistently. It is ideal if your planned exercise training contains some of the following ingredients:

- Personal health and fitness goals.
- Social support, exercising with friends.
- Competition, if it challenges you and motivates you. The FITTPRO model, found at ► www.exerciseismedicine.org, can give basic guidelines about frequency (5–7× weekly), intensity (50–70% mHR), type of exercise (mixing aerobic, resistance, and strength), duration (30–60 minutes), and suggestions for increasing these factors by 10 percent per week.
- Overcoming or improving states of illness, personalized goals, and programs.

Box 35.9 Types of Exercise Training

The following flow chart can depict basic types of training that can be combined and coordinated for whole-body MET. These play different roles in building physical and psychological health and resilience. Together with my 12–12 recipe for more standing and movement, these areas illustrate the ISMET model:

- Aerobic training builds endurance and cardiovascular and psychological health.
- Anaerobic training such as sprint intensity training (SIT) or high-intensity interval training (HIIT) builds and maintains muscle mass, speed, stimulating hormone production, and a healthy metabolism.
- Flexibility and balance training, such as tai chi and yoga, balances muscles and enhances breathing, flexibility, and balance.
- Strength and resistance training builds strength and power, stimulating hormone production and protects from sarcopenia.
- Play, gardening, dance, and sports activities can balance other times of training and bring extra fun and variation to the mix of MET.

Physical therapy and targeted training are specialized trainings to achieve specific physical goals or target specific muscles, muscle groups, or function.

Moderate aerobic exercise training, high-intensity interval training (HIIT), and sprint intensity training (SIT) have been shown to be effective in improving the symptoms and progression of chronic diseases. Different forms, doses, and combinations of these are appropriate for different individuals and needs. HIIT can be twice as effective as moderate-intensity aerobic training for people with lifestyle-induced diseases [30].

Dr. Phil Maffatone, who has trained over 10,000 amateur and elite athletes, recommends that at least 80% of your training time should be in the low-moderate fat-burning endurance zone, which he basically calculates with 180 minus your age. When you do your MET, you can mix up the above types of training, so that each of these types is done each week. When time is an issue, you can get a great workout in 15–20 minutes with HIIT or SIT workouts.

Box 35.10 Training Zones

The number 220, minus your age, is the most common way to, on a gross level, estimate the maximum pulse/heart rate (max HR) or the liverpool model for calculating your max HR which is often a little more accurate. Take 217 minus your age times 0.85. The following are the amounts of effort and heart rate that give different kinds of advantage:

- 50–75% of your max HR for aerobic conditioning and endurance training (55–65% of this is the max fat burning zone). Long MET sessions of 1–3 hours
- 75–95% max HR for medium to hard training, where sprinting and intervals are done. Short-duration MET training. 15–60 minutes including warm-ups and cool down

Box 35.11 Training Intensity

Training intensity guidelines vary but are also, for the most part, similar. ACSMs (American College of Sports Medicine) guidelines and other organizations (► www.acefitness.org) can be summarized as the following:

- 220 minus age and then the following level of effort (Borg scale of 1–20 and percentage of max heart rate):
  - Low effort, Borg scale: 9–12: 50–63% of max HR (you can sing)
  - Moderate: Borg scale: 13–14, 64–76% of max HR (you can talk)
  - High/intense effort: Borg scale: 16–18, 77–93% max HR (you cannot talk)

35.2.3.3 Fitness and Lifestyle Assessments

Fitness assessments are offered in many training centers and gyms. There are also plenty of these available online or in books or clinic brochures. One of the simplest is doing the following four easy tests that can assess your fitness, but these fitness tests and others should be combined with anthropometric testing, a physical exam and lab analysis for a more comprehensive personal analysis.

1. The push-up test (measures muscular strength and endurance)
2. The crunch test (measures abdominal strength and endurance)
3. The 3-minute step test (measures aerobic fitness)
4. The 1-mile walk test (measures aerobic fitness)

Nutritionists, dieticians, and lifestyle coaches can use clinical questionnaires to evaluate the ISMET status of the client/patient and then follow up with coaching, either online or via office visits. There are many online questionnaires, including ones accessible in the functional medicine tool kit for those who become members of the institute for functional medicine (► www.functionalmedicine.org).

35.2.3.4 Integrative Lifestyle Therapies

Integrated standing, movement, and exercise training (ISMET) is a vital part of a holistic and integrative lifestyle strategy to promote healthy aging and decrease the ravages of chronic disease. Standing, movement, and exercise training maintain or upgrade normal physiological and biochemical functions, thereby preventing breakdown of function and development of progressive pathology. ISMET can be part of an integrative system of overall lifestyle changes that include meditation, nutrition, supplementation, and psychosocial support.

It would be great if we can expand our recommendations from nutrition programs to comprehensive lifestyle programs, such as the ones that Dr. Dean Ornish has repeatedly shown are very powerful [31].

Incorporating an integrated lifestyle program that includes a personalized ISMET strategy will be more common in the days and years to come as the science and experiences emerge that confirm the efficacy and power of patient/consumer driven self-care and healthcare. The convenience of the information and technology revolution will both bring increased temptations that distract from ISMET, while making available technology – such as wearable-monitoring devices – that will drive and increase the efficacy of personalized lifestyle medicine programs. As the science and monitoring technology evolve, we will be able to prove to ourselves and others the value of ISMET and lifestyle medicine.

35.2.3.5 Both Undertraining and Overtraining Can Lead to Higher Disease Risk

The effects of physical activity on markers on specific IGF-1 markers for disease prevention can be seen in a study from Poland conducted in 2015. The study demonstrated that MET has a positive effect on the balance of IGF-1 and IGFBP in the blood, therefore contributing to prevention of disease through the proper regulation of these important signaling molecules. The majority of these studies indicate that mechanical loading is a key mechanism linking IGF-1/IGFBPs concentration and selected chronic diseases development. The duration and intensity of physical activity have a significant impact on IGF-1 and IGFBP serum. The highest concentration of IGF-1 in serum was after eccentric training. "Overtraining" increases unfavorable and unbound IGF-1 levels and contributes to the increased incidence of hormone-cancer and osteoarthritis. Irregularity of the GH/IGF-1 axis may affect the development of rheumatic diseases, metabolic syndrome, and cardiovascular diseases [32].

35.2.3.6 Single Exercise Training, Combined Exercise Training, and Lifestyle Programs

Many studies show examples of improved insulin resistance, decreased metabolic syndrome and decreased diabetes markers, and pathology with exercise training. However, these studies can also be looked at comparing the effects of endurance training, strength training, and total lifestyle programs. One study with 250 adults showed benefits with both endurance training and strength training, but the improvements were even greater when these two were combined. Even more improvement came after combining endurance and strength training and using a more comprehensive exercise, diet, and lifestyle program [33].

Several lifestyle intervention programs have demonstrated that a comprehensive program including diet and exercise is much more cost-effective and successful than pharmaceutical intervention with the drug metformin for the treatment of diabetes [34, 35].

35.3 MET and Nutrients for People with Various Conditions

35.3.1 Commonalities Across Conditions

35.3.1.1 Therapeutic MET for Rehabilitation (TMETR)

Most hospitals and many clinics and private practices have programs for rehabilitation of sports injuries; auto-, home-, or work-related accidents; war casualties; and various forms

of physical limitations or handicaps. This can involve the use of many physical modalities, machines, body work, exercise prescriptions, and surgical procedures that are used by many different types of trained professionals. That which is in its infancy, however, is the aggressive use of TMETR for chronic disease unrelated to acute accidents or injuries.

Although the American College of Sports Medicine (► www.acsm.org) and institutions in many countries, including my own country of Sweden, have some guidelines (► www.fyss.se) for TMETR for specific chronic conditions, these are seldom used in the clinical practice. Primarily, as with personalized nutrition programs, there is no or very little training of doctors, nurses, dietitians, health coaches, chiropractors, physical therapists, or acupuncturists, concerning the use of exercise prescriptions. The field of TMETR for chronic disease states is still very young, especially compared to the use of TMETR in physical rehabilitation from injuries. Until the value of TMETR for chronic disease application is further studied, used, and incorporated into health professional training, the use of TMETR will be an underutilized powerful asset in the similar way personalized nutrition has been.

I will present information that introduces and validates TMETR not only for injuries but primarily for chronic disease states. In the functional medicine model, as eloquently stated by one of the pioneers in medicine, William Osler, "The good physician treats the disease, the great physician treats the patient who has the disease." We are more interested in understanding and caring for the patient than for the disease. "The patient is more important than the disease the patient has." Following some guidelines of aerobic and strength training for a disease state is helpful, but ultimately that information and recommendation must be adjusted to each patient. So TMETR must ultimately be personalized to the living situation, family and support group, limitations, possibilities, socioeconomic status, motivations, goals, and aspirations of the unique person with the disease.

Box 35.12 Seven Great Goals for TMETR Is to Restore Health

1. Personalize, communicate, and coach the TMETR.
2. Alleviate suffering.
3. Halt and reverse pathology.
4. Restore and improve function.
5. Improve quality of life.
6. Build resilience/organ reserve/organ capacity.
7. Reduce risk for chronic disease reoccurrence.

35.3.1.2 MET and Physical Therapies for Injuries

MET and correct physical therapy is a very important adjunct to knee surgeries and other medical procedures. Many times, the correct use of MET and physical therapy can substitute for surgery and bring as good as or better results than surgery and at a much lower cost. According to medical investigator Norman Swan, about 20% percent of knee replacement costs (over $1 billion) incurred by the Australian healthcare system were unnecessary [36].

35.3.1.3 Unique Considerations for Inflamm-Aging, Cardiometabolic Disease, Dementia, Sarcopenia and NAFLD

In the following sections, we will investigate four chronic complex conditions that cause a great deal of suffering and a huge strain on our healthcare system. These are also models of how an integrative lifestyle program, including diet, MET, and food supplementation, can be combined to achieve very good results. These four conditions are cardiometabolic syndrome, dementia/Alzheimer's, sarcopenia, and nonalcoholic fatty liver disease (NAFLD). Their common etiology is a combination of underlying causes such as toxicity, chronic insulin resistance, toxicity, and inflammation that are causative or a result of these problems. If we scratch below the surface of these conditions, we will find the same culprits that are causative: insulin resistance, inflammation, toxicity and obesity, inactivity, poor stress management, poor food choices, cigarette smoking or toxins in the environment, and other lifestyle factors. These factors potentiated by genetic and epigenetic factors often lead to years of suffering from chronic diseases that transgress across body systems and disease. First, however, let us examine the process of chronic inflammation on disease etiology and progression.

Inflammation control: moderate MET decreases the risk of chronic inflammation. Moderate endurance and strength training have been shown to decrease chronic inflammation, and flexibility and balance exercise practices, such as yoga, have been shown to lower inflammation markers. Ambarish Vijayaraghava and his research colleagues revealed in a fascinating study that, "Regular practice of yoga lowers basal TNF-α and IL-6 levels. It also reduces the extent of increase of TNF-α and IL-6 to a physical challenge of moderate exercise and strenuous exercise" [37].

The nutrient and oxygen needs of the mitochondria are very important also to prevent mitochondrial inflamm-aging, a chronic low-grade inflammation leading to dysfunctional mitochondria and oxidative stress. The microRNAs are involved in this process, which is hypothesized in an article in *Experimental Gerontology* from 2014 [38].

This chronic inflamm-aging in the mitochondria, which occurs in some hard-training athletes, can perhaps account for damage to heart and muscle cells from overtraining. Intense exercise for long periods of time increases the risk of chronic inflammation [39].

Elite training runs the risk of both injuries and chronic inflammation, if the training, sleep, and nutrition protocols are not carefully planned and monitored. Antioxidant and anti-inflammatory foods and supplements can balance this and protect from meta-inflammation or injuries.

The big culprit in creating chronic inflammation in our society is not overtraining but inactivity, in combination with inflammation-stimulating processed foods. The following illustration shows how inactivity and obesity contribute to inflammation (◘ Fig. 35.4).

Box 35.13 Impact of Sarcopenia

- On an individual level:
  - Sarcopenia greatly diminishes independence and quality of life.
  - Sarcopenia reduces individual health and happiness.
  - Sarcopenia increases the processes of inflammation and insulin resistance that underlie the progression of many types of diseases.
- On a societal or public health level:
  - Sarcopenia increases the risk of all-cause mortality and disability.
  - Sarcopenia puts every patient who has surgery at greater risk of complications.

35.3.2 Sarcopenia

Sarcopenia, the loss of muscle tissue that is primarily a by-product of the aging process and inactivity, contributes to obesity, diabetes, dementia, and the cardiometabolic syndrome. The main cause of sarcopenia is physical inactivity, especially lack of resistance training. Muscle loss and fat gain is reversed by fitness and resistance training.

Sarcopenia and the aging process are associated with less efficient function of the mitochondria, the effects of which were well summarized in an article by Marita Rippo et al. in Experimental Gerontology in 2014. "Mitochondria are intimately involved in the aging process. The decline of autophagic clearance during aging affects the equilibrium between mitochondrial fusion and fission, leading to a build-up of dysfunctional mitochondria, oxidative stress, chronic low-grade inflammation and increased apoptosis rates, the main hallmarks of aging" [40].

Box 35.14 Multifactorial Causes of Sarcopenia

Like most chronic conditions associated with aging, sarcopenia has some multifactorial causes associated with the following imbalances:

- Hormonal changes (decreased levels of testosterone, human growth hormone, DHEA, etc.)
- Chronic inflammation
- Ectopic fat deposition
- Decreased satellite cell health
- Blunted responses to anabolic stimuli
- Decreased metabolism
- Inactivity

Without MET, especially strength training, both muscle mass and strength decline every year after the age of 50, and it accelerates after age 70. Muscle mass declines at the average rate of 0.9% in men and 0.65% per year in women after age 75, doubling the rate of loss per year from 10 to 15 years earlier. Loss of muscle mass is usually more pronounced in the lower extremities, an influential factor in age-related functional impairment there. This often results in movement restriction, poor quality of life, disability, and mortality risk. At age 75, the loss of strength per year, without extra strength training, is two to five times faster than loss of muscle mass [41].

Strength training or resistance exercise, the act of loading muscle against an external force, remains the most effective form of exercise in counteracting decreased function and sarcopenia. Because aging is associated with declines in hormones, muscle mass, muscle function, and aerobic capacity, more resistance training is needed [42].

Per figures from the Journal of the American Geriatric Society, "The estimated direct healthcare cost attributable to sarcopenia in the United States in 2000 was $18.5 billion ($10.8 billion in men, $7.7 billion in women), which represented about 1.5% of total healthcare expenditures for that year. The excess healthcare expenditures were $860 for every man with sarcopenia and $933 for every sarcopenic woman. A 10% reduction in sarcopenia prevalence would result in savings of $1.1 billion (dollars adjusted to 2000 rate) per year in U.S. healthcare costs" [43].

35.3.2.1 Unique Considerations for Dementia

Alzheimer's has been referred to as type 3 diabetes by some researchers and doctors because of the similar underlying pathophysiology and processes that lead to both diabetes type 2 and dementia/Alzheimer's disease. Insulin resistance, toxicity, inactivity, obesity, oxidative stress, and obesity have been closely correlated with both diabetes and dementia.

MET has been shown to be one of the best strategies to decrease cognitive decline [44]. Reductions of mean blood flow values are significantly correlated with the severity of dementia [45]. Increased oxygenation through MET has many advantages for keeping brain tissue healthier. Recent results show that MET also helps move glymphatics, which carry away waste products and cellular debris that accumulate from an aging brain. MET has also specifically been shown to affect hippocampal-dependent cognition and to increase blood perfusion to these areas [46]. High-flavanol cocoa has also been shown to improve memory by stimulating the input region of the hippocampus, the dentate gyrus [47]. In addition to a bigger and healthier hippocampus, MET stimulates the production of brain-derived neurotrophic factors (BDNFs) that appear to influence energy metabolism, appetite, and important aspects of neurocognitive function [48]. Not only that, but a study from Karolinska Institute in Stockholm has shown that there is indeed an antidepressant effect from running that is associated with an increase of hippocampal cells [49]. In addition to the benefits to the hippocampus, different types of MET affect different parts of the brain. According to a Canadian study of elderly women, resistance training had a more profound effect on staving off cognitive decline compared to exercise programs designed to tone and balance the body [50].

According to an article by Teal Burrell, different types of exercises affect different parts of the brain to a lesser and stronger degree [51]. Neuroimaging techniques such as

MRI and SPEC scans confirm the positive influences of increased blood flow to the brain. Some of these effects include improved performance across cognitive domains and core functions that improve executive decisions [52]. Dr. Daniel Amen, a neurologist who has done more than 120,000 SPEC scans, affirms the strong positive effects of MET and other lifestyle improvements as highly restorative for damaged or low-functioning brains. MET gives us better cognition and protection against dementia, and there is a dose-response relationship [53, 54]. Not only does MET sharpen the aging mind, it keeps people happier in their golden years. The elderly who do MET have less depression, better moods, higher self-esteem, and self-confidence. They also sleep better, enjoy more energy, and have better resilience [55].

35.3.2.2 Unique Considerations for Sarcopenia

Consistent exercise training is the primary treatment to prevent and affect sarcopenia. A balance of endurance and primarily strength exercises at least 3 days per week is usually effective. It is never too late to start. Older people get just as much out of MET as younger people [56]. Casual walks and light physical activity will not do much for reversing sarcopenia. A study on the elderly in Iceland illustrated that moderate to vigorous physical activity is needed to be done consistently at least three times per week for effective results on the elderly [57].

The older one is the more important it is to engage in muscle sparing and muscle building. In a 1994 study presented in *The New England Journal of Medicine*, high-intensity resistance exercise training is shown to be a feasible and effective means of countering muscle weakness and physical frailty in very elderly people. In contrast, multi-nutrient supplementation without concomitant exercise does not reduce muscle weakness or physical frailty [58].

The best approach is to engage in endurance training, strength training, and yoga or stretching for flexibility, balance, and core strength. When possible, Nordic walking is preferable to normal walking. Walking at a more strained rate with poles helps activate more muscles, your metabolism, and more hormones. Taking a 30–60-minute walk daily is great, but make it a power walk or Nordic-power walk every other day. If you swim, bike, row, or run, make every other session a moderate to vigorous one and make sure to warm up before and after. Three sessions of 45–60 minute moderate to vigorous workouts per week that include strength training and HIIT or SIT seem to be a great goal to shoot for, since it both deals with the ravages of sarcopenia and puts the brakes on brain aging. Remember though the 12–12 goal: 12 hours a day sleeping and sitting and 12 hours standing and moving.

The combination of exercise training and supplementation reinforces the effects each can have on improving strength, balance, and speed. Protein, creatine, vitamin D, and calcium together showed a positive effect [59]. Sufficient protein drinks during or after the workout will help build muscle. Use branched-chain amino acids or whey protein during and after your 2–3 toughest weight training, SIT, or HIIT sessions. A plant-based healthy diet and the daily intake of omega-3 supplements and good multivitamin and mineral supplements are a great complement to your exercise plan for decreasing the risk of inflammation and injury.

35.3.2.3 Unique Considerations for Nonalcoholic Fatty Liver Disease NAFLD

Like many other recognized lifestyle diseases, such as diabetes, cardiovascular disease, and dementia, nonalcoholic fatty liver disease is increasing in epidemic proportions where cultures have adopted the modern lifestyle of inactivity and indulgence in junk foods. These problems have seen a dramatic increase in the last 20 years all over the world in places that have adopted the Western lifestyle. In the United States alone, the increase has been dramatic, increasing by 170% in the brief period of 2004–2013 [60].

The 2004 documentary film, *Super Size Me*, by Morgan Spurlock demonstrated the power of junk foods and healthy foods on our health outcomes and specifically on the increase and decrease of liver enzymes. This movie brought the message loud and clear that the intake of substances other than alcohol can elevate your liver enzymes and threaten your health. In the movie, the host was shocked that eating three fast food meals daily resulted in elevated liver enzymes within a few weeks, starting on the path of liver pathology. A healthy plant-based diet reversed this progression within several months. Not only has a plant-based diet been demonstrated to reverse fatty liver damage, so have many herbs, phytonutrients, and exercise training. Nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) have been shown to be very responsive to diet, exercise training, and nutritional supplements. Lifestyle therapies have been shown to have a positive effect on decreasing the progression of this common and rising chronic disease process.

There are studies showing the ability of herbs and nutrients in protecting liver cells. Isoflavone-rich supplements alone have been shown to protect against fatty liver disease through various pathways which modulate fructose production, fatty acid β-oxidation, lipid synthesis, and oxidative stress [61]. In addition, studies show there can be beneficial effects of probiotics and prebiotics in protecting liver cells from development of NAFLD by regulating the intestinal barrier function [62].

Different kinds of MET, whether endurance, strength, HIIT, or flexibility and balance, have been shown to have positive effects on degeneration due to the improved milieu surrounding and within the tissue. The increase in oxygen and nutrients are used for restoration and regeneration of liver cells and tissue. One study by Takahashi shows that resistance exercise comprising squats and push-ups helps to improve the characteristics of metabolic syndrome in patients with nonalcoholic fatty liver disease [63].

Endurance training, such as aerobic swimming training, can prevent NAFLD via the regulation of fatty acid trans-

port-, lipogenesis-, and β-oxidation-associated genes. In addition, the benefits from aerobic swimming training were achieved partly through the PANDER-AKT-FOXO1 pathway [64].

35.3.2.4 Unique Considerations for Spinal Cord Injuries

The practice and science of the rehabilitation of spinal cord injuries, accidents, and traumas have been investigated thoroughly in the last century. The advances during the last decade of advanced stem cell and other modern techniques are a big boost to the tried-and-tested combination of physical therapy, MET, therapeutic modalities, and surgery to bring relief for spinal cord injuries, to help accident-injured patients, or to work athletes back into shape. Many studies have been done over the years to show the advantage of the value of combining physical therapy, movement, and pulse current for injury and trauma rehab [65].

Another study shows the value of MET for not only helping with a spinal cord injury but the other pathologies or risks that can accompany the injury. The increased risk of cardiovascular - and other chronic disease in persons inflicted with spinal cord injuries can be improved by consistent MET [66].

The goals of physical therapy and MET should be not only to improve function after accidents, handicaps, or injuries but also to decrease the risk of chronic diseases that can increase in the future.

35.3.2.5 Unique Considerations for Rheumatoid Arthritis RA

MET especially resistance and strength training, has been shown to be a safe and effective means of restoring muscle mass and functional capacity in patients with established and chronic rheumatoid arthritis (RA). The authors of a study of the effects of resistance training for appropriate RA patients recommend programs similar to theirs be included in disease management [67].

35.3.2.6 Unique Considerations for Cancer

Undertaking regular exercise in carbohydrate-restricted states may be a practical approach to achieve the physiological benefits of consistent p53 signaling [68].

HIIT can be performed by female cancer survivors without adverse health effects. Here, HIIT and LMIE (low-to-moderate-intensity exercise) both improved work economy, quality of life and cancer-related fatigue, body composition, or energy expenditure [69].

Studies have shown that the single or combined use of MET and the nutrient supplement resveratrol may improve the effects of chemotherapy and protection from some of the cardiotoxicity of the agent dexrazoxane, (DOX) [70].

MET helps cancer survivors control body weight, improve aerobic capacity, reduce fatigue, and improve their gait, balance, and mood [71].

35.3.2.7 Unique Considerations for Parkinson's

More and more Parkinson's (PD) patients are turning to the gym and their bicycles to improve their disease symptoms and the quality of their lives. Results can be astounding and powerful sometimes, as reported by many doctors and patients and in a study reported in the Clinical Journal of Sports Medicine. "The results of the present research synthesis support the hypothesis that patients with PD improve their physical performance and activities of daily living through exercise. Future studies should include the development of standardized exercise programs specific for problems associated with PD as well as standardized testing methods for measuring improvements in PD patients" [72].

35.3.2.8 Unique Considerations for MS

It is not only walking that is important for multiple sclerosis (MS) patients but walking downhill may be even more helpful. The stimulation and firing of certain nerves and muscle groups during downhill walking seem to have a powerful effect. According to a study reported in International Journal of MD Care 2016 "After the intervention, significant improvement was found in the downhill group versus the uphill group in terms of fatigue, mobility, and disability indices; functional activities; balance indices; and quadriceps isometric torque (P <0.05). The results were stable at 4-week follow-up" [73].

35.3.2.9 Unique Considerations for Schizophrenia

MET seems to be very beneficial for those afflicted by schizophrenia, especially resistance training, according to a study from Brazil. "In this sample of patients with schizophrenia, 20 weeks of resistance or concurrent exercise program improved disease symptoms, strength, and quality of life [74].

After careful review of the Functional Medicine Matrix (IFM Matrix) and the Medical Symptoms Questionnaire (MSQ), you have determined that part of the patient's clinical picture has an emotional or mental component. Along with the nutritional treatment plan, the patient may require another form of care or a multidisciplinary approach. If this is the case, it is time to consider some form of psychotherapy or a type of complementary or alternative mind-body medicine. In order to understand how the brain affects the body, creating or potentiating illness, we must examine some of the research.

Research of modern mind-body medicine dates back to the 1960s, although the concept has been recognized as far back as Hippocrates.

» Disease is not an entity, but a fluctuating condition of the patient's body, a battle between the substance of the disease and the natural self-healing tendency of the body. –Hippocrates

A psychiatrist, George Solomon, began to investigate the impact that emotions had on inflammation and the immune system in general. This new field was called psychoneuroimmunology [1].

Dr. Candace Pert (1946–2013) was a significant contributor to the emergence of mind-body medicine as an area of legitimate scientific research in the 1980s. She has been called "The Mother of Psychoneuroimmunology" and "The Goddess of Neuroscience" by her many fans. To her colleagues, she was an internationally recognized neuroscientist and pharmacologist who published more than 250 research articles and many books on how the brain, endocrine, immune system, and many other organs and systems interact to create disease processes or with the correct interventions create wellness through peptide/receptor cellular communication.

"A feeling sparked in our mind or body will translate as a peptide being released somewhere. Brain, organs, tissues, skin, muscle and endocrine glands all have peptide receptors on them and can retrieve, repress or store emotional information (memories) and or behaviors," she wrote. "You can access emotional memory anywhere in the peptide/receptor network in any number of ways. I think unexpressed emotions are literally lodged in the body [2]."

Emotions, largely ignored within the traditional confines of science and medicine, are actually the key to understanding psychoneuroimmunology and its emerging picture of how the body and mind affect each other. By examining and treating the triad of mind, body, and spirit, we can close the gap and acquire a positive result that of whole wellness (Fig. 36.1).

Fig. 36.1 The overlap of integrating mind, body, and spirit to create whole wellness

36.1 Mind-Body Techniques

Mind-body techniques aid in the management of pain and many other diseases because they reduce anxiety, encourage relaxation, improve coping skills, and ease tension. Managing stress will decrease stress hormones and increase good emotion-modulating neuropeptides. The goals of mind-body techniques are to reduce stress hormone levels and to reset emotional cellular memory, so that the body is better able to fight off illness.

Some conditions that mind-body techniques may be helpful for include:

- Anxiety
- Asthma
- Autoimmune disorders
- Cancer
- Coronary heart disease
- Depression
- Fibromyalgia
- General eating disorders
- Hypertension
- Insomnia
- Menopause
- Mental health issues
- Obesity
- Pain (acute and chronic)
- Poststroke
- Stomach and intestinal problems
- Weight loss

36.2 Six Common Mind-Body Techniques

36.2.1 Neuro Emotional Technique (NET)

36.2.1.1 What Is It?

NET uses a methodology of finding and removing neurological imbalances related to the physiology of unresolved stress. NET is a tool that can help improve many behavioral and physical conditions.

36.2.1.2 How Does It Work?

NET is based on the physiological foundations of stress-related responses. As discovered in the late 1970s, emotional responses are composed of neuropeptides (amino acid chains) and their receptors, which lie on neurons and other cells of remote tissues in the body. The neuropeptides are ejected from the neuron and carry the encoded information to other sites within the body. These neuropeptides are in a category of neurochemicals known as Information Substances (IS), which are released at times of stress-related arousal and become attached to remotely positioned neuroreceptors. Significantly, this process also happens when a person recalls to memory an event in which a stress originally occurred. This is a key factor in the NET treatment. Thus, the physiological status of the body is emotionally replicating a similar physiological state that was found in the original conditioning event by the process of remembering. It is at this point that the practitioner applies the principles of the technique to then "reset/erase" the original event through the nervous system. This technique is highly effective, although currently taught to chiropractors, acupuncturists, and psychotherapists only. This technique is worth a co-referral to a trained practitioner within the interdisciplinary team.

The ONE Research Foundation was established in 1993 by Neuro Emotional Technique (NET) founder Scott Walker, D.C., to raise funds for research to demonstrate empirically the validity of the BioPsychoSocial (BPS) model as an effective methodology for intervening in a broad spectrum of physical, emotional, and psychological conditions. The ONE Research Foundation (ONE) is comprised of individuals who are committed to the natural noninvasive healing of the mind and body. ONE is a nonprofit 501(c)(3) dedicated to making these natural methods available to all as the standard of care [3].

36.2.2 Biofeedback

36.2.2.1 What Is It?

Biofeedback is a noninvasive drug-free form of treatment. It is a process that enables an individual to learn how to change physiological activity for the purposes of improving health and performance. Precise instruments measure physiological activity such as heart function, breathing, muscle activity, and skin temperature. These instruments rapidly and accurately "feedback" information to the user. The presentation of this information, often in conjunction with changes in thinking, emotions, and behavior, supports desired physiological changes. Over time, these changes can endure without continued use of an instrument.

36.2.2.2 How Does It Work?

The therapist attaches sensors or electrodes to the body. These sensors provide a variety of readings – feedback – which is displayed on equipment, usually a television monitor, for the patient to see. With this information, patients can learn to make changes so subtle that at first, they cannot be consciously perceived. With practice, the new responses and behaviors can help to bring relief and improvement to a variety of disorders.

36.2.3 Neurofeedback

36.2.3.1 What Is It?

Neurofeedback is a natural, self-regulating approach that helps restore the brain's ability to function in the way it was designed to function. Also known as EEG biofeedback, brain training and brain computer interface (BCI), neurofeedback utilizes the operant conditioning learning model to achieve self-regulation. Additionally, monitoring the brain's bioelectrical system also advises us of chemical activity within the brain. It is a safe, noninvasive, painless learning procedure during which sensors are placed on the surface of the patient's head.

36.2.3.2 How Does It Work?

A neurofeedback session involves the client sitting in a comfortable chair in a quiet room. He or she will have electrodes placed on the area of the scalp where the training will occur, which is determined by the QEEG interpretation. The sensors record brain electrical activation levels and enable participants to learn to improve mental performance, normalize behavior, and/or stabilize mood. The information is displayed on a computer screen, together with sounds, which change according to the brain's activity levels. Therefore, the patient can read, understand, and influence his or her brainwave activity. Once the patient learns to access and regulate the brain more effectively, symptoms begin to improve or performance optimizes. The visual feedback on the computer screen and auditory feedback through speakers or headphones are positive reinforcement. Creating these reward parameters involves skill and training. It is perhaps the biggest breakthrough in noninvasive medicine in the last 50 years.

Medical conditions that have been found to benefit most from neurofeedback assessment and treatments include autism, ADHD/ADD, mood disorders, postanesthesia, head injury, PTSD, sleep interruption, and stroke rehabilitation [4].

36.2.4 Cognitive Behavioral Therapy

36.2.4.1 What Is It?

Cognitive behavioral therapy is a psychosocial intervention that is among the most widely used evidence-based practices for treating mental disorders. Guided by empirical research, CBT focuses on the development of personal coping strategies that target solving current problems and changing unhelpful patterns in cognitions, behaviors, and emotional regulation. It was originally designed to treat depression and is now used for a number of mental health conditions.

36.2.4.2 How Does It Work?

Cognitive behavioral therapy requires the patient and therapist to work as a team, collaborating to solve problems. Rather than waiting for problems to get better after talking about them repeatedly from week to week, patients can take an active role in their own treatment, using self-help assignments and CBT tools between sessions to speed up the process of change. Each session is focused on identifying ways of thinking differently and unlearning unwanted reactions.

In adults, CBT has been shown to have effectiveness and a role in the treatment plans for anxiety disorders, depression, eating disorders, chronic low back pain, personality disorders, psychosis, schizophrenia, and substance use disorders, in the adjustment, depression, and anxiety associated with fibromyalgia and with postspinal cord injuries [5].

36.2.5 Emotional Freedom Technique (EFT)

36.2.5.1 What Is It?

Emotional freedom technique, also known as tapping. EFT combines the physical benefits of acupuncture with the cognitive benefits of the traditional talk therapy for a much faster result. Most aspects of our lives are not working the way we would like due to a disruption in the body's energy system. This may be from a past trauma or memories which cause negativity, anxiety, stress, physical pain, and unresolved emotional issues. EFT is an amazing healing tool and can help reset the subconscious mind and eliminate old beliefs that patients may not realize they are holding onto.

36.2.5.2 How Does It Work?

According to the EFT manual, the procedure consists of the participant rating the emotional intensity of their reaction on a Subjective Units of Distress Scale (SUDS) (a Likert scale for subjective measures of distress, calibrated 0–10) and then repeating an orienting affirmation while rubbing or tapping specific points on the body. It's a similar approach to acupuncture, but instead of needles, we tap on the main energy spots on our body, called meridians, to release negative emotions. Some practitioners incorporate eye movements or other tasks. The emotional intensity is then rescored and repeated until no changes are noted in the emotional intensity. Proponents of EFT and other similar treatments believe that tapping/stimulating acupuncture points provides the basis for significant improvement in psychological problems [6].

36.2.6 Hypnotherapy

36.2.6.1 What Is It?

Hypnotherapy is a form of psychotherapy that is used to create subconscious change in a patient in the form of new responses, thoughts, attitudes, behaviors, or feelings. It is undertaken with a subject in hypnosis.

36.2.6.2 How Does It Work?

The therapist consults with clients to determine the nature of their problems and prepares them to enter a hypnotic state by explaining how hypnosis works and what they will experience. He or she will then induce the client into a hypnotic state using individualized methods and techniques of hypnosis based on interpretation of test results and analysis of the client's problem. A person who is hypnotized displays certain unusual behavior characteristics and propensities, compared with a non-hypnotized subject, most notably heightened suggestibility and responsiveness. The goal of hypnotherapy is to increase motivation or alter behavior patterns. The therapist may train the client in self-hypnosis conditioning.

36.3 Summary

The above techniques are only a few of the many wonderful complementary techniques available. See Fig. 36.2 for other suggestions. Although some modalities do not have a strong evidence base, they have historical recognition of value, some as far back as thousands of years in traditional medical practice. Just because they are not researched in a RCT format doesn't mean that they are not highly effective. The way we live, how we think, what we eat, and how we feel affect our health. The value of these therapies as part of the patient's treatment plan is truly worthwhile. You may be asking at this point, "what technique should I choose for the patient?" The simple answer is: the best technique is the one that the patient likes and will do. Always remember, "there is a cork for every bottle."

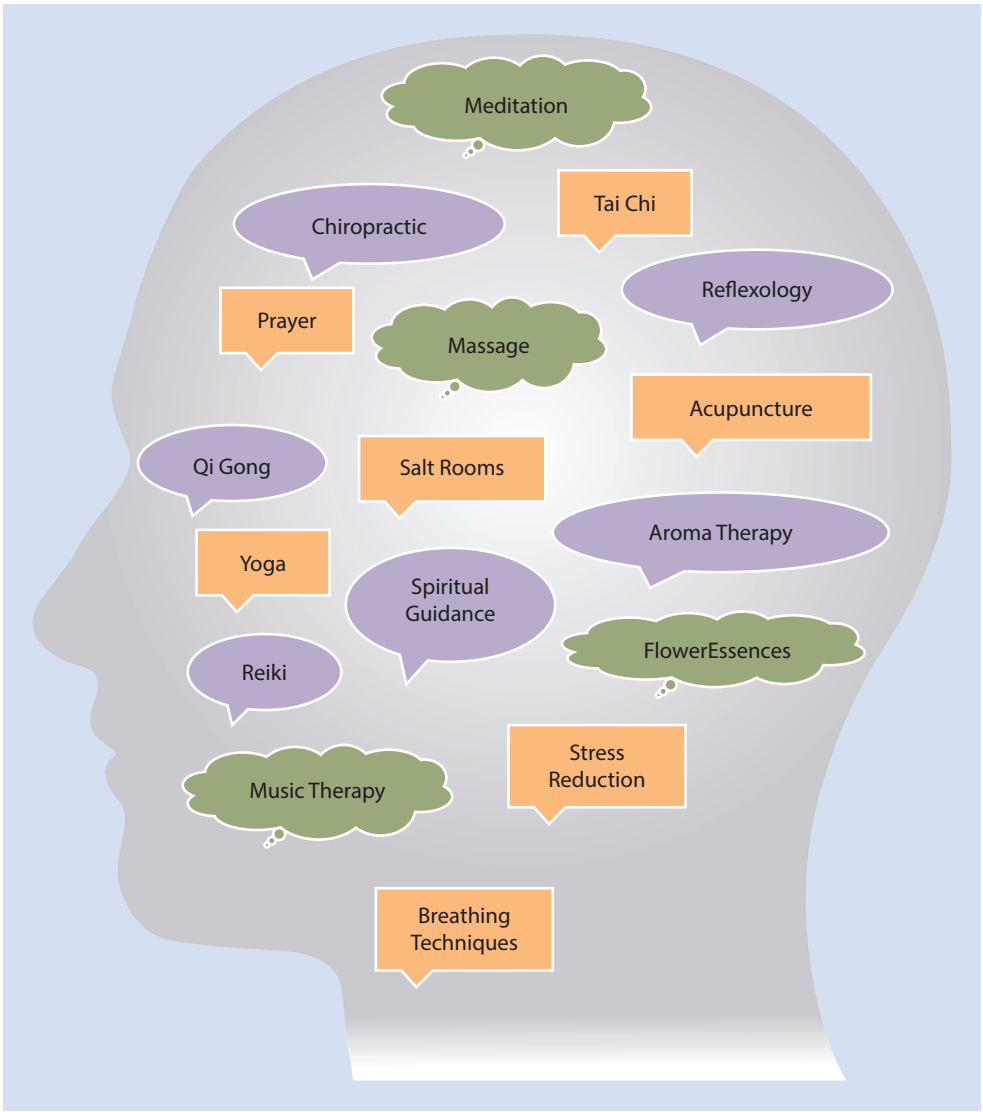

Fig. 36.2 Further suggestions for mind-body techniques not discussed that are commonly used in integrative medicine

37.1 Who Is the IFMNT Practitioner?

Integrative and Functional Medical Nutrition Therapy (IFMNT) is a term championed by the Executive Committee of Dietitians in Integrative and Functional Medicine (DIFM), a dietetic practice group of the Academy of Nutrition and Dietetics. DIFM and others in the Integrative and Functional Medicine arena have used IFMNT as a specific approach to medical nutrition therapy (MNT) that incorporates both Integrative and Functional Medicine methodology to deliver a "food as medicine" approach to nutrition care. This style of care requires education and training beyond the core nutrition curriculum that exists for traditionally trained medical and allied healthcare practitioners, such as the required educational competencies for registered dietitians-nutritionists as determined by the Accreditation Council for Education in Nutrition and Dietetics (ACEND), the accrediting body of the Academy of Nutrition and Dietetics.

The basic tenet of this emerging area of healthcare centers on optimizing nutritional status and correcting underlying system imbalances by establishing nutritional therapies that enable the body to function optimally. Because IFMNT interventions are nutrition-based therapies rooted in dietary interventions and dietary and herbal supplements, the IFMNT-trained nutrition professional is poised to play a critical role in this medical paradigm. This version of diet therapy is relatively new, and much of the growth and momentum of Integrative and Functional Medicine, including IFMNT, grew as a result of consumer demand. In response to this call for a more thoughtful and natural approach to healing, paired with a growing body of evidence lending credence to IFMNT practices, an increasing number of medical professionals are seeking out opportunities to become trained and proficient in IFMNT.

Among dietitians and nutritionists, interest in this specialty area of nutrition and health is high, as demonstrated by the exponential growth of DIFM. Yet the information and specific training necessary to deliver IFMNT have not yet widely trickled down to the student level in most accredited dietetics programs [1, 2]. In recent years, many more opportunities for learning have become available to nutrition professionals, a trend that is sure to continue across disciplines.

Dietitians and certified nutritionists are not the only IFMNT practitioners. IFMNT practices have been employed and embraced by many other healthcare providers, including medical doctors, naturopathic doctors, osteopaths, physician assistants, nurses and nurse practitioners, chiropractors, and licensed acupuncturists. Organizing bodies, such as the Holistic Nurses Association, exist across disciplines and serve to bring together those practicing under similar philosophies. Because many different types of medical professionals are practicing Integrative or Functional Medicine or are interested in offering these services to their patients, the IFMNT provider can function independently in a private practice setting or as part of an Integrative/Functional Medicine team. In fact, these interdisciplinary teams have started to revolutionize medical institutions in ways that were difficult to imagine only a decade ago.

Integrative and Functional Medicine has become better accepted by both conventional institutions and health professionals in recent years, further encouraging the growth and interest of the Integrative-Functional Medical paradigm, of which IFMNT is an important part. One example is the recent opening of the Cleveland Clinic's Center for Integrative & Lifestyle Medicine, with its expressed dedication to address "the increasing demand for integrative healthcare by researching and providing access to practices that address the physical as well as lifestyle, emotional, and spiritual needs of patients." Similarly, New York Presbyterian created the Integrative Health and Wellbeing program in conjunction with Weill Cornell Medical Center, which employs an interdisciplinary team including medical doctors, registered dietitian nutritionists, licensed acupuncturists, and nurses. These types of institutions have the potential to measurably change the kind of health and medical interventions available to the public on a large scale.

37.2 What About Their Approach Sets Them Apart?

In contrast to a conventional, symptom- or disease-centered approach to medicine, Integrative and Functional Medicine practitioners offer a different approach; the practitioner works in partnership with the patient to identify the underlying causes and metabolic imbalances driving the symptoms and disease state. The *integrative and functional medical model* uses evidence-based research to provide patient-centered care in order to create a unique personalized care plan based on each person's specific environment, lifestyle, and genes [3]. A major component of environment is a person's diet, and nutrient status is a recognized determining factor for health. Thus, the foundation of any integrative and functional intervention rests firmly on dietary habits and optimizing nutritional status. This is where IFMNT comes in. IFMNT represents the same kind of patient-centered approach for the nutrition professional. This approach moves away from a one-size-fits-all methodology to nutrition and wellness, acknowledging and harnessing the body's innate ability to heal itself, given the right conditions. An IFMNT practitioner recognizes that optimal health is more than simply the absence of disease.

To provide patient-centered care, an IFMNT practitioner gathers information by listening to the patient's story, looking for hints and clues about the etiology of the underlying imbalances that trigger symptoms. The focus is on the whole person, who is more than simply a patient with a disease. Establishing a *therapeutic relationship* between patient and practitioner is important and promotes healing (see ▶ Chap. 6). An individual's beliefs, attitudes, and motivations are all considered relevant to physical and emotional well-being and are typically explored as part of the "story." The

mind-body-spirit connection is not only acknowledged but honored by IFMNT, (see ▶ Chap. 36) as well as physical, social, and lifestyle factors unique to each person. In fact, the concept of individuality is at the forefront of IFMNT. Voluntary actions such as decision-making, emotional responses, stress responses, and lifestyle habits are taken into account, yet so are involuntary actions within the microenvironment of the body, such as nutrient metabolism and absorption, cellular functions, and interactions between organ systems, largely influenced by genetic variability and epigenetic influences.

Aside from an individual's dietary and lifestyle choices, which influence overall health, people have unique metabolic patterns based on genetics and epigenetic influences that affect nutrient requirements. The interactions between diet, genes, and environment are considered and evaluated as part of an IFMNT practitioner's approach. Even a minor imbalance in the body can trigger a cascade of biological effects that may eventually lead to presentation of symptoms, compromised health, or chronic disease. For example, chronically low-normal vitamin D may contribute to osteoporosis, poor immune function, and other consequences. Chronically low-normal vitamins B12, B6, and folate can result in hyperhomocysteinemia, which increases the risk for cardiovascular disease and blood clots. Inadequate vitamin B12 status is also linked with fatigue, depression, and anxiety disorders. This is why IFMNT practitioners utilize a wide range of assessment tools and measures, including a nutrition-focused physical examination and laboratory data, in an effort to determine nutrient status. These same tools also help to identify key system imbalances that may contribute to symptoms and influence metabolism and health. Rather than suppress a metabolic function to mask a symptom, the goal of IFMNT is to restore optimal metabolic function to promote health and healing. Therefore, the focus is on true healing: the reversal of the metabolic disruptions that influence a disease process and create symptoms, not just managing or masking symptoms. This focus is at the heart of IFMNT.

In order to address underlying metabolic disturbances at play, an IFMNT practitioner is well-versed in biochemical processes and nutritional biochemistry. These metabolic pathways are complex and reliant on nutrient cofactors to operate optimally. Even slight nutrient deficiencies or "chronic insufficiencies" left uncorrected over a long period of time can disrupt metabolic function. According to the triage theory developed by Bruce N. Ames, when faced with chronic nutrient deficiency or insufficiency, the body must prioritize available micronutrients to support the functions most critical to survival and reproduction. This prioritization occurs at the expense of the functions that protect against future cellular damage and aging. [4, 15]. This is how chronic insufficiencies can contribute to accelerated aging, chronic disease, physiological stress, and chronic inflammation over years. The effects of nutrients, and thus nutrient deficiencies and chronic insufficiencies, in metabolic pathways are important for an IFMNT practitioner to understand (see ▶ Chap. 46).

Chronic Insufficiency versus Nutrient Deficiency

Overt nutrient deficiencies resulting in long latency deficiency diseases are a public health concern, yet these deficiency diseases (such as rickets, beriberi, and scurvy, the deficiency diseases of vitamin D, thiamin, and vitamin C, respectively) are rare in the United States and Canada [5]. However, established lower limits for what is considered "within normal limits" for specific nutrients may fall well outside the *optimal range* for ideal metabolic functioning. In fact, suboptimally low levels of these same vitamins (vitamin D, thiamin, and vitamin C) are often seen in clinical practice. Lab values that fall on the high or low edges of normal limits are typically overlooked in conventional medicine. Practitioners may be inadvertently missing opportunities to optimize nutrition status, allowing nutrient chronic low-level insufficiencies to contribute to long-term chronic disease risk [6].

Because nutrients serve as cofactors for all biochemical processes in the body, IFMNT acknowledges that chronically low or suboptimal levels of certain nutrients may indeed take a toll on human health by inhibiting or slowing down metabolic processes. While chronic nutrient insufficiencies may trigger minor signs and symptoms of metabolic imbalances – even in the absence of overt disease states – diminished nutrient status over the long term can trigger progression into chronic diseases. The integrative and functional medical model maintains that there are consequences to insufficient nutrient status over time, such as mitochondrial decay and increased DNA damage [4]. Therefore, IFMNT practitioners may favor optimal ranges when evaluating nutrient laboratory data, rather than relying on conventional laboratory reference ranges, which are based on plus or minus two standard deviations of levels observed in the general population. In line with recognizing genetic individuality and person-centered care, functional lab testing may be used in addition to conventional blood chemistries to provide more specific information as to whether nutrient cofactors are present in levels that are optimal for a specific individual.

Laboratory Data for the IFMNT Practitioner

- Conventional biomarkers may include:
  - Complete blood count (CBC)
  - Complete metabolic panel (CMP)
  - Serum nutrient status (e.g., vitamins, minerals)
  - Red blood cell nutrient status (e.g., magnesium, zinc)
  - Kidney and liver function tests
  - Cholesterol panels
  - Homocysteine levels
  - Ammonia levels
  - Uric acid levels
  - Heavy metals

- Fatty acids panel
- Amino acids panel
- IgE food allergy panels

- Genetic information may include:
  - Single nucleotide polymorphisms (e.g., MTHFR, VDR, COMT)
  - Haplotypes (e.g., celiac disease haplotpes HLA-DQ2 and HLA-DQ8)
- Functional testing may include:
  - Digestive stool analyses
  - Microbial stool analyses
  - Organic acids panel
  - White blood cell micronutrient status
  - Methylmalonic acid (MMA)
  - Formiminoglutamic acid (FIGLU)
  - Non-IgE food sensitivity panels

Once the subjective and laboratory information is gathered, an IFMNT practitioner may use both conventional and integrative therapies, as appropriate. Integrative and functional approaches are generally employed to focus on identifying the root causes of symptoms and diseases to focus on preventive or restorative care. Traditional, non-Western, approaches may also be used, such as principles of Traditional Chinese Medicine or Ayurveda. The IFMNT practitioner will make use of any evidence-based approach, whether from conventional or alternative medicine practices. Modalities such as food elimination diets and dietary supplements (e.g., vitamins, minerals, herbs, botanicals, probiotics) are commonly used, as are metabolic detoxification support and digestive support programs. Because IFMNT practitioners recognize the value of mind-body interventions, they may also recommend other modalities such as yoga, Qigong, meditation, guided imagery, sound healing, and healing touch. Whatever the treatment plan, IFMNT practitioners use their vast knowledge of the dynamic interaction between biological systems and biochemical pathways, nutrient status, biochemical individuality, genetics, and epigenetics to create an effective, holistic nutrition care plan [7].

37.3 The Functional Medicine Matrix

"Functional Medicine," as a concept, was proposed by Jeffrey Bland, PhD, in the early 1980s. Through his vision and leadership, the Institute of Functional Medicine (IFM) emerged. As with Integrative Medicine, Functional Medicine seeks to address the underlying causes of disease states and uses a systems biology-oriented approach that recognizes the interconnectedness and interplay between the various organ systems, while aiming to foster a therapeutic relationship between patient and practitioner [3]. Particular attention is paid to acknowledging each individual's biochemical uniqueness in order to personalize medical care. Functional Medicine practitioners consider the complex interactions between genetic predispositions, environmental factors, diet, and lifestyle to assess, prevent, and treat chronic disease.

IFM represents one of the major leaders educating healthcare providers in the theories and practices of Integrative and Functional Medicine. There are several qualified organizations that offer educational programs, certification courses, and publications in Functional Medicine (see Resources). As such, IFM developed the first assessment tool, the *Functional Medicine Matrix*. The Matrix serves as architecture for organizing the complexity of each case to synthesize information and create target interventions for patient care. It offers a unique system for homing in on clinically relevant information that is part of the patient's "story" and helps the practitioner organize the information to help clarify the complex interactions between symptoms that are characteristic of chronic disorders. It provides a framework to aid the practitioner in identifying and interpreting the various factors involved in promoting health and preventing disease in each individual (Fig. 37.1).

The Functional Medicine Matrix is divided into three main parts: (1) the patient's story, (2) an assessment of lifestyle factors, and (3) physiological assessments, observations, and other signs of clinical imbalances. The patient's story is further delineated into three subsections: antecedents and predispositions, the "triggering event(s)," and mediators that appear to contribute to the patient's medical condition, health crisis, or current set of symptoms. Lifestyle assessments, referred to as fundamental lifestyle factors, include dietary habits, exercise, sleep, relationships, and life meaning and purpose, with the latter including attitudes and core beliefs. Biological and physiological assessments are represented in the largest section, "Clinical Imbalances Found in the Functional Organizing Systems." This section is where systems data are aggregated and analyzed, including information such as inflammatory biomarkers, body composition, lab test results, toxicity/detoxification, and physiological imbalances. Integrated throughout is the understanding that the mind-body-spirit connection influences each individual patient and must be honored. The Functional Medicine Matrix represents one of the first assessment tools for Functional Medicine practitioners.

37.4 Opportunities for Education (Certification, Credentialing, and Other Accredited Programs)

For many years, RDNs and other nutrition professionals were primarily self-taught in the concepts and practices of Integrative and Functional Medicine, as there had been a lack of accredited programs that offered comprehensive education around IFMNT. With the exception of Bastyr University in Seattle, WA, the University of Kansas Medical Center in

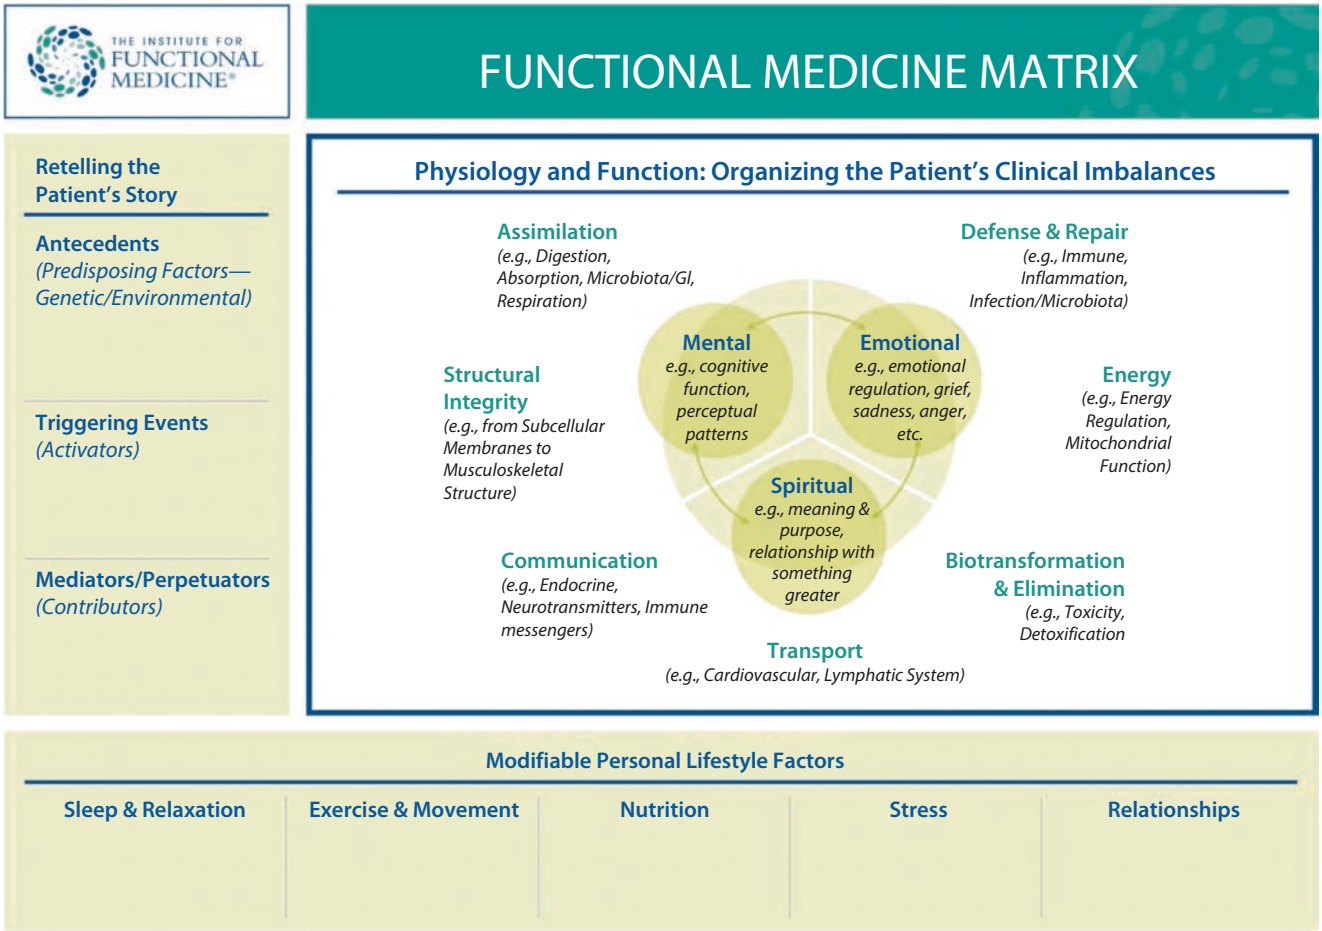

Fig. 37.1 Functional Medicine Matrix. (Used with permission from The Institute for Functional Medicine ©2015)

Kansas City, KS, and the Certified Nutrition Specialist (CNS) credential, recognized and accredited programs were in short supply. In the 1990's, other trailblazers developed programs for healthcare professionals with a focus on nutrition, such as The University of Arizona Andrew Weil Center for Integrative Medicine and IFM. Fortunately, the tides have shifted, and several accredited programs now offer advanced degrees in IFMNT, as well as a multitude of certifications and other training courses (Table 37.1).

37.5 Major Advocate for Development of IFMNT: Dietitians in Integrative and Functional Medicine (DIFM)

A subgroup of the Academy of Nutrition and Dietetics (formerly the American Dietetic Association), Dietitians in Integrative and Functional Medicine (DIFM) had been previously known as Nutrition in Complementary Care. It was originally established in 1998 by a group of like-minded dietitians interested in expanding their skills in topics such as functional foods, dietary supplements, and alternative medical systems, such as Traditional Chinese Medicine and Ayurvedic Medicine. In 2009, the group changed its name to DIFM to better reflect its role in the emerging Integrative and Functional Medicine community. As of 2019, DIFM has more than 5,500 members consisting of RDNs, dietetic technicians (DTRs), dietetic interns, and students interested in practicing an integrated and personalized approach to health and healing.

Dietitians in Integrative and Functional Medicine (DIFM) Mission and Vision [8]

- *Vision:* Optimize health and healing with integrative and functional nutrition
- *Mission:* Empower members to be leaders in integrative and functional nutrition
- *Values:* Innovation, integrity, and compassion

DIFM's contribution to the field of IFMNT has been vast. It offers members opportunities for continuing education and rolled out a certification program in 2017.

Table 37.1 List of IFMNT Training Programs

Organization	Educational Opportunities
Academic Programs and Degrees	
Bastyr University	*Bachelors of Science degrees in:* Nutrition Nutrition & Culinary Arts Nutrition & Exercise Science Combined program in Nutrition and Didactic Program in Dietetics Herbal Sciences *Masters of Science degrees in:* Nutrition Research Combined program in Nutrition and Didactic Program in Dietetics Nutrition and Clinical Health Psychology Non-degree Dietetic Internship
Maryland University of Integrative Health	Doctoral Degree in Integrative Nutrition (online) Masters Degree in Nutrition and Integrative Health
Rutgers University	Masters of Science (MS) Degree in Health Science Integrative Health and Wellness
University of Bridgeport	Masters of Science in Nutrition (online) Dual degree, Masters of Science in Nutrition and Doctor of Naturopathic Medicine Bachelors of Science in Nutrition
University of Kansas School of Health Professions, Departments of Integrative Medicine and Dietetics and Nutrition	*Non-degree*: graduate certificate: Dietetics and Integrative Medicine (DIM) 12 hour certificate (online) *Degree*: Dietetic Internship Fellowship and MS in Dietetics & Nutrition with Integrative Nutrition emphasis
Certificate, Accreditation and Training Programs	
Academy of Nutrition and Dietetics	Integrative and Functional Nutrition Certificate of Training Program (online)
Arizona Center for Integrative Medicine	iHELP Program
Bauman College	Nutrition Consultant Training Program (online option)
Certified Nutrition Specialist (CNS)	Board for Certification of Nutrition Specialists (BCNS) American College of Nutrition (CAN) (MS or PhD eligible)
Certified Clinical Nutritionist (CCN)	Clinical Nutrition Certification Board (CNCB) International and American Association of Clinical Nutritionists (IAACN)
Duke University	Integrative Health Coaching Certification
Institute for Functional Medicine	Institute for Functional Medicine Certification Program (IFMCP) Applying Functional Medicine in Clinical Practice (AFMCP) Introduction to Functional Nutrition Course (online, free)
Integrative and Functional Nutrition Academy (IFNA)	Integrative and Functional Nutrition Certified Practitioner (IFNCP) Advanced Practice Credential (online) IFNCP Certificate of Training (online)
Next Level Functional Nutrition IFMNT	Integrative and Functional Nutrition Foundations Course (online) IFMNT Certificate of Training Program (online) Advanced Studies (online)
Rutgers University	Graduate certificates available in Complementary and Alternative Medicine Graduate certificate in Health Coaching Graduate Certificate in Integrative Medicine Research
University of Kansas School of Health Professions, Departments of Integrative Medicine and Dietetics and Nutrition	Graduate Certificate: Dietetics and Integrative Medicine (DIM) 12 hour certificate (online)
University of Miami	Integrative and Complementary Academic Medicine: Clinical Nutrition Conference Series

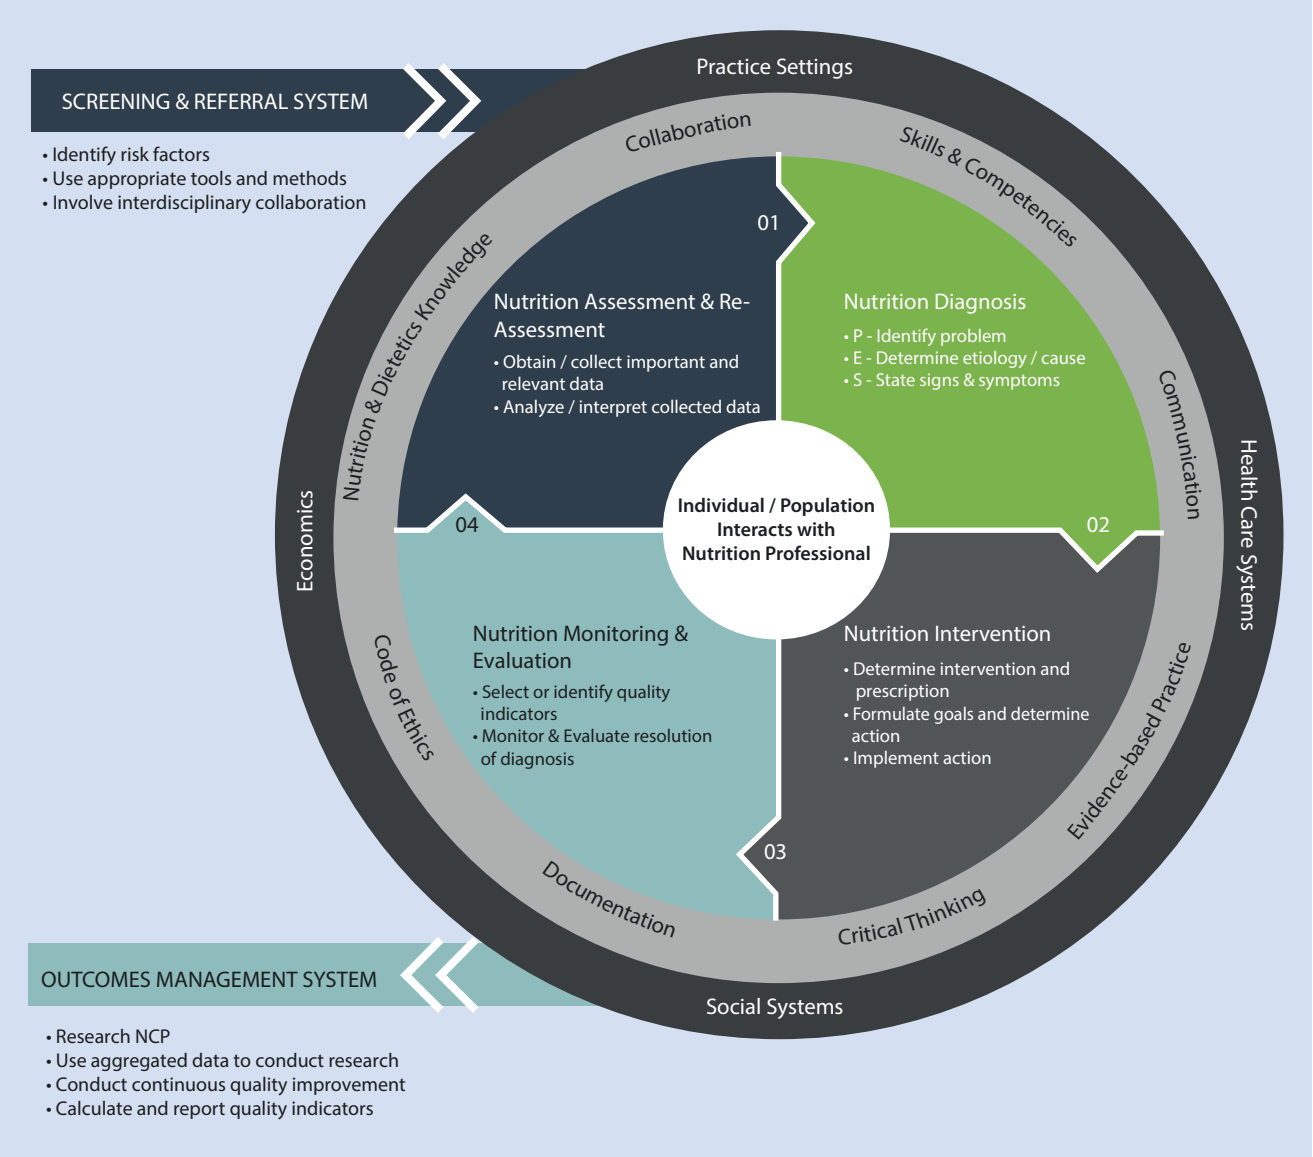

Fig. 37.2 Nutrition Care Process and model. (Reprinted from Swan et al. [13]. With permission from Elsevier)

37.6 Standards of Practice and Professional Performance

In 2011, DIFM developed and published core competencies as part of their Standards of Process (SOP) and Standards of Professional Performance (SOPP), establishing an official framework to guide the practice and performance of registered dietitian nutritionists (RDNs) practicing IFMNT. These were updated and revised in 2019. The SOP for IFMNT builds upon the previously established four steps of the *Nutrition Care Process*, which provides a general framework for the nutrition professional to personalize care and tailor interventions to each individual. First described by the Academy of Nutrition and Dietetics and published as part of the Nutrition Care Model, the four steps of the Nutrition Care Process (NCP) are nutrition assessment, diagnosis, intervention, and, finally, monitoring and evaluation. These steps are designed to facilitate safe and effective nutrition services, promote evidence-based practice, and serve as a framework for critical thinking and decision-making for all RDNs in all settings [7, 9, 14] (Fig. 37.2).

Also previously described by the Academy of Nutrition and Dietetics are the Standards of Professional Performance (SOPP), which detail competency levels for credentialed RDNs and standards of professional behavior. The SOPP are designed to serve as guides for self-evaluation and to assess one's own individual performance. They also serve as tools to determine additional education and skills necessary to advance one's individual level of practice [10]. These tools allow the RDN to continually evaluate his and her own overall competency by the self-evaluation of skills, learning, training, education, and existing knowledge, as well as responsibility and accountability in the practice of nutrition and dietetics [11].

Steps in the Nutrition Care Process

The Nutrition Care Process includes the following steps [9]:

- *Nutrition assessment*: Collection and documentation of information, including health history, biochemical data, labs and medical test results, previous medical evaluations, information from a nutrition-focused physical, anthropometric data, and diet record
- *Diagnosis*: Information collected from the nutrition assessment is synthesized in the selection of appropriate nutrition diagnoses
- *Intervention*: The RDN will determine the appropriate nutrition intervention to address the root cause of the problem with the goal of alleviating signs and symptoms of the previously determined diagnoses
- *Monitoring/evaluation*: Monitoring and evaluation are used to determine if the patient is making progress toward or has achieved established goals

The SOPP are divided into several specific standards, with each standard describing a focus area or domain meant to serve as a guide for self-evaluation and professional development. The six domains of professional performance published in the 2019 SOPP are as follows: quality in practice, competence and accountability, provision of services, application of research, communication and application of knowledge, and utilization and management of resources. These standards are to be used by RDNs as a guide for self-evaluation and demonstrating competence, and as a roadmap to expand their practice and identify areas for professional development. Each focus area standard has several indicators or quantifiable actions that explain how each standard might be used. The DIFM-developed SOP/SOPP can help determine whether an RDN is qualified to provide IFMNT and clearly describes the skills, knowledge, education, and competencies required to safely and effectively provide quality IFMNT. It further allows RDNs to categorize themselves as one of three competency levels of practice: competent practitioner, proficient practitioner, and expert practitioner [14].

In order to further support IFMNT practitioners, expert RDNs Kathie Swift, Diana Noland and Elizabeth Redmond developed the IFMNT Radial,which was published as part of the 2011 SOP/SOPP and revised in 2018. The Radial customized the NCP for the IFMNT practitioner and incorporates the key factors at the core of IFMNT, facilitating the evaluation of complex information using the NCP [14]. It represents the first of such tools developed specifically for the IFMNT practitioner.

37.7 The IFMNT Radial

Published within the SOP/SOPP in 2011 and updated in 2018, three expert IFMNT practitioners established a visual conceptual framework to aid RDNs in implementing IFMNT in their practice. This patient-/client-centered model for critical thinking facilitates the shared decision-making process between patient and practitioner and offers a specialized version of the NCP for the IFMNT practitioner. Its circular architecture signifies the multidirectional motion and interrelationships between all aspects of health, imbalances, and disease states.

At the center of the Radial is the NCP, as the focal point of any IFMNT practice is to provide personalized nutrition care. The steps in providing this care are assessment, diagnosis, intervention, monitoring, and evaluation. The imagery in the center circle depicts food as a determining factor in health and disease. Surrounding the center circle are five circles representing each of the five key factors to evaluate a person's health: Diet, lifestyle and environment; signs and symptoms; biomarkers; metabolic pathways; and biological systems to consider. Since IFMNT recognizes that each of these areas is influenced by a person's biochemical and genetic uniqueness, the imagery of DNA and microbiota strands link the five key areas together signifying that each of these areas is interconnected, with any imbalance of one potentially affecting the others. Additional influences to be considered include precipitating factors, including stress and belief systems, toxic exposure, pathogens and infections, and allergens and intolerances. These potentially antagonistic factors all affect metabolism and overall health [7, 14] (Fig. 37.3).

37.7.1 Key Area: Food, Lifestyle, Environment

The food, lifestyle and environment area represents the patient's "story" and a subjective description of overall habits, which an IFMNT practitioner must consider as part of the NCP. Since food choices are an important determinant of health and disease, food preferences, access to foods, culture, and traditions are major factors to be discussed and understood by the practitioner. It also includes the health of those around the patient, how often he or she exercises and moves, sources and levels of stress, and the coping methods each person uses. It may include his or her access to nature, fresh air, and the amount of sunlight they are exposed to on a regular basis, as well as the kinds of relationships they have in their lives. Tools utilized might include a questionnaire or nutrition intake survey, food frequency questionnaire, or a food record. This is where the practitioner might begin to determine various triggers, antecedents, or precipitating factors related to the present health concern [7, 12].

37.7.2 Key Area: Nutrition Physical Signs and Symptoms

A major feature of IFMNT is the *nutrition-focused physical exam*, which enables the practitioner to assess and evaluate signs and symptoms. Visual symptoms can be clinically relevant, such as skin color, texture and moisture, and the appearance of the tongue and nails. Other tools employed here

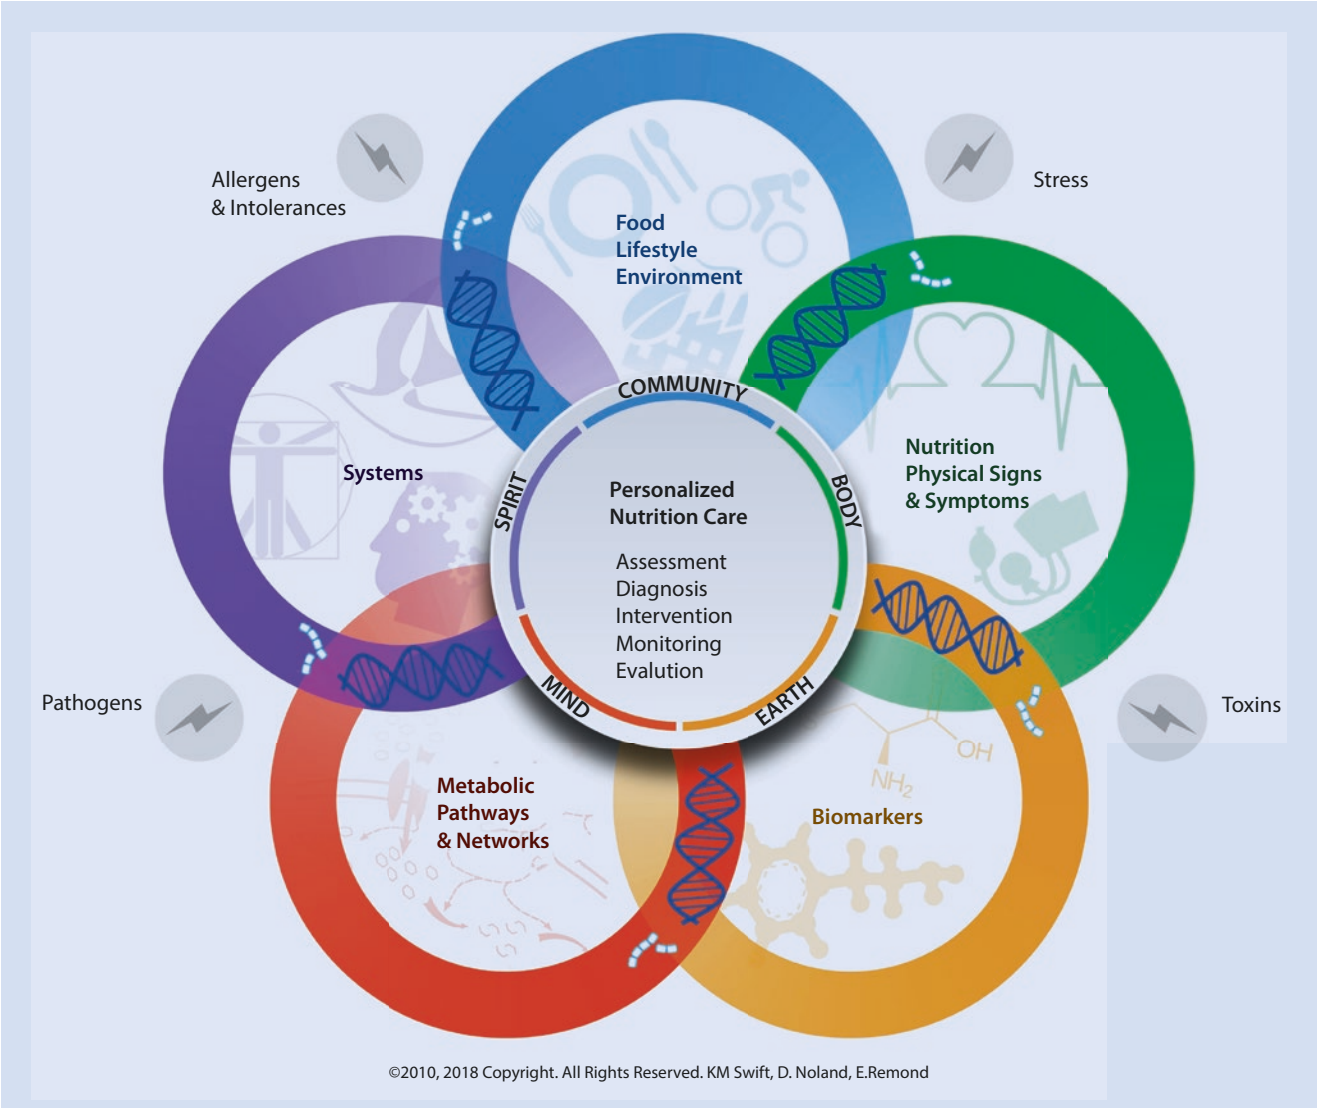

Fig. 37.3 Integrative and Functional Medical Nutrition Therapy (IFMNT) Radial. (Courtesy of Kathie Madonna Swift, Diana Noland, Elizabeth Redmond)

might include a multi-system questionnaire or other clinical signs and symptoms as described by the patient. From this information, the IFMNT practitioner can glean a systems analysis. In other words, this key area helps to shed light on body systems that may require support, such as digestive, endocrine, immune, nervous, reproductive, or detoxification/biotransformation systems [7, 12].

37.7.3 Key Area: Biomarkers

Biomarkers are of considerable importance to any practitioner, including those practicing IFMNT. Biological measurements, such as anthropometrics, vital signs, and laboratory data, are used to help shed light on abnormalities reported by the patient or identified as part of the nutrition-focused physical exam. Conventional biomarkers, such as blood and urine tests, can be used to evaluate nutrient status and look for nutrient insufficiencies and deficiencies that may be impacting health, as does more advanced functional testing for macro- and micronutrient status. These and other laboratory measurements are critical to IFMNT practice because they seek information on how well metabolic pathways are functioning. Each of these pathways is driven by complex molecular cascades that are largely reliant on nutrient cofactors that can be measured either with conventional or functional testing. Other influencers of these metabolic pathways include things like accumulated toxins, heavy metal interference, digestion and absorption issues, dysbiosis, and single nucleotide polymorphisms that can be measured using specialty labs and functional diagnostic testing [7, 12].

37.7.3.1 Examples of Conventional Tests

- Waist-hip ratio
- BMI
- Blood tests (e.g. complete blood count (CBC), comprehensive metabolic panel (CMP), vitamin and mineral

levels, immunoglobulin markers, cholesterol panel, homocysteine, thyroid panel, iron panel, food allergy panels, MTHFR, high-sensitivity C-Reactive Protein (CRP), hemoglobin A1C, sedimentation rate)
- Urinalysis (e.g. iodine levels, selenium levels, bacteria count, white blood cells, red blood cells, glucose, ketones)

37.7.3.2 Examples of Functional Tests

- Organic acids testing
- Genomics (e.g., MTHFR, VDR, GST, COMP, 23andMe, lipoprotein(a), detoxification panel, apoE)
- Digestive and microbial stool analyses
- Provoked urinary heavy metal testing
- Food sensitivity testing
- Salivary cortisol testing
- Salivary hormone testing
- Dried urine hormone testing

37.7.4 Key Area: Metabolic Pathways & Networks

Metabolic pathways are the biological machinery of the body, and overall health depends solely on how well these pathways run. The metabolic pathways of the body are driven by enzymes, the biological catalysts that trigger the conversion of one molecule to another. These enzymes are dependent on micronutrient cofactors, which can be measured and assessed by examining biomarkers. Even a subclinical micronutrient insufficiency can have a disruptive effect on metabolic pathways because the body prioritizes available micronutrients for the most important biological functions. Micronutrient insufficiencies may be insignificant in the short term but over time can contribute to the development of chronic conditions, poor antioxidant status, increased oxidative stress, premature aging, and a compromised ability to heal from injury or illness. Understanding nutritional biochemistry allows the IFMNT practitioner to better understand and recognize micronutrient imbalances, suboptimal metabolic processes, and the potential effects on the present state of health [7, 12].

This area focuses attention on assessing the integrity of the metabolic pathways to identify any core imbalances that may be present. By reviewing biochemical markers and pathway intermediaries, the IFMNT practitioner gathers information on metabolic pathway functionalities, which can then be interpreted within the context of the patient's current health status [12].

37.7.5 Key Area: Systems

The systems area serves to summarize and synthesize the findings from the other key areas and clarifies their overall effect on health status. By using the Radial, the IFMNT practitioner can identify the various causes that contribute to a specific malady, as well as identifying core imbalances that may be the root cause of several different symptoms. In this way, the "systems" area clarifies the opportunities for intervention and allows the practitioner to prioritize each inbalance and intervention.

Major system imbalances may include disruption in cellular integrity, digestion, detoxification, energy metabolism, oxidative stress and inflammation, nutritional status, immune system, endocrine systems, cardiovascular, and neurological systems [7].

37.7.6 Precipitating Factors

Linking each circle of the Radial are microbial and DNA strands with examples of precipitating factors that influence overall health, resilience, and predisposition to illness. In this way, all areas of the Radial are interconnected and influenced by each person's unique biochemistry and genetics. Each person's individual genome, epigenome and microbiome influences their health and biology in unique and complicated ways. Some of these factors include stress, toxic exposure, infection and pathogens, and allergies and intolerances [14].

Once the IFMNT practitioner has made a comprehensive assessment, including all relevant aspects of the Radial, he or she can develop a treatment plan that prioritizes the areas where the most important system imbalances lie. In terms of the Radial, this will be the circles with the greatest number of dysfunctions, specifically those that are triggers of the patient's primary symptoms and health concerns [12].

37.7.7 IFMNT Radial Summary

The IFMNT Radial provides a framework for the IFMNT practitioner to be thorough and organized in prioritizing information. It also helps the practitioner identify where further investigation is warranted. Organizing findings in this way can help the practitioner examine clinical findings into key imbalances, further clarifying underlying causes of disease and symptoms from a systems biology approach. In this way, the Radial is "a model for critical thinking that embraces both the science and the art of personalized nutrition care with considerations of multiple conventional or complementary care disciplines" [7].

37.8 Summary

An increase in demand for a more natural, holistic approach to healing, as well as the growing body of evidence supporting the safety and efficacy of Integrative and Functional Medicine practices, has driven the expansion of Integrative and Functional Medicine practitioners. Because nutrition and diet modification are the foundation of Integrative and Functional Medicine interventions, the growth in IFMNT-trained practitioners and those seeking training has also grown exponentially. Many healthcare providers have embraced IFMNT practices across disciplines, bringing nutrition and MNT as a modality for healing to the forefront of Integrative and Functional Medicine.

https://doi.org/10.1007/978-3-030-30730-1_38

A defining feature of integrative and functional medicine is the careful collection of the patient's story. The patient's story builds on the conventional (acute) medical model of gathering a patient's past medical history, history of present illness, review of systems, and accounts for the complexity of chronic disease. This information can illustrate to the clinician and the patient how the patient's life events and health story have contributed to their health status at the time of the consultation.

The importance of the patient story is emphasized by the idea that integrative and functional medicine practitioners treat each patient from the perspective of the "N of 1," meaning that the practitioner views the patient as an individual and takes into account the nuances of the patient's metabolism, lifestyle, genetics, stressors, and environment. Thus, each patient is considered his or her own control when evaluating the effectiveness of a therapy or treatment.

Gathering a useful patient story requires a clinician to ask careful questions that the patient might find culturally and personally sensitive [1]. The way a practitioner performs the patient interview can determine whether patients feel comfortable enough to share their stories and follow the recommended plan of care. The practitioner's interviewing skill can be honed over time. It is also important to keep in mind that the story will continue to develop as the patient works with the practitioner.

There are several goals of gathering a comprehensive patient story: (1) identifying antecedents, triggers, and mediators that impact the patient's health; (2) establishing a therapeutic relationship between practitioner and patient by building trust and rapport with the patient; (3) having a starting point and reference for the provider and the patient to build on during future appointments; (4) identifying any barriers or challenges that the patient might have (e.g., poor community or family support, physical, psychological, or emotional challenges); (5) creating a sense of hopefulness in the patient and the provider that there are therapeutic options for a patient who may have lost hope in any other medical options; and (6) informing the patient of the intervention plan.

The Institute for Functional Medicine (IFM) Matrix illustrates the complex and comprehensive information gathered from the patient (Fig. 38.1). The IFM Matrix is a guide for learning about the patient's health story from the standpoint of mechanism history. This means that the practitioner asks about the patient's health from the perspective of chronic

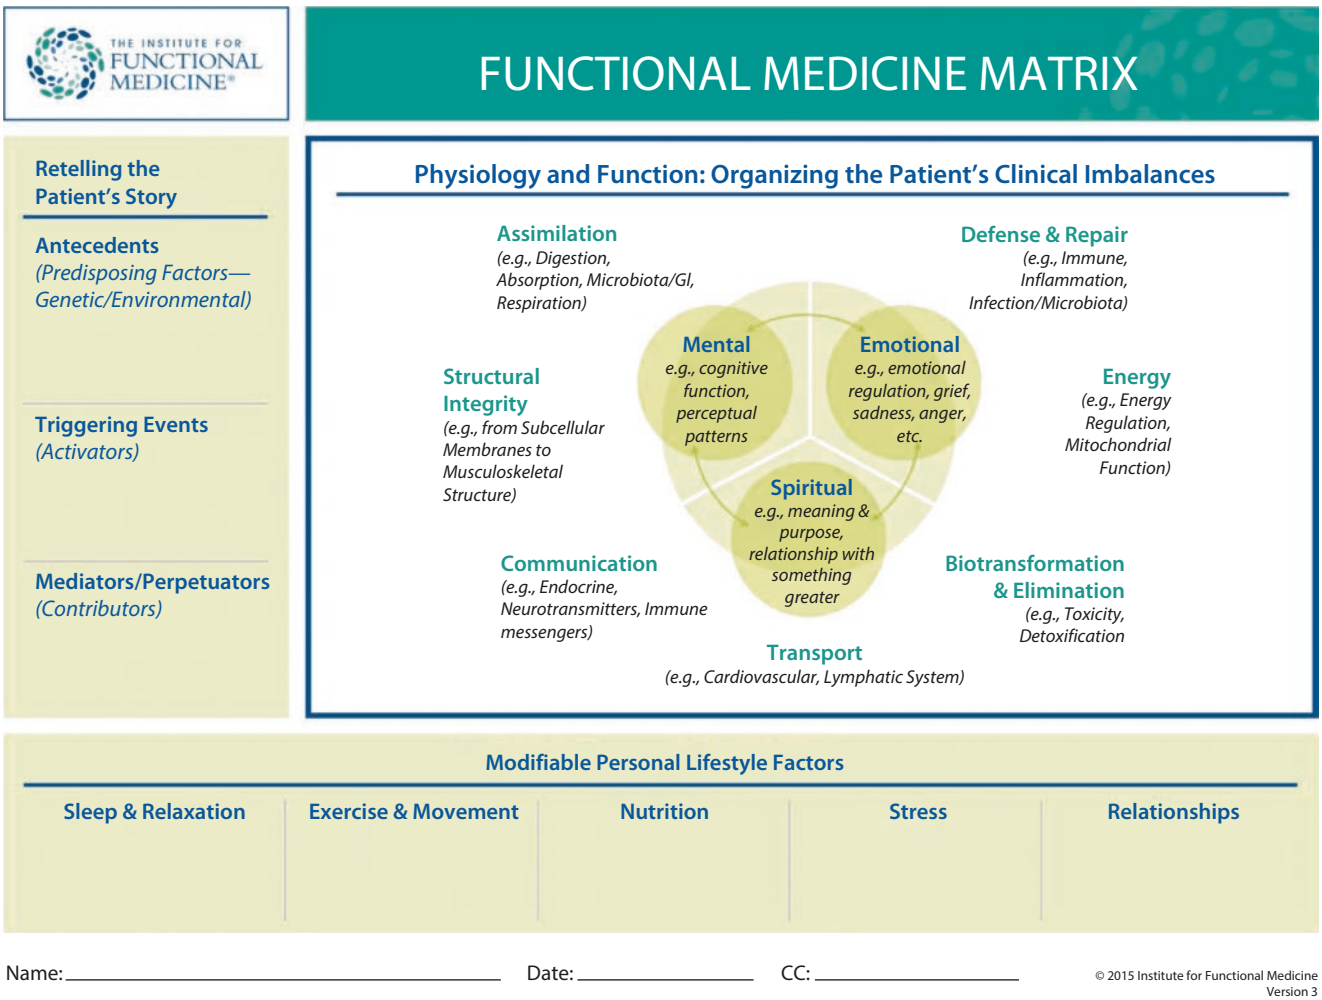

Fig. 38.1 Functional Medicine Matrix. (Used with permission from The Institute for Functional Medicine ©2015)

disease mechanisms and core imbalances. In other words, the practitioner can fill in the components of the IFM matrix as the patient tells his or her story.

The patient story is both a narrative and a means to note patterns that can provide clues to metabolic imbalances. It also informs the patient's intervention plan.

38.1 Patients, Providers, the Therapeutic Approach, and Relationship-Centered Care [1]

There are distinct roles that providers and patients take with respect to the therapeutic approach to healing. Patients are expected to take an active role in their own healing. One of the most important aspects of the provider and patient is the therapeutic relationship between the two parties. Relationship-centered care lowers overall healthcare costs [2, 3].

Providers see themselves as a navigator for the patient, who is the pilot of their own healthcare. Providers also take into account the beliefs and cultural nuances of each patient and understand the healing journey is unique to each individual [1]. Providers help patients overcome barriers to wellness and healing. In addition to educating, mentoring, and coaching patients, providers typically live their own therapeutic, healthy lifestyle; they do this for various reasons: [1] to empathize with the changes the patient is being asked to make, [2] to live a healthy lifestyle to be able to best care for themselves and their patients, and [3] to best guide patients on their healing journey.

The therapeutic approach to healing involves a holistic mind-body-spirit view. The mind accounts for the patient's mental health and knowledge base, especially regarding the understanding of his or her own lifestyle choices and their impact on their health outcomes. The body is probably where conventional healthcare spends most of its focus, checking anthropometrics (height, weight, body mass index), blood pressure, cholesterol levels, and other measurable changes. Integrative and functional practitioners also incorporate mind-body and spiritual aspects into the care plan. Spirituality can encompass religion, spiritual practices, mindfulness and/or meditation, and even the patient's community support. Each one of these aspects of the mind, body, and spirit is acknowledged as contributing to the patient's well-being, which the provider often conveys to the patient.

The therapeutic approach to healing also includes evidence-based practice that encompasses three facets [4]:

- The patient's goals and vision for health.
- Evidence in the scientific literature.
- The practitioner's clinical experience.

Combined, these three aspects of evidence-based healthcare can be weighed through gathering the patient's story and through the therapeutic relationship. Evidence is also collected from a variety of sources.

Ultimately, compassion and support are critical to the healing encounter between provider and patient. Whether or not a cure is possible for a patient's condition, the provider can always give encouragement and help guide the patient toward healing and wellness, if the patient sees that as an important goal.

38.1.1 "PEECE" in Practice

Rakel and Fortney describe the concept of "PEECE" in clinical practice in their chapter on "The Healing Encounter" in the textbook "Integrative Medicine" [1]. The acronym stands for Positive prognosis, Empathy, Empowerment, Connection, and Education. Positive prognosis refers to the concept of hope and enhancing positive patient expectations. Empathy and connection enhance the feeling of being cared for by the practitioner. Empowerment and education give the patient motivation to seek health-promoting behaviors.

38.1.2 The Patient's Story and the Institute for Functional Medicine Matrix

One method of organizing and seeing the influence of the patient's story on his or her own health is by using the Institute for Functional Medicine's (IFM) Matrix [5] (Fig. 38.1). The IFM Matrix is a tool that can help the clinician record and visualize the impact of the patient's story on his or her health. On the left perimeter of the matrix, the clinician is prompted to ask the patient to retell his or her life and health story. The clinician can record this in a timeline format or can make notes in each of these categories:

- Antecedents (predisposing factors – genetic/environmental).
- Triggering events (activators).
- Mediators/perpetuators (contributors).

In an IFM presentation, Dr. Dan Lukaczer, ND, [6] describes antecedents as "factors, genetic or acquired, that predispose [an] individual to an illness." He defines triggers as "factors that provoke the symptoms and signs of illness" and mediators/perpetuators as "factors, biochemical or psychosocial, that contribute to pathological changes and dysfunctional responses." Examples of antecedents, triggers, and mediators include stress, infections (chronic or acute), toxic exposures, foods, and allergens, sensitivities, and/or intolerances.

The clinician can use the central part of the matrix to record, organize, and visualize the patient's clinical imbalances: assimilation, structural integrity, communication, transport, biotransformation and elimination, energy, defense, and repair. In the middle of the matrix, the practitioner is reminded of the importance of the patient's mental, emotional, and spiritual health. Along the bottom border of the matrix, the clinician is reminded of the modifiable lifestyle factors that should be reviewed with the patient to find out where excesses or deficiencies might appear. These lifestyle factors include sleep, relaxation, exercise, movement, nutrition, stress, and relationships. While listening to the

patient's story, the clinician can fill in the information on the matrix to create a visual to work from and create a personalized plan of care for the patient.

38.1.3 Patient Example

A 30-year-old woman visits with persistent hives. She has seen her primary care physician, a dermatologist, and an allergist and has tried several creams and medications. She has some relief of her symptoms, but she still has hives. She sought out a consultation from an integrative and functional dietitian, who asked her about the onset of her symptoms (prior to and during her two pregnancies) and her triggers (stress and pressure on her skin). She said the hives would persist for weeks, and several would develop while others were healing. After getting the patient's medical background, she shared that she hates and avoids all fish and seafood (antecedent/mediator) and that her son has skin rashes when he drinks cow's milk. She also says that the symptoms persisted after the birth of her second child. A mechanistic understanding of the essential fatty acid/eicosanoid pathway helps illustrate how the patient's story may give clues for laboratory testing for the patient and a means to intervene. The dietitian recommended nutritional lab testing: high-sensitivity C-reactive protein (hsCRP), vitamins D, B12, folate, and an omega-3 index. The labs showed that she was, in fact, deficient in omega-3 fats and vitamin D was deficient at 17 ng/dl. The patient's story helped inform what was driving the hives to persist; it led the practitioner to consider the mechanisms of inflammation and immune dysregulation, which can be affected by the eicosanoid cascade (omega fatty acids) and vitamin D's effect on the immune system. The family history of hives in her son following milk ingestion advises the practitioner to also check food sensitivities in the patient. After successful reintroduction of deficient micronutrients and food elimination, the hives resolved.

The Nutrition-Focused Physical Exam

Mary R. Fry

39.1 Background/Introduction – 638

39.2 Conclusion – 691

References – 692

Learning Objectives

- Recognize the importance of the nutrition physical exam for both nutrition professionals (dietitians and nutritionists) and medical providers.
- Identify signs of nutritional status and hydration from physical examination.
- Relate pertinent physical examination findings to their nutritional (and medical) causes.
- Compare and contrast anthropometric measures and their clinical utility.

39.1 Background/Introduction

The nutrition-focused physical assessment (NFPA), also referred to as the nutrition-focused physical exam (NFPE), is a vital part of a nutritional assessment and forms an integral part of the nutrition care process (NCP) model, which is comprised of the following separate and consecutive steps: assessment, diagnosis, intervention, monitoring, and evaluation [1]. The nutrition progress note for the NCP model is correspondingly referred to as an "ADIME" note. This model was devised, in part, to ensure a comprehensive nutrition assessment. A nutrition-focused physical exam forms an integral part of the NCP model assessment step, which itself is comprised of five domains:

- Food/nutrition-related history
- Medical/psychological or behavioral history
- Anthropometric measurements
- Biochemical data/tests/procedures
- Nutrition-related physical findings

Findings from each of these five domains are required to systemically analyze and integrate the findings from each portion of the NCP model in order to accurately determine nutritional status [1–3].

Furthermore, each of the steps listed above (and their domains) informs the subsequent step and actions to be taken by the nutrition care professional. For example, dietary and medical history should focus on the physical exam and subsequent laboratory assessments, which can then result in a clear and accurate working nutritional diagnosis (or diagnoses). This diagnosis then informs and guides clinical intervention and the monitoring/evaluation thereof [2–5].

Despite the critical role that the nutrition-focused physical exam plays in a comprehensive nutritional assessment, it did not become a part of a dietitian's (or nutritionist's) practice or education until the 1990s, a full decade after the concept for integrating it into the nutritional assessment was proposed [6–9]. Despite nearly three decades passing since its integration into practice, a vast majority of dietitians still do not readily incorporate it into a routine patient assessment [5].

A prospective Internet-based survey of registered dietitians in the USA reported the following as factors limiting the incorporation of the NFPE into practice: workload (70.3%), lack of prior education (42.4%), and training (43.5%) [9]. Regarding workload or time, 52.3% of US dietitians surveyed by Mackle et al. [10] cited time as a limiting factor to using the NFPE, and 25.3% cited confidence in their ability to competently perform the NFPE.

The majority of those surveyed reported that they did not receive sufficient training to competently perform the NFPE on their patients, with the exception of the following assessments: height (96.4% of those surveyed reported feeling competent to measure), weight (97.4% of those surveyed reported feeling competent to measure), waist circumference (78.0% of those surveyed reported feeling competent to measure), and skinfold measurements with a caliper (65.2% of those surveyed reported feeling competent to measure) [9].

To date, similar analyses have not been conducted for nutritionists in practice, but similar practice patterns and competencies in the NFPE are likely, based on a comparison of the average curriculum across these professions. As it happens, the practice of integrative nutrition may be even more challenged in the realm of the NFPE, with a wider variety of functional tests to learn about and gain competency in, and with fewer opportunities for hospital-based internships (where a variety of NFPE skills are generally more likely to be practiced).

On the medical front, physicians' use of the physical exam is similarly threatened or arguably underutilized. In the "Physician's Perspective," published in *The New England Journal of Medicine* [11], Dr. Jauhar attributes the demise of the physical exam in medicine to a discomfort with uncertainty and a fear of subjective observation. Technological methods of diagnosis are increasingly seen as more certain and legally defensible. Rathe's commentary on the "Complete Physical" [12] concurs, stating that failure to diagnose (accurately) commonly results in medical malpractice suits.

However, proponents of the physical exam emphasize its importance in supporting the development of trust, empathy, and relationship-building. Verghese and Horwitz [13] contend that physicians skilled in physical exams order fewer unnecessary tests and make better use of the information gained from these tests than counterparts who eschew or limited their use of the physical exam.

As to a physician's knowledge of nutrition (since the emphasis of this chapter is on the nutrition-focused physical exam), a recent review of the status of nutrition education in US medical schools reports that "the amount of nutrition education medical students receive continues to be inadequate" [14]. The survey conducted in this study questioned nutrition educators at medical schools directly (109 surveyed, with 105 completing the survey) and found that only 27% of the schools surveyed provided the minimum 25 hours

of nutrition instruction recommended by the National Academy of Sciences. Moreover, medical residents, recent graduates, and practicing physicians surveyed in other studies reported feeling ill-prepared to provide nutritional counsel and care [14].

The NFPE is a full head-to-toe exam of a patient in which their appearance and function are assessed in order to detect any signs of malnutrition, nutrient deficiencies, or nutrient toxicities [5]. In the realm of integrative and functional nutrition, this can be expanded to include signs of suboptimal organ system function and imbalances (which will be covered extensively in the tables associated with this chapter).

The goal of a NFPE is to identify factors that may impede normal dietary intake and habits that may impact nutritional status and/or that may reflect conditions that are nutritional in nature [8] or to examine the fat, muscle, fluid, and micronutrient status of a patient and whether or not it is outside of normal levels as a result of inflammation, illness, and/or excess or deficient nutrient intake [15]. Dietitians and nutritionists are not qualified/permitted to diagnose medical conditions; however, they are qualified to make a nutritional diagnosis, which is defined as a condition that can be resolved or improved by nutrition intervention [16]. The NFPE is designed to assess and diagnose nutritional conditions and is to be used to inform other domains of the nutritional assessment as well as to guide and inform that monitoring and evaluation of a patient's case, enabling the nutritionist to gauge the patient's response to the intervention [1, 4]. The NFPE can bring medicine, nutritional sciences, food science, and technology together to address suspected nutrition-related health conditions and imbalances [4].

The components of the physical exam were loosely defined originally and ranged from body composition measurements (height, weight, percentage body fat, assessment of muscle tissue) to vital signs, visual assessment for clinical signs of nutrient deficiencies, and oral, cardiac, pulmonary, abdominal, and dermatological examination [8]. A more current working definition of the NFPE for dietitians derived from Touger-Decker [8] is the measurement of vital signs and body composition (height, weight, and bioelectrical impedance analysis, among others); inspection for clinical signs of nutrient deficiencies; auscultation of heart, lung, and abdominal signs; and examination of the head, neck, oral cavity, skin, and cranial nerves. Touger-Decker goes on to differentiate NFPE skills into those expected of an entry-level practitioner: vital signs (pulse, blood pressure); head, neck, and oral examination, including extraoral (lips, eyes, nose, ears) and intraoral (hard and soft tissue, tongue, teeth, and saliva); recognition of the components of lymph node and cranial nerve examination; dermatologic examination for both nutrient deficiencies and edema; body composition analysis (bioelectrical impedance analysis and calipers); cardiac and pulmonary auscultation; and an abdominal exam. For a more advanced practitioner, competence in performing all of the aforementioned techniques is expected, along with the ability to *conduct* lymph and cranial nerve exams versus just recognizing their components. Esper [1] describes the NFPE as a system-based examination, which is similar to the physical exam performed by a licensed healthcare provider. It is outlined: general inspection, vitals, skin, nails, head/hair, eyes/nose, mouth, neck/chest, abdomen, and musculoskeletal. Examination techniques employed are similar to those utilized in a physical exam performed by a licensed healthcare provider and include inspection, palpitation, and auscultation (note that percussion is seldom performed by dietitians/nutritionists) [17].

Medical nutrition therapy (MNT) involves the assessment of a patient with one or more medical conditions which can place an individual at nutritional risk. MNT has been shown to decrease the duration of hospital stays and decrease the need for/use of more costly medical interventions and can, in some cases, obviate the need for hospitalization [2]. Integrative and functional medical nutrition therapy (IFMNT) takes dietetics and medicine to another level with the focus on optimizing nutritional status to optimize health and, in turn, reduce the risk of nutrition-related disease [18].

The IFMNT model is an extension of the NCP model. The IFMNT approach is encapsulated in the following radial, with the NCP's ADIME at its core and an array of factors to consider radiating out from this. In this chapter, a conventional dietetics approach to the NFPE will be covered as part of a more extensive and integrated IFMNT approach. The NFPE of an integrative nutritionist is more comprehensive and sensitive (to detect early and subtle changes that reflect suboptimal nutrient status and health) than that classically taught to dietitians. Note that in the IFMNT radial below, at least three of the five factors (biomarkers, systems, signs and symptoms) influencing nutritional status rely on NFPE findings [19] (Fig. 39.1).

To thoroughly perform this exam, each body region is covered below, along with possible pertinent abnormal findings, for reference. Note that the scope and techniques described below extend beyond a typical NFPE performed by a dietitian as functional signs and techniques are included (as are, in some cases, more medically oriented techniques and findings). These additional examination tools and techniques can aid in detecting early signs of nutrient deficiency or toxicity and functional imbalances that could be caused by or contribute to changes in nutritional status.

It is my hope that this chapter revivifies the physical exam for dietitians, nutritionists, and other healthcare providers and, in so doing, fosters more comprehensive and qualitative nutritional and nutrition-oriented medical care and enhances the patient-provider relationship (Table 39.1).

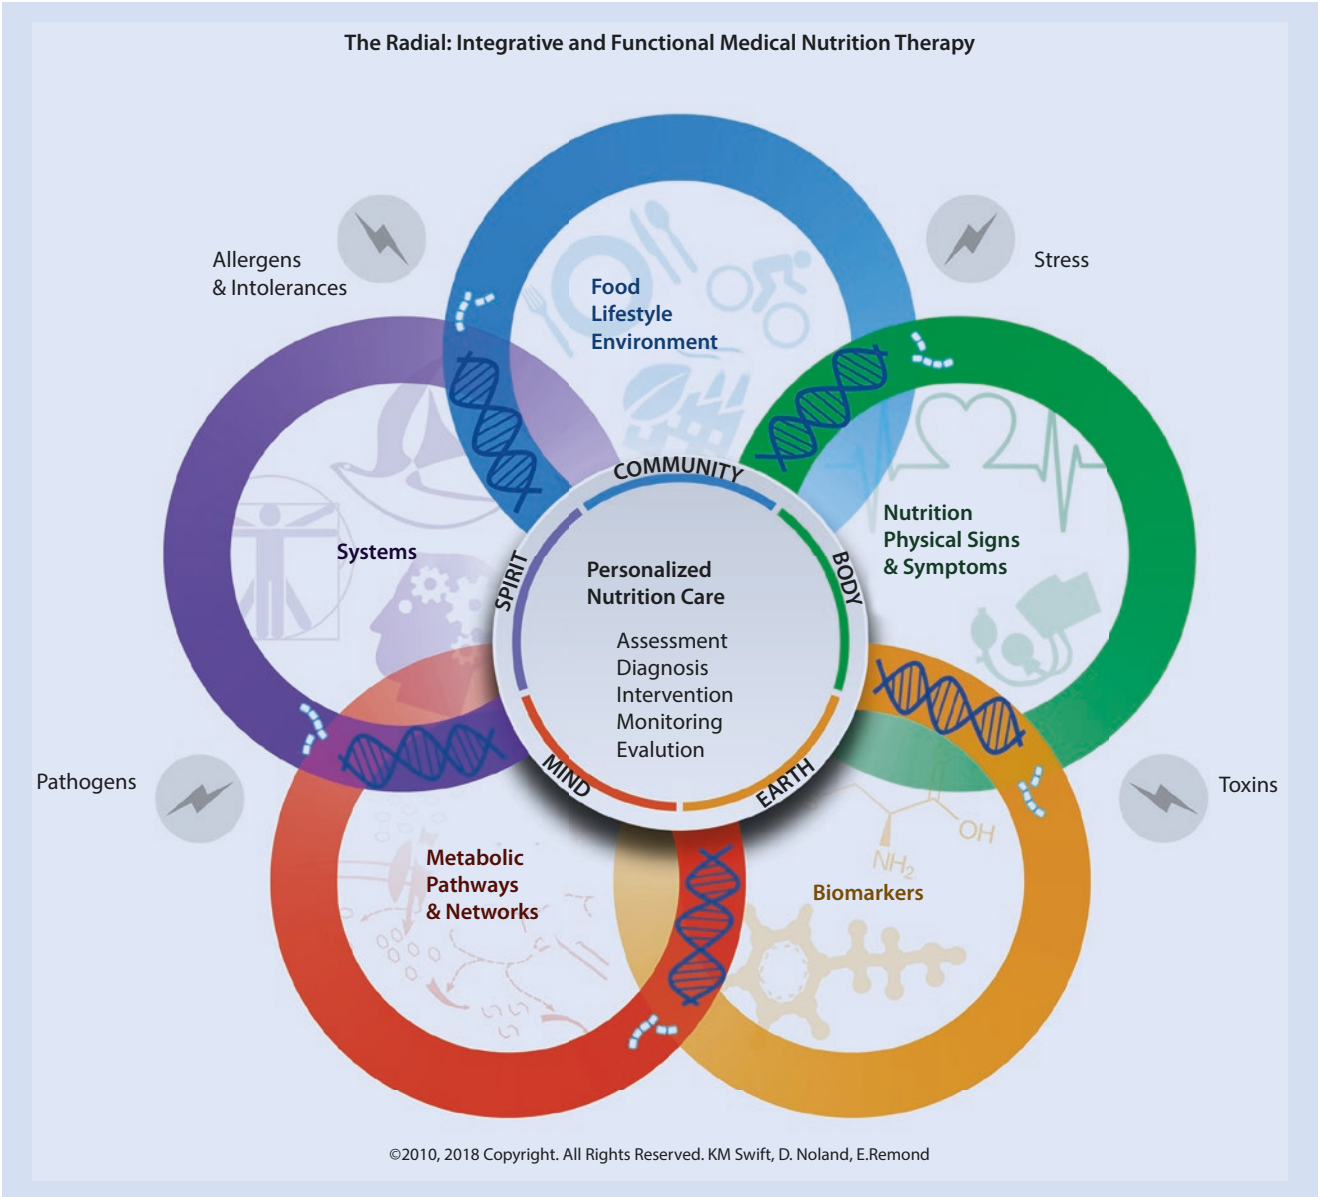

Fig. 39.1 Integrative and Functional Medical Nutrition Therapy (IFMNT) Radial. These factors influence one's function (physiologic) as well as one's nutritional status. Further, they provide a common language and bridge between nutritionists/dietitians and medical providers (particularly those practicing functional medicine), thus facilitating collaboration and coordination of care. (Courtesy of Kathie Madonna Swift, Diana Noland, Elizabeth Redmond)

Table 39.1 Nutrition-focused physical exam reference table

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
General (also referred to as "Global Examination") [2]	*This section of the physical exam is devoted to a general survey of the patient for alertness, affect, speech, coordination body size (overweight/obese or wasting), and habitus (*i.e., *build – endo-, meso-, or ectomorphic) and body movements. This is where your first impressions of the patient/client are formed. You are looking to assess their overall state of health, are they currently ill or frail, or fit or robust? Are they showing signs of mental or physical distress? What is their level of consciousness and alertness? How are they groomed? Do you detect any unusual odor?* [16] *This global exam will drive what you focus on for the remainder of your exam, so pay careful attention to these clinical findings.*		
	Grooming [20]	Poorly groomed (unkempt, unclean clothing, and personal hygiene [grooming/care of the hair, skin, teeth, mouth, overall body])	Dementia Psychiatric disorders (psychosis, schizophrenia in particular) Homelessness or poor living conditions Essential fatty acid (EFA) imbalance Vitamin B_{12} status insufficiency
	Clothed inappropriately for the season [20]	Cold intolerance	Anemia (iron-deficient) Low thyroid function
	Shoes untied or slippers [20]	Pedal edema	See "Edema" section below
	Toes of shoes cut out [20]		Gout or foot ulcers Neuropathy with burning feet "Burning feet syndrome" – thiamine deficiency (accompanied by peripheral neuropathy)
	Body piercings or tattoos [21]		May be at increased risk of hepatitis C
	Odor	Body	Poor hygiene (see "Grooming" above) Disturbances in skin microflora balance [22] Diet (spices (cumin), garlic, and onions) Stress [23] Steroid hormone imbalances SNPA ABC11 538G/A or G/G polymorphism associated with strong axillary odor with perspiration and staining of clothes (axillary osmidrosis) [24] Trimethylaminuria (fish malodor syndrome) is a genetic metabolic disorder that results in an odor of decaying fish [25] Liver disease (ammonia) Kidney disease (uremia) Chronic genital infections
		Breath [21, 26]	Alcohol (evaluate for macronutrient status – energy, protein, and micronutrient status: iron, thiamine, riboflavin, pyridoxine, niacin, folate) Fruity/acetone odor – diabetes – due to ketosis [27] Garlic odor with selenium toxicity Putrid – may have bacterial overgrowth in GI Uremia with renal disease
	Pain	Wincing or painful grimace, increased perspiration, protecting the affected area [21]	Examine/evaluate the painful region or symptoms further for the etiology or origins thereof
	Alertness	Evaluate by asking/observing the patient's awareness of their environment and their attention span	Allergies or suboptimal liver function/toxicity Fatigue [28] Medication [28] Narcolepsy [28] Attention deficit disorder/attention deficit hyperactivity disorder [28] Dementia [28] Schizophrenia [28]

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Orientation	Oriented to person, time, and place?	Essential fatty acid (EFA) imbalance Vitamin B_{12} insufficiency Phosphorus and niacin status for insufficiency
	Affect	Flat	Iron and vitamin B_{12} insufficiency Dysthymia/depression Hypothyroidism/suboptimal thyroid function Schizophrenia
	Speech	Dentures click when talking	May be related to weight loss
		Pressured and/or rapid speech	Hypomanic/manic (bipolar disorder) Rule out hyperthyroidism or thyroid storm as cause
	Skin color	*To evaluate pigmentation, check the conjunctiva, nail beds, palms (loss of crease in severe anemia), lips, and tongue*	
		Hyperpigmentation	Niacin deficiency (with peeling in sun-exposed areas), folate, and/or B_{12} deficiency [29], protein energy malnutrition (when on extremities) [30] Addison's disease
		Hypopigmentation In dark-skinned individuals, examination of the palms and soles may be helpful	Vitiligo, pallor, and anemia (iron, folate, or B12 deficiency [29], arterial insufficiency) B_{12} deficiency (associated with vitiligo) Copper deficiency (hypopigmentation on the neck, axilla, and/or trunk in Menkes disease) [30]
		Pallor	Anemia
		Erythema (redness) [16, 31]	Facial redness, suspect: fever, menopause, rosacea, hyperthyroidism, niacin supplementation, caffeine, spicy food intake, or possibly inflammation Redness in other locations of the body may result from inflammation, injury, rash or infection, or allergy (red ears) Riboflavin, zinc, and EFA deficiency [30]
		Yellow (jaundice) To see jaundice in the lips, blanch with a glass slide or small flat glass implement It is typically first noted in the eyes and then seen in the face, mucous membranes, and eventually all of the skin	Results from excess amounts of bilirubin in circulation as a result of increased hemolysis, liver disease, or obstruction of the flow of bile to the intestine [16] If it spares the sclera (white part of the eyes), it is carotenemia and not jaundice It can occur in pernicious anemia (vitamin B_{12} deficiency) [16, 29, 31]
		Orange	Carotenemia – look at the palms, soles, and face. Results from excess consumption of carotenoids
		Brown [21] Melasma (also known as chloasma or the "mask of pregnancy") is characterized by dark, discolored patches on the skin (mainly facially) and is generally seen in women of reproductive age) Acanthosis nigricans – velvety brown-to-black markings in areas of body creases (skin folds, armpits, over joints in the fingers and toes) [16]	Sun exposure Melasma can occur in pregnancy (and with sun exposure, use of oral contraceptives) Acanthosis nigricans can occur with obesity and metabolic syndrome, dyslipidemia, hypertension, Addison's disease, pituitary disorders, hypothyroidism, polycystic ovarian syndrome (PCOS), and administration of growth hormones, oral contraceptives [32], with excess niacin supplementation [30]. Its presence in children heralds the development of metabolic syndrome. It can also be seen in those with lymphoma and cancers of the genitourinary or gastrointestinal tract or from medications and nutrient supplementation (nicotinic acid) [16]. Excess niacin intake (may be accompanied by blistering) Hemochromatosis (iron storage disorder)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Gray	Iron toxicity [30]
		Cyanosis [16, 31]	Decreased oxygenation of the blood (note that testing for oxygen saturation is generally considered a more accurate of blood oxygenation) Central cyanosis: cyanotic lips, buccal mucosa, tongue – see in COPD, heart disease, abnormal hemoglobins Peripheral cyanosis: cyanotic nail beds can occur with exposure to cold, anxiety, CHF, Raynaud's disease, and venous obstruction Hemoglobinopathy
		Purpura (bruising)	Vitamin C/K insufficiency If bruising readily with trauma, may be due to essential fatty acid (EFA) insufficiency [30] Easy bruising – can be due to platelet disorders (aplastic anemia), liver failure, hypersplenism (splenomegaly), autoimmune disorders, alcoholism, and hematologic malignancies
		Use of makeup or cosmetics	May affect accuracy of skin assessment (hide skin tone, lesions, acne) Tip: inquire about brand of cosmetics (ensure lowest toxin cosmetics are used) [33]
	Edema (peripheral) [30, 34]	Positive pitting test: Depressing skin over suspected edematous area and then removing pressure yields a pit that remains for over 5 seconds	Protein, energy, zinc, and thiamine status for insufficiency Low serum albumin [3]
	Weight loss, wasting, or cachexia [21, 26] (Sarcopenia is referenced later in this table)	Check temporal lobes and cheeks – well-demarcated bony prominences and veins [3, 29]	Protein, fat, and energy insufficiency Malnutrition (a risk factor for infection and poor wound healing) Cancer Dysphagia Vomiting/diarrhea Malabsorption HIV/AIDS (lipodystrophy)
	Overweight/ obesity [20, 21]	BMI Waist-hip ratio (WHR) Waist-to-height ratio (WHtR) Skin caliper testing Bioelectric impedance analysis (See "Aanthropometrics" table following this table)	Excess caloric intake/insufficient physical activity/ endocrinological imbalance (e.g., low thyroid function)/ genetics Assess for toxicity (particularly dioxins and heavy metals) Tip: educate the patient about risks of excess weight, diabetes, heart disease, stroke, hypertension, osteoarthritis, sleep apnea, some types of cancer, inflammation, and dysbiosis
		Central obesity [34] "Apple shape" Adiposity is concentrated in the upper half of the body (neck, cheeks, shoulder, chest, upper abdomen) More common in men	Increased risk of metabolic syndrome (hypertension, insulin resistance, inflammation, cardiovascular disease, dyslipidemia, sleep apnea) with increased visceral adiposity

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Peripheral obesity [34] "Pear" shape Adiposity is concentrated in the lower half of the body (lower abdomen, pelvic girdle, buttocks, and thighs) More common in women	Carries health risks of obesity, but lower health risks than central obesity
	Uncoordinated gait (ataxia)		Thiamine or copper deficiency [1] Mitochondrial dysfunction [20] Essential fatty acid imbalance [20] Toxin burden [20]
	For additional gait disturbances, see the "Neurological" section later in this table		
	Amputation [26]		Possible diabetes complications Possible history of severe infection Possible history of traumatic injury/accident Amputations will affect calculations of weight and require calculation of an adjusted weight
	Body movements [4]	Can the individual feed independently (i.e., do they have limited use of hands or inability to sit upright)?	Lack of ability to independently feed must be addressed to ensure sufficient nutrient intake
	Posture [20]	Dowager's hump/stooped posture	Bone loss (osteomalacia or osteoporosis) Vitamin A and D, magnesium, or calcium insufficiency Tip: consider further testing (DEXA and N-telopeptides cross-links (NTx) to monitor response to interventions) [35] Depression Parkinson's disease [36]
		Preference to sit erect, neck veins distended	Left-sided heart failure [21]
		Preference to lean forward, arms crossed	Chronic obstructive pulmonary disease (COPD) [21]
		Fetal position	May be due to pancreatitis [34]
		Bend toward the side of the lesion	May be due to renal or perirenal abscesses [34]
		Still: avoid movement as it provokes pain	May be due to peritonitis [34]
		Restless	May be due to intestinal obstruction [34]
	Tanner stage	Evaluate if developmental age is consistent with chronological age	Assess for signs of macronutrient and micronutrient deficiencies that may have delayed growth and development Assess for developmental delays that may have affected food and nutrient intake [16]
Bates – mini	**Breathing**	Labored Rapid, shallow Wheezing	(See "Respiratory" section of table below)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Subjective global assessment (SGA) of nutritional status [16, 26, 34]: Tool to assess malnutrition based on patient's history and physical exam. It is also a powerful predictor of postoperative complications. Assesses recent loss of body weight, changes in the usual diet, the presence of significant GI symptoms and the patient's functional capacity, and three elements of the physical exam Assess the following using a scale of normal (0), mild (1+), moderate (2+), and severe (3+) **History assesses:** Recent loss of body weight Changes in the usual diet Presence of significant GI symptoms Functional capacity **Physical exam assesses:** **Subcutaneous fat loss** – assess the following sites for a lack of fullness (i.e., the skin fits loosely over the tissues): triceps, midaxillary line (costal margin), palmar areas of the hand, interosseous muscles (between the thumb and forefinger as an example), and deltoid region of the shoulder –Assess using a scale of normal (0), mild (1+), moderate (2+), and severe (3+) **Muscle wasting** – assess by palpation (and inspection at a distance, as helpful). Examine the quadriceps and deltoids. "Squared off" shoulders are visible with muscle wasting and subcutaneous fat loss **Loss of fluid from the intravascular space**- ankle or sacral edema, ascites. Assess for edema via palpation (pitting test) **Score/classes:** Class A (well-nourished) Class B (moderately malnourished) Class C (severely malnourished)			
Vital signs	*The utility of a vital sign is to give the clinician an early indication of ill health or imbalances. They are the signs of life* [16] *or "vitality." They serve to establish a baseline and are a helpful tool for monitoring and evaluation thereafter*		
	Temperature *Average normal temperature is 97.7 degrees Fahrenheit (or 36.5 degrees Celsius). (McGee)*	Elevated	Confers increased food and fluid requirements [3]. Can indicate infectious disease, trauma (surgery/injury), malignancies, immune disorders, blood disorders (hemolytic anemia), infarctions, and medications. Fever with chills (shaking) – accurate sign of bacteremia [31]
		Depressed	Hypothyroidism or Wilson's temperature syndrome, hypoglycemia, insomnia, severe stress/shock, exposure to cold, anemia, diabetes, Addison's disease, infection, liver/kidney failure, paralysis, excess alcohol intake, starvation, medications [21] Note that a depressed body temperature can lead to deleterious consequences metabolically (enzymes do not function optimally at lower body temperature) Wide variability of temperature can be seen in adrenal insufficiency [16, 31]
	Pulse	*Measure radial pulse for at least 15 seconds to obtain (30 seconds is preferred). A number of different qualities of the pulse are measured/observed in Ayurvedic and Chinese medicine diagnostics.* ***Normal sinus rate = 50–95 beats per minute (bpm)***	
		Elevated (tachycardia) >100 bpm	Anemia, hyperthyroidism, with elevated body temperature, anxiety, pain, exercise, medications (antidepressants and others) [3, 31] Prognostic: can portend increased complications and poorer survival rate across many clinical disorders Magnesium, calcium, and/or niacin insufficiency may be a cause of tachycardia
		Depressed (bradycardia) <50 bpm	Exercise/training (i.e., improved conditioning), heart disease, hypothyroidism, medications [3]
	Irregular heart rate/rhythm may be due to potassium deficiency (can be seen with diuretics), magnesium deficiency, dehydration, or allergies		

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Respiratory rate	Measure of the number of breaths per minute Respiratory rate is the only vital sign under voluntary control (why measuring it without telling the patient is advised (so take before/after take patient/client's pulse) Take for 30–60 seconds to ensure accuracy Normal respiratory rate = 20 breaths/min (ranges from 16 to 25 breaths/min) [31]	
		Increased (tachypnea) >25 breaths/min	Dyspnea (difficult or labored breathing) with patient lying down that is relieved while sitting up – can be due to ascites, pleural effusion, morbid obesity, congestive heart failure (CHF), or severe pneumonia Rapid deep breathing (hyperventilation) – can occur with exercise, anxiety, metabolic acidosis, and brain stem injury [21] Can affect calorie and protein requirements as well as type of food eaten and quantity [3] – as eating may increase energy expenditure, fatigue, or dyspnea [16]
		Decreased (bradypnea) <8 breaths/min	Diabetic coma, medication-induced or due to increased intracranial pressure
		Kussmaul respirations – rapid and deep –seen in patients with metabolic acidosis (most other abnormal respiratory rates see shallow respirations). The rate can be fast, slow, or normal [21] Cheyne-Stokes breathing/periodic breathing – alternating periods of hyperpnea and apnea. Occurs when there is enhanced sensitivity to carbon dioxide. Seen in stable congestive heart failure, neurological disorders, hemorrhage, infarction, tumors, meningitis, and some head trauma (brain damage), from medications, and at high altitudes or during sleep (considered normal) With fluctuations of respiration come fluctuations in mental status Prognostic: in a patient with heart disease, this respiratory rate is associated with a poor prognosis	
	Blood pressure When evaluating hypertension in children and adolescents – use blood pressure for male/female by age and height percentiles table(s) [26]	Systolic blood pressure – maximal arterial pressure during systole (the phase of cardiac contraction) Diastolic blood pressure – minimal arterial pressure during diastole (the phase of cardiac relaxation) Normal blood pressure: 120–129/80–84 mm Hg <120/80 mm Hg Recommendation to take the mean of at least 2 seated blood pressure readings on 2 or more days before deciding on a diagnosis of hypertension [16] Common errors in measuring: wrong cuff size (kids), auscultatory gap, stethoscope pressure too firm, inappropriate level of the arm, feet not firmly on the floor, terminal digit preference (clinician's like to round to the nearest 0. 5 or another preferred number) [26, 31, 37] "White coat hypertension" – temporary increase in blood pressure when in a medical environment. Consider ABPM (ambulatory blood pressure monitoring) if persists. ABPM periodically measures and records blood pressure over 24-hour period (or longer)	
		Elevated (hypertension) > 120/80 mm Hg	"Masked hypertension" – blood pressure readings are normal in a medical visit but elevated in everyday life [16] Can be seen with blood loss, myocardial infarction and cardiac failure, irregular heart rate, medications [3] May be due to excess sodium intake (in those with a single nucleotide polymorphism (SNP) that codes for salt sensitivity) [38] Potassium, magnesium and calcium [37, 39], and vitamin D insufficiency [29, 30]
		Depressed (hypotension)	Medications Anorexia, electrolyte loss, or dehydration [16]

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Postural or orthostatic hypotension: As a patient stands after lying supine, blood volume shifts to lower body. Normally blood pressure can stay stable during this shift (via compensatory mechanisms to increase cardiac output, heart rate, vascular resistance, and circulation of the blood to the body (from the heart)), which involves increased sympathetic outflow. If compensatory mechanisms fail, (decrease in systolic blood pressure of 20 mm Hg or a decrease in diastolic blood pressure of 10 mm Hg within 3 minutes of rising from sitting or supine position), a diagnosis of postural hypotension is made [40] Note that this may be accompanied by a feeling of dizziness or lightheadedness on standing, weakness or fatigue, and syncope Occasionally orthostatic dyspnea/chest pain can be seen [16, 40] Postprandial hypotension (decrease in systolic blood pressure of at least 20 mm Hg within 75 minutes of a meal) is related to orthostatic hypotension [40]	Associated with adrenal insufficiency, dehydration, blood loss, shock, anemia, pregnancy/postpartum, hypothyroidism, eating disorders, hypokalemia, acute hyperglycemia, AIDS, anxiety or panic disorder, eating disorders, prolonged bed rest, cardiovascular conditions (congestive heart failure, MI, arrhythmia, myocarditis, pericarditis, valvular disease, venous insufficiency), alcohol, medications (antiadrenergics, antiarrhythmics, antianginals, antidepressants, diuretics, sedatives, neuroleptics, antiparkinsonian agents, narcotics) [40] Can see more commonly in those >65 y.o. and in those who are frail [40], less physically active at work or who have multiple comorbidities (such as CHF, stroke, chronic kidney disease [41] Prognostic: associated with an increased risk of dementia [42] and may predict a poor prognosis in elderly patients with dementia [43] May be predictive of increased risk of mortality [44]
	Pulse pressure [16, 31]	Pulse pressure = systolic blood pressure (mm Hg) – diastolic blood pressure (mm Hg), e.g., blood pressure is 120/80 mm Hg; pulse pressure is 40	
		Elevated >40 The pulse pressure becomes elevated as the aorta becomes more stiff (may be due to high blood pressure or atherosclerosis)	Magnesium deficiency Severe iron-deficient anemia and in hyperthyroidism Prognostic: a high pulse pressure may be a strong predictor of heart problems and may indicate heart valve incompetence In older adults, a pulse pressure > 60 is a risk factor for cardiovascular disease, and elevated pulse pressures in older adults in general are considered a sensitive marker for carotid artery stenosis (can increase the risk of stroke, coronary heart disease, and sudden death) [16]
		Depressed <40	May indicate poor heart function
	Tip: interventions to address hypertension usually also address pulse pressure		
	Oxygen saturation [16, 31] Also known as "O_2 Sat" Factors affecting measurement: cold digit, hypotension, excessive ambient light, motion, discoloration of nail bed (if performing on hand) – can be due to bruising under the nail or darker nail polish Indicates how well the blood is becoming oxygenated by the lungs – more specifically, the degree of oxygenation of hemoglobin Can measure on finger/pinna (earlobe) or toe [measure in patient while supine and then raise the leg (keeping the O_2 Sat monitor clipped on the toe) 12–16 inches]. Hold there for 15 seconds. The O_2 Sat should not decline more than 2% Normal: 90–99% O_2 Sat (optimal 95–99%)		

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Increased	Not clinically significant
		Decreased <90%	Anemia, smoking (cigarettes), shock, pneumonia and other pulmonary diseases, congenital heart disease, chronic obstructive pulmonary disease (COPD), emphysema, alpha antitrypsin deficiency [45], obesity, hyperventilation syndrome, sleep apnea, high altitude, medications (narcotics, anesthetics) Clinical significance: negatively impacts wound healing (95% O_2 Sat needed for optimal wound healing)
		Decreased toe O_2 Sat (i.e., >2% change with raised leg test)	Indicative of compromise in health of blood vessels in legs (peripheral vascular disease, heart failure, stroke, diabetes, hypertension, hyperlipidemia, atherosclerosis, cardiac surgery) [37]
Skin	The skin is considered an organ of vicarious elimination – skin lesions and pathologies thus often lead us to examine impaired elimination in the body – due to digestive imbalances (constipation and other dysfunctions), toxicity, and other causes. Skin changes can also point to impaired absorption of nutrients or alterations in the utilization of nutrients. The nutrient requirements of the skin are dependent on those nutrients needed for the replacement of its cells and layers thereof [30]. With the skin turning over fairly rapidly, it is often a marker of fairly recent changes in nutritional status		
	Color (see above "General" section of this table)		
	Temperature (see above "General" section of this table)		
	Moisture	Decreased perspiration (hypohidrosis)	Thiamine deficiency [30] Medications, skin trauma or disorders, diabetes, alcoholism, neuropathies, Sjogren's syndrome [46]
		Increased perspiration (hyperhidrosis)	Thiamine deficiency [30] Medications, tumor, injury, diabetes, gout, menopause [46]
	Lesions	Examine for the following: Location and distribution (generalized or localized) – i.e., extensor or flexor surfaces, all over or only in specific regions (acne – typically face, upper chest, and back), psoriasis (knees, elbows (and maybe other areas such as scalp), *Candida* in skin folds Arrangement (linear/clustered/annular (in a ring)). A ring pattern can be ringworm. A unilateral, dermatomal pattern is suggestive of herpes zoster or shingles Type (macule, papule) – a macule is a flat, nonpalpable, circumscribed area of discoloration less than 1 cm in diameter (a freckle), a papule is a raised, palpable skin lesion <1 cm in diameter – may be pigmented or nonpigmented (e.g., nevus) Color Examine ABCDEs: (asymmetry, border (ragged/irregular vs. smooth), color (more than one shade), diameter (increased (> 6 mm)), elevation (not as specific a finding so often excluded))	
		Acne	Zinc, vitamin A excess [29, 30], omega-3 fatty acids, iodine/vitamin B_{12} insufficiency [30] May be related to higher glycemic load in diet/hyperinsulinemia [47] Correlated with consumption of dairy products [40] Pubertal hormonal changes, sex hormone imbalances Food allergy, gastric hydrochloric acid deficiency, blood sugar dysregulation
		Rosacea	Vitamin B_{12} intake [30] Food allergies and sensitivity to carbohydrates May be due to decreased gastric acid and pepsin production [29]

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Skin tags Pedunculated soft lesion (appear like grain of puffed rice cereal attached at one end) May be pigmented Typically found on the eyelid, neck, or axillae	Can occur due to friction of clothes/jewelry in some cases Diabetes, insulin resistance, elevated triglycerides, low LDL (low-density lipoprotein) cholesterol [48]
		Actinic keratosis Actinic keratoses (AK) are premalignant lesions that result from long-term exposure to sun (damage therefrom)	Diet may play a role in the development of AK, with moderate intake of oily fish (tuna, salmon, and sardines) and wine being protective [49] Prognostic: AK are strongly predictive of all forms of skin cancer
		Urticaria	May be due to food allergies Chronic form associated with autoimmune thyroid conditions [50] Approximately 30–50% of those with chronic urticaria are autoimmune-mediated [51]
		Petechiae	Vitamin C, K insufficiency
	Texture	Rough	Hypothyroidism Keratosis pilaris or follicular hyperkeratosis – thickening of the outermost layer of the epidermis producing small red bumps at the base of the hair follicles on the back of the arms and the anterior thighs Vitamin A, copper, zinc, and/or EFA insufficiency Excess vitamin A [29, 30] Pancreatic enzyme insufficiency (EFA, vitamin A malabsorption) [29]
		Scaling	Vitamin A, zinc, EFA insufficiency, or vitamin A excess
		Dry (xerosis)	Essential fatty acid, vitamin A, biotin, zinc insufficiency [29]
		Wrinkles	Protein and/or energy insufficiency [30] Increased wrinkle score associated with decreased bone density or fracture risk (suggests that collagen contributes to both) [32, 52] (Around the eyes) sleep deprivation
	Wounds and ulcers	Poorly healing	Decreased oxygenation of the blood [16] Diabetes, steroid use, malignancy, or AIDS [3] Zinc, copper, vitamin C, protein, and/or EFA, deficiency [3, 30] vitamin A [29]
		Scars	(Cue to inquire about surgery/injury)
		Keloids Hypertrophic growth of scar (grows larger than the original scar)	Etiology is unknown More common in individuals with darker skin Preliminary research suggests that keloids may be associated with insufficiency of EFAs, soluble fiber, and phytochemicals [53] Tip: Weigh risks/benefits of surgical procedures as there could be significant scarring/scar tissue with procedures
		Fissuring (dermatomalacia)	Vitamin A deficiency [30], niacin, zinc insufficiency [29]

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Rashes	Dermatitis, eczema	Macronutrient (protein and energy) insufficiency Micronutrient (riboflavin, niacin, zinc) insufficiency [3, 29, 30] EFA insufficiency [3, 29, 30] Vitamin B_{12} toxicity [30] Seborrheic form related to deficiencies of biotin, riboflavin, vitamin B_6, zinc, and EFAs [29, 30] Tip: Consider possible imbalances in GI function and/or the microbiome and evaluate for food allergies [29]
		Dermatitis herpetiformis	Gluten intolerance/gluten-sensitive enteropathy, celiac disease
		Psoriasis	Vitamin A or zinc insufficiency [29, 30] Clinical significance: considered sign of bowel toxemia and suboptimal liver health
	Hydration/turgor	To assess, lightly pinch the back of the patient/client's hand, over the sternum or on the inner thigh (using your thumb and forefinger). If the skin does not return to the normal tension/form within 3 seconds, there is decreased turgor [16] Note that this is less reliable in patients of increased age (the skin loses elasticity) Other signs of decreased hydration include dry mucous membranes, dry axillae, sunken eyes, and longitudinal tongue furrows [34]	Decreased turgor with insufficient riboflavin [29] Insufficient water/electrolytes Decreased turgor can result from the use of diuretic medication
	Edema	Due to excess fluid accumulation in the tissues due to ↑venous pressure (CHF), ↑vascular permeability (inflammation), ↓oncotic pressure (hypoalbuminemia), lymphatic obstruction (lymphedema), and deposition of additional tissue (myxedema (hypothyroidism), lymphedema (obesity) Pitting or non-pitting related to protein content of edema fluid. Low protein leads to more rapid pitting and recovery Pitting test (depressing over suspected edematous area and then removing pressure yields a pit that remains for over 5 seconds) Non-pitting edema – depression over 5 seconds leads to only slightly pitting and resumes to normal skin tone rapidly (rated as 1 + trace) to pitting edema (1.3–2.5 mm), 2–5 minutes to recover from (rated at 4+ severe)	Nephrotic syndrome, CHF Protein, energy, zinc, niacin, and thiamine insufficiency [30] Hypervitaminosis A Low serum albumin Evaluate for allergies

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Vascularity	Capillary fragility Evaluate with blood pressure cuff: increase the venous pressure in the forearm with a blood pressure cuff and inspect the skin for petechial eruptions (draw a 1 inch circle 10 cm below the elbow crease before inflating the cuff to a pressure midway between the patient's systolic and diastolic pressure). Wait up to 5 minutes for any petechiae to form	If >10 broken capillaries (petechiae) in the circle, consider vitamin C deficiency [30]
	Pruritus	Itchiness	Parasites, allergies, chlorine exposure (topical), cancer, iron deficiency or niacin or vitamin A toxicity [29, 30] Hypothyroidism, liver disease, kidney failure
	Dermatographism	Writing on the skin (with blunt object), the "draw test" – produces localized hives that last 15–30 minutes	Associated with hypersensitivities/allergies, heat, stress, cold exposure (exaggerated histamine response)
Nails [16, 29, 30, 54, 55, 56]	Fingernails protect the distal ends of our fingers and toes. They are comprised of keratin (which is derived from the sulfur-rich amino acid cystine). Nails (both fingernails and toenails) can show signs of nutrient insufficiency/toxicity and exposure to toxins and systemic or localized disease or other conditions. A healthy nail structure requires sufficient protein and fat in the diet and sufficient hydration (to remain flexible). The nails are a sensitive, early marker of nutritional imbalances (with changes often preceding other clinical signs or laboratory findings). Clinical significance: Nail nutrient deficiencies often link to gastrointestinal health **Nail anatomy** – the nail plate is what one considers the "nail." The pinkish color of it is due to a vascular nail bed that is attached to the lunula (white moon of the nail). The cuticle extends from the nail fold and seals the space between the fold and plate from excess moisture. The "end" of the nail is referred to as the "free edge" Fingernails grow ~ 0.1 mm every 6–10 days and are completely renewed in 6 months (toenails grow more slowly) (at about 1/3 of the rate of fingernails). This timing can help to estimate the onset/exacerbation of medical conditions or diseases (measure the distance from the nail bed to the lesion/nail pathology and multiply out by 0.1 mm to approximate the days since the pathology started). With age, nails can lose luster and become more yellow and thickened (especially the toenails) **Examination** – be sure to ask if the patient bites or chews their nails and had an injury to the nails in the last 6 months or up to a year and if they recently/currently had (or have) polished nails		
	Shape or growth change		
Figure 39.2	**Clubbing**	Nail plates have exaggerated upward curve and curl around the fingertips Look for Schamroth's sign: Disappearance of diamond-shaped window between digits that is normally present when paired digits are juxtaposed (anteriorly) (Fig. 39.3)	Iodine deficiency Vitamin A excess Inflammatory GI disorders (IBD, celiac) Dysentery Fistulas Idiopathic pulmonary fibrosis Pulmonary malignancy Hodgkin's lymphoma Tuberculosis Asbestosis Chronic obstructive pulmonary disorder (COPD) Cirrhosis Congenital heart disease Endocarditis

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Figure 39.4	**Koilonychia** (spoon nails)	Nail plates are depressed and appear flat or scooplike. This can be normal in children Water drop test [16] to evaluate for this nail change: Place a drop of water on the nail – if it does not drip off, the nail is flattened (early koilonychias)	Riboflavin, niacin, vitamin C, zinc, copper, chromium, selenium, protein (especially methionine and cysteine), and iron insufficiency Iron deficiency anemia Plummer-Vinson syndrome Malabsorption Hypochlorhydria Hemochromatosis Raynaud's disease Lupus (SLE) Nail-patella syndrome Thyroid disorders Rheumatic fever Syphilis Persistent occupational exposure of hands to petroleum-based solvents Trauma to the nail
Figure 39.5	**Onycholysis**	The nail bed becomes separated from the nail plate	Iron deficiency anemia, pellagra (niacin deficiency) Cronkhite-Canada syndrome (low protein in the blood) – rare Psoriasis Eczema Infection (onychomycosis) Hyperthyroidism/thyrotoxicosis (referred to as "Plummer's nails") Sarcoidosis, amyloidosis, and/or connective tissue disorders Trauma to the nail
Figure 39.6	**Pitting**	Few patterns: 1. Ridges across the nail plate 2. Red-brown spots ("oil drop sign") 3. Rows	Patterns correspond to: 1. Eczema 2. Psoriasis 3. Alopecia areata (autoimmune)
Figure 39.7	**Beau's lines**	Depressed horizontal furrows across (transverse) the nail plate	Malnutrition Protein, calcium, niacin, zinc, vitamin A, and vitamin C insufficiency (May be seen in those with recent history of anorexia) Carpal tunnel syndrome Severe illness that disrupts nail growth (mumps, measles, myocardial infarction) Hypotension Hypocalcemia Uncontrolled diabetes Surgery Chemotherapy or immunosuppressive therapy Exposure to cold temperatures (Raynaud's disease) Trauma to the nail
	Unusually wide, square nail plates		Hormonal (endocrine) disorders
	Unusually long, narrow nail plates		Pituitary hormone deficiency Marfan syndrome
	Chronically chipped, sawtooth nails	Nail edge has sawtooth pattern from chipping	Malnutrition, vitamin deficiencies Radiation exposure Chemical exposure/damage

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Figure 39.8	**Ridging of the nails**	Often accompanies brittle nails	Mineral malabsorption Protein insufficiency Insufficient fat intake Iron deficiency (with central ridge(s)) B vitamin insufficiency (thiamine, riboflavin, niacin, pyridoxine, folate) Zinc, vitamin A insufficiency
	Onychomadesis	Spontaneous separation of the nail plate from the nail bed originating from the proximal end. The nail is then shed as it grows	Hypocalcemia Idiopathic After severe systemic illness Drug reactions Infections Cronkhite-Canada syndrome Trauma to the nail
	Acrodynia	Red tips with nail growth abnormalities	Mercury toxicity
	Onychorrhexis (Brittle nails)	Irregular, frayed and torn nail borders Called "onychoschizia" if the nail splits	Protein, EFA, iron, biotin, boron, folate, zinc, calcium, magnesium, silica, sulfur, zinc, vitamin A, carotenoid, vitamin C, vitamin D, and vitamin B_{12} insufficiency Selenium or vitamin A toxicity Anorexia Hyperthyroidism Hypochlorhydria Metabolic bone disease Cronkhite-Canada syndrome Tip: in postmenopausal women and older men, check bone density
	Absent lunula	No visible half-moon on nail	Zinc, protein insufficiency
	Color change		
Figure 39.9	**Terry's nails**	Most of the nail bed is white except for a pink band near the nail tip. Due to decreased vascularity and increased connective tissue in the nail bed Generally, the lunula is obliterated	Niacin, protein insufficiency Copper toxicity Cirrhosis Hepatic failure Diabetes mellitus Congestive heart failure Hyperthyroidism
	Azure lunula	Blue half-moons in the nail bed	Copper toxicity Wilson's disease (hepatolenticular degeneration) Silver poisoning (blue-gray) Quinacrine therapy Impaired circulation
	Yellow lunula	Yellow half-moons in the nail bed	Tetracycline therapy
	Brown/black lunula	Brown/black half-moons in the nail bed	Excess fluoride Hyperthyroidism (nail plate brown)
	Red lunula	Red half-moons in the nail bed	Cardiac failure
Figure 39.10	**Half-and-half nails (Lindsay's nails)**	The proximal half of the nail is white, and the distal half (horizontally) is pink or brown, and the lunula is obliterated	Niacin zinc insufficiency Renal failure (pathognomic)

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Figure 39.11	**Muehrcke's lines**	Two white lines (arcuate) parallel to the lunula and separated from the nail bed with normal nail. Due to abnormality of vascular nail bed – so does not move with nail growth Lines disappear transiently with blanch test	Malnutrition (protein deficiency) Acrodermatitis enteropathica (rare, inherited form of zinc deficiency) Hypoalbuminemia (pathognomic) Nephrotic syndrome Liver disease
Figure 39.12	**Mees' lines (Reynolds/Aldrich lines)**	Longitudinal white streaks from the cuticle to the free edge	Niacin, calcium, zinc insufficiency (hypocalcemia Acrodermatitis enteropathica (zinc deficiency)) Renal failure Hodgkin's lymphoma Myocardial infarction, congestive heart failure Leprosy Malaria Sickle cell anemia Carbon monoxide poisoning Arsenic poisoning Thallium poisoning Chemotherapy (cancer)
	Hapalonychia	Nails thin causing the bending and breaking of the free edge and longitudinal fissures	Kwashiorkor Insufficient intake of protein and/or fat Vitamin A, pyridoxine, and vitamin C and D insufficiency Calcium, silica, iron, sulfur, and zinc insufficiency
	Pallor		Iron, vitamin B_{12} insufficiencies/anemia, selenium and riboflavin insufficiency
	Yellow nail	Nails grow more slowly and develop "heaped up"/thickened appearance and lunula disappear. Thought to be due to abnormal lymph drainage or leakage of protein as a result of increased microvascular permeability [16]	Rule out smoking and recent nail polish use Beta carotene excess Vitamin D insufficiency Long-term use of tetracycline Type 2 diabetes [48] Lymphedema Pleural effusion Bronchiectasis Sinusitis Rheumatoid arthritis Nephrotic syndrome Thyroiditis Tuberculosis Raynaud's disease Immunodeficiency Cancer (possibly) Tip: vitamin E may help as an intervention
	White nails		Selenium, zinc insufficiency
	Red nails		Malnutrition, lupus, carbon monoxide angioma, or polycythemia
	Brown/gray nails		Vitamin B_{12} insufficiency, diabetes mellitus, hyperthyroidism [54], or cardiovascular disease
	Blue nails		Peripheral cyanosis Copper toxicity
	Longitudinal striations (Trachyonychia)		Protein, calcium, pyridoxine, biotin, and vitamin C insufficiency Vitamin A excess Alopecia areata Vitiligo Atopic dermatitis Psoriasis

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Figure 39.13	**Splinter hemorrhage**	Longitudinal red streaks from nail bed toward proximal margin. Signify bleeding of the capillaries	Scurvy (vitamin C deficiency) Oral contraceptive use Pregnancy Chronic hypertension SLE Rheumatoid arthritis Psoriasis Peptic ulcer Subacute bacterial endocarditis Trichinosis Trauma to the nail
	Telangiectasia	Dilated blood vessels in the nail at the margin of the finger nails	Rheumatoid arthritis SLE Dermatomyositis Scleroderma
Figure 39.14	**Punctate leukonychia**	White spots or patches between the nail and the nail bed. Due to subungual air bubbles	If isolated dots, can be due to trauma to the nail (including repeated manicures) or zinc, selenium, and niacin insufficiency If on the entire nail, likely due to a congenital disorder
	Longitudinal melanonychia	Brown/black discoloration – streaks spread from the nail bed to the surrounding finger	Vitamin D, folate, and vitamin B_{12} insufficiency Malnutrition (protein deficiency) GI polyps (discoloration on the nail is in spots) Benign nevus Normal variant in darkly pigmented people Melanoma (large patch or collection of small freckles most commonly on the thumb and big toes)
	Other changes/evaluation		
Figure 39.15	**Paronychia**	Infection around the fingernail Can have redness, pus, swelling, and tenderness (Acute – *Staphylococcus* infection Chronic – fungal)	EFA, zinc, and vitamin C insufficiency [29]
	Hangnails		Zinc, vitamin C, folate, and protein insufficiency
	Ragged cuticles		Boron and iron insufficiency
Figure 39.16	**Onychophagia**	Nail biting	Stress Anxiety
	Onychotillomania	Nail picking	Stress Anxiety
	Capillary refill test	Technique: Nails must be unpolished. Apply pressure to the nail until it blanches/turns white. Remove pressure. Patient is to hold the hand above the heart, while the time it takes for blood to return to the tissues (nail turns pink) is measured Indicator of tissue perfusion and hydration	Blanch time > 2 seconds (i.e., decreased capillary refill): Dehydration Vitamin A and C insufficiency Peripheral vascular disease (arteriosclerosis, hypertension, diabetes mellitus, smoking, heart disease, abnormal cholesterol) Shock, hypothermia
Head	Examine the head, scalp, and hair		

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Hair	Examine for quality, quantity, distribution, color, texture, and baldness. Look for hair loss diffusely or in patchy areas on the scalp. Be sure to inquire about any chemical processing, dying, or bleaching of hair which could affect the color and/or texture of the hair. Normal hair loss is considered to be 50–100 hairs per day		
	Hair loss [34, 57, 58]		Stress of serious illness or injury, parasites, heavy metal toxicity, oral contraceptives Protein, iron, zinc, or biotin insufficiency, anemia In women, hair loss can occur following (may be up to 2 months after) extreme stress from a major illness, from following a very low-calorie diet, from rapid weight loss (post-bariatric surgery), polycystic ovarian syndrome (PCOS), thyroid disease, or as a result of medication [16] Alopecia areata – autoimmune disorder (immune system attacks hair follicles) – patchy hair loss Tip: may respond to zinc and biotin supplementation [16]
	Baldness		Vertex baldness with hypertension or high cholesterol – possible marker for increased risk of coronary heart disease [59] In women, frontal baldness is associated with PCOS (usually seen with hirsutism)
	Sparse or thin hair		Protein, zinc, iron, biotin, linoleic acid, and/or manganese insufficiency [4, 16, 32] Vitamin A excess Hyperthyroidism
	Hair that is easy to pluck		Protein, zinc, and iron insufficiency
	Premature graying		PABA (para-aminobenzoic acid) deficiency Vitiligo Stress
	Dry/brittle		EFA and/or manganese insufficiency [29] Hypothyroidism
	Dandruff		EFA, fat-soluble vitamin insufficiency (due to biliary dysfunction) Calcium, pyridoxine, and other B insufficiencies Antioxidant insufficiency (selenium especially) Excess refined carbohydrate intake Hypochlorhydria
	Flag sign	Bands of depigmented hair can appear horizontally (transverse to the length of hair) during periods of inadequate protein intake When protein intake returns to normal, pigmented hair will grow again – creating the alternating band-like appearance	Kwashiorkor, protein deficiencies in ulcerative colitis, and other conditions
	Corkscrew hair	At the base of the hair follicle	Vitamin C insufficiency
	Menkes steely hair		Copper insufficiency (due to disordered copper metabolism) [29]
Scalp	**Itchiness**		Calcium insufficiency Skin rash (psoriasis or other)
	Psoriasis		Sulfur insufficiency Imbalanced omega-3 or omega-6 fatty acid ratio

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Face	**Affect**	See above under "General" section	
	Asymmetry		Stroke/neurological issue Bell's palsy – paralysis of muscles on one side of the face (with inability to control facial muscles) generally idiopathic, though may be due to diabetes, Guillain-Barre syndrome, Lyme disease, viral infection (recent URI), or other causes (tumor) Facial nerve (CN7) defect
	Facial nerve (CN7) examination: Ask patient to make a variety of facial expressions – raise eyebrows bilaterally, close the eyes, frown, smile, show their teeth, and puff out their cheeks {Bates}		
	Vertical creases near midline of the forehead		Consider duodenal ulcers
	Seborrheic dermatitis		Biotin, riboflavin, vitamin B_6, zinc, and EFA insufficiency Can be seen with diets high in refined sugars Can be due to food allergies (research supporting this in children) [60]
	Myxedema	Characterized by a relatively hard edema of subcutaneous tissue, with increased content of proteoglycans in the fluid. May also see swelling in the neck if goiter	Hypothyroidism
	Loss of lateral 1/3 of eyebrow		Hypothyroidism
	Dilated capillaries on cheeks and nose		Excess alcohol, gastric hydrochloric acid deficiency
	Flushing	May also be seen with red ears	Allergy
	Yellow skin		Pernicious anemia (vitamin B_{12} deficiency) [16, 29, 31]
	Brown, patchy pigmentation of the skin	Especially on cheeks with parotid enlargement and a "moon" facies	Protein-calorie deficiency
	Acne	See "Skin" section of table above	
	Acne rosacea	See "Skin" section of table above	
	Tics/abnormal movements	Evaluate for with smile test	Facial nerve (CN7) defect Tourette's syndrome
	Chvostek's sign	To test for this sign, percuss at the top of the cheek (just below cheek bone) with tip of the index or middle finger. Will see repeated contractions of the facial muscle if this sign is present	Calcium and magnesium deficiency Tetanus, tetany Hyperventilation (induces hypocalcemia)
	Trigeminal nerve examination (CN5) examination: Pain and light touch are examined across three zones of this nerve on the face (ophthalmic, maxillary, and mandibular). Motor function of CN5 is evaluated by feeling for contraction of temporal and masseter muscles as well as evaluation of the corneal reflexes		
	Hair growth	Excess in women (hirsutism) Frontal baldness and acne may be present with hirsutism	Hormonal imbalance (excess androgens). Cushing's, PCOS, elevated cholesterol, sleep apnea, insulin resistance, diabetes, tumors, and medications

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Eyes	Eye physiology: The eye is a sphere enclosed by three layers – outermost is the sclera/cornea; then there are the choroid, ciliary body, and iris; and the innermost layer is the retina The eyeball is largely covered by the sclera (the "white" of the eye). Over the iris is the cornea – this is transparent so light can pass through the eye The eye is composed of two chambers of fluid separated by the lens. These carry nutrients and are transparent to allow light to pass through the eyes. The shape of these chambers changes to allow vision at different distances The iris is a radial muscle that controls the size of the pupil (allows it to dilate or constrict) In a nutrition physical exam, the eyes are examined largely with a penlight. Physicians and ophthalmologists typically use ophthalmoscopes to visualize the retina and can detect retinal hemorrhages and changes in the retinal arteries that occur with hypertension and diabetes		
	Eyelids	Ptosis	Neurological/muscular disease [21]
		Retracted lid	Neurological/muscular disease, mechanistic (includes atopic dermatitis and essential hypertension [61]
		Exophthalmos	Hyperthyroidism (Graves' disease)
		Angular palpebritis or blepharitis	Riboflavin, niacin, or pyridoxine insufficiency
		Periorbital edema	Allergies, local inflammation, myxedema, nephrotic syndrome/fluid-retaining state
		Dark circles under the eyes	Allergies (allergic shiners), dysbiosis, liver congestion with detoxification problems (phase I and II detoxification) [20], hypochlorhydria, pancreatic insufficiency, adrenal hypofunction, and mineral deficiency [57, 58] Fatigue, sleep deprivation [62]
		Dennie's lines (horizontal creases across the lower eyelids) [60]	Food allergies
		Meibomian gland dysfunction	May be due to oxidative stress Tip: may benefit from omega-3 fatty acid supplementation
	Lesions (lumps, swellings around the eyes)	Xanthelasma (Slightly raised, yellowish, and well-circumscribed plaques that appear along the nasal portion of one or both of the eyelids)	May accompany lipid disorders such as hypercholesterolemia [57]
	Conjunctiva	Conjunctivitis	Allergies, irritation, infection
		Inflammation	Vitamin A or riboflavin insufficiency
		Conjunctival pallor	Iron, folate, and B_{12} insufficiency
		Bitot's spots (foamy, superficial patches on the conjunctiva) [1]	Vitamin A deficiency
		Conjunctival xerosis (dryness)	Vitamin A or riboflavin deficiency (or environmental/chemical irritation) Diabetes [63]
	Pupils	Dilation	Allergy (especially dairy) [29]
		Swinging flashlight test Test of pupillary response to light Shine penlight first in one eye and then the other Normal response: as light swings from one eye to the other, each pupil should constrict briskly Optic nerve or retinal lesion: dilates upon exposure to light	Optic nerve (CN2) or retinal lesion

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Nystagmus	Thiamine insufficiency [29] Medication, CNS diseases Inflammation of inner ear Albinism Astigmatism, myopia Defects in CN3, CN4, and CN6
	Lens and cornea	Corneal arcus	Vitamin A deficiency Dyslipidemia (middle-aged men) (DN)
		Corneal scar, ulcerations	Vitamin A deficiency
		Corneal xerosis (dull appearance)	Vitamin A deficiency
		Keratomalacia (cornea is soft)	Vitamin A deficiency
		Xerophthalmia	Vitamin A deficiency
		Pterygium	Epidemiologic evidence of an association between obesity and pterygium in women [64]
		Cataracts	Dysglycemia, vitamin C insufficiency May be marker of oxidative damage and ultimately coronary heart disease (CHD)
		Glaucoma	Hereditary Chronic subclinical inflammation May be associated with imbalances in oral microbiome [65]
		Kayser-Fleischer rings (Greenish-brown deposition of copper in annular ring around periphery of the cornea (where it meets the sclera/white of the eye))	Results from inherited accumulation of copper in the liver due to inherited ceruloplasmin defect Wilson's disease
	Iris	Iritis	Trauma, can also be seen with certain diseases, such as ankylosing spondylitis, Reiter syndrome, sarcoidosis, inflammatory bowel disease, and psoriasis. Infectious causes may include Lyme disease, tuberculosis, toxoplasmosis, syphilis, and herpes simplex and herpes zoster viruses
		Iris contraction test (A variation on the swing flashlight test: upon exposure to light in a darkened room, the pupil should contract immediately and remain contracted)	With adrenal insufficiency, the pupil will not remain contracted with exposure to light, but will dilate. This dilation will occur within 2 minutes and can last for 30–45 seconds before another contraction. It is best to time when the dilation occurs and how long it lasts. Subsequent retesting can then serve as a monitor for adrenal status as interventions are employed
	Optic (CN2) and oculomotor (CN3) examination: assess extraocular movements ("H" and "X" in space) and evaluation of pupillary response to light and accommodation		
		Ophthalmoplegia Weakness or paralysis of one or more of the extraocular muscles	Thiamine deficiency [29]
		Nystagmus	Thiamine insufficiency [29] Medication, CNS diseases Inflammation of inner ear Albinism Astigmatism, myopia Defects in CN3, CN4, and CN6

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Vision changes	Reduced visual acuity	Essential fatty acid deficiency [29] Optic nerve defect
		Reduced night vision	Vitamin A [29], zinc insufficiency
		Color blindness Inherited poor color vision usually affects both eyes, and the severity doesn't change over one's lifetime Examine with Ishihara or Hardy Rand and Rittler testing	Diabetes, glaucoma, macular degeneration, Alzheimer's disease, Parkinson's disease, chronic alcoholism, leukemia, and sickle cell anemia Medications can alter color vision, such as some drugs that treat heart problems, high blood pressure, erectile dysfunction, infections, nervous disorders, and psychological problems Ability to see colors deteriorates slowly as you age Exposure to some chemicals (carbon disulfide and fertilizers) may cause loss of color vision [66]
		Retinal field defect	Vitamin A, vitamin E deficiency [29]
		Macular degeneration Use Amsler grid to examine	Tip: lutein, zeaxanthin, and vitamin C may help prevent macular degeneration
		Visual contrast	Can use to assess loss of visual contrast sensitivity in macular degeneration, cataracts, and glaucoma and can help prevent falls in elderly due to loss of contrast sensitivity A number of factors can affect the ability to perceive visual contrast: nutritional deficiencies, alcohol consumption, medication or drugs, exposure to endogenous or exogenous toxins, including but not limited to neurotoxins, biotoxins, volatile organic compounds (VOCs), mycotoxins, mold, microbial, VOCs, parasites, cyanobacteria, dinoflagellates, heavy metals, Lyme disease Visual contrast testing is used to track the progress of patients undergoing treatment for Lyme disease Can measure neurotoxicity in those with M.S. Note: Loss of visual contrast is not diagnostic, but may warrant further evaluation for these conditions [67, 68]
		Photophobia	Zinc deficiency [29]
		Floaters	Those with nearsightedness are more prone to floaters (also those with diabetes and a history of cataract surgery) Vitamin C and K and bioflavonoid insufficiency
Ears	**Diagonal earlobe crease**		Highly associated with cardiovascular disease (in men)
	Tophi on external earlobe		Gout
	Hair in the ear canal		Associated with coronary artery disease
	Excess cerumen (wax) in the canal		EFA insufficiency or allergies
	Tinnitus		Cardiovascular disease, allergies, aspirin toxicity, B12 deficiency [69]
	Acoustic nerve (CN8) examination: assess for hearing by rubbing fingers together on either side of the ear at varying distances and asking the patient to localize as well as evaluating for conductive hearing loss (Weber and Rinne tests with tuning fork) [21]		
Nose	**External nose**	Examine for redness, dryness, rashes/skin abnormalities	

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Rhinophyma A thickening and reddening of the skin on the nose. Can see broken blood vessels	Related to excess alcohol ingestion Hypochlorhydria May be related to acne rosacea
		Malar rash (also referred to as "butterfly rash" for the butterfly shape with the wings of the butterfly on the cheeks and the body over the bridge of the nose) It is a purplish, scaly rash	Systemic lupus erythematosus (SLE) Niacin deficiency
		Salute sign/allergic salute [60] Occurs from rubbing the nose (due to nasal drip/rhinitis) with an upward movement of the hand Allergic crease horizontal lines across lower portion of the nose from rubbing the nose with the hand (saluting)	Allergies (especially dairy)
		Nasolabial seborrhea (Seborrheic rash around the base of the nose and perioral region)	Pyridoxine, EFA deficiency [29]
		Nasolabial dyssebacia (a disorder of the sebaceous glands characterized by excess oil production, inflammation, exfoliation, and fissuring of the sebaceous glands (which appear moist and reddened) around the base of the nose and perioral region)	Riboflavin deficiency [29]
	Nasal canal/ intranasal [34, 57]	Intranasal polyps	Allergies (chronic rhinitis) Salicylate sensitivity (often seen with asthma) [29]
		Epistaxis (nosebleeds)	Vitamin C, vitamin K, and flavonoid insufficiency [60] Allergies Local trauma Infection Dry air Hypertension or coagulation disorders Medications

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Smell Evaluate sense of smell using smell identification test [UPSIT]: Self-administered 40-item test with smell card booklet Smell discrimination test: Sniffin' Sticks [70]	Hyposmia – decreased ability to smell	Zinc deficiency, pernicious anemia May be due to nasal polyps, cadmium poisoning, smoking, asthma, allergy, diabetes, hypothyroidism, fibromyalgia, MS, schizophrenia, sarcoidosis, SLE, hepatic or renal failure, tumor Medications: zinc-based intranasal sprays; intranasal medications; antibiotics; antidepressants; antilipidemic; medications for hypertension, rheumatism, and hyperthyroidism; chemotherapeutic medications; and opioids [71] Smell disorders are present in a number of neurodegenerative illnesses and part of their early diagnosis (changes in the sense of smell are the first sign of idiopathic Parkinson's disease). Can also be a sign of early Alzheimer's disease [72] Olfactory (CN1) defect Prognostic: Decreased olfactory discrimination is a significant predictor of future cognitive decline [71]. Olfactory dysfunction in old age predicts mortality [73]. Lack of ability to identify smells related to overall health and one's life expectancy may be negatively associated with lowered olfaction [73]
		Anosmia – lack of ability to smell	Unilateral anosmia may be due to trauma Chronic infection or inflammation of the nasal passages
		Hyperosmia – increased ability to smell	Hyperosmia can occur with Addison's disease, head injury, multiple chemical sensitivity, before or during migraine attacks, and following rapid chronic withdrawal of drugs Depression often accompanies cases of hyperosmia [74]
		Peanut butter test Test patient with closed eyes, for their ability to detect the odor of peanut butter, one nostril at a time. Hold a container of peanut butter medially below the nostril (ideally it is not a very wide mouth (1 oz. is ideal) container) and move up 1 cm at a time during the patient's exhalation. If an odor is detected, note the distance between the patient's nostril and the top of the container with a 30-cm ruler	Left nostril impairment of odor detection in patients with probable Alzheimer's disease and with mild cognitive impairment This test may also be useful for monitoring disease progression (the asymmetry was greatest in early stages of the disease. With disease progression, the right nostril became more impaired – resulting in an overall decrease of asymmetry [75]
Sinuses	Examine externally – looking for pain, tenderness, redness, and swelling over the affected sinus(es)		
	Congestion or (post)nasal drip		Chronic allergies Yellow-green sputum suspicious of infection
	Dysbiosis		Can be due to hypochlorhydria and pancreatic enzyme deficiency
Mouth	Due to the rapid turnover of cells in the oral mucosa, a number of diseases, disorders, and imbalances have clues, or definitive diagnoses, which can be made from examining the mouth early in the course of disease (lead poisoning, eating disorders, nutritional deficiencies, etc.). Prior to starting the exam, it is advised to ask the patient about any recent changes in taste, burning sensations, pain, or bleeding of the gums or mucosa (Radler and Lister)		

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Lips	Cheilosis, angular stomatitis Redness, cracking of one or both angles of the mouth	Riboflavin, niacin, pantothenic acid, pyridoxine, folate, B_{12}, iron, and or zinc deficiency [29, 57, 76] Infection (*Candida* in those with dentures, *Staph.* for those without) Poorly fitting dentures (saliva leaks to the mouth corners – Causing skin irritation)
		Cheilitis	Early sign of Crohn's disease Nutritional deficiencies of cheilosis and/or excess vitamin A
		Actinic cheilitis Usually on the lower lip	Excess exposure to sun (loss of pigment in the lips and may be scaly and thickened)
		Lip ulcers or sores	Cold sores: selenium deficiency [29] From herpes labialis (herpes simplex virus I (HSV-1) – cold sores) If you see lesions on or around the upper border of the lip – usually it means it is herpes. Herpes lesions can be precipitated by stress and adrenal overload and calcium and EFA deficiency: deficiency of lysine, exposure, vitamin C, and/or flavonoids [29, 58] Cancer (squamous cell carcinoma) – usually affects the lower lip (may be a scaly plaque, ulcer, or nodular). Seen in those with fair skin and history of prolonged sun exposure
		Enlarged lip	Trauma Angioedema (which can be secondary to food allergies)
		Pigmented lip	In Peutz-Jeghers syndrome, you will see multiple pigmented spots on the lips and oral mucosa and intestinal polyps. There is a slightly higher risk of gastrointestinal malignancies in this condition
	Palate	Visualize the roof of the mouth Assess the pharynx (pillars, tonsils, uvula) for movement, enlargement, or lesions Use the tongue blade in the middle 1/3 of the tongue. Traction forward and down and have the patient say "Aah" (elevates the soft palate and allows one to assess cranial nerve function… more on this later). Don't touch the back of the tongue or you can elicit the gag reflex Note that those in a state of parasympathetic stress will have an easy gag reflex (due to increased alkalinity with too much potassium relative to calcium)	
		Candida (thrush) White discharge on palate/ pharynx or mucosa	May be due to iron and/or vitamin C deficiency Medications (antibiotics, corticosteroids) Occurs with reduced immunity and malabsorption Can result from dry mouth Diabetes, HIV, cancer, renal failure [76]
		Blue-gray	Hemochromatosis
		Psoriasis May cause pain and discomfort and thus affect the types of foods consumed and quantities	May be an indication of the liver and GI imbalances (both associated with psoriasis)

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Pharynx	Absence of the uvula	May be surgically removed (as may be done for obstructive sleep apnea)
		Swollen uvula	Pharyngitis
		Tonsillitis	May be due to allergies
		Enlargement of tonsils	Vitamin A and/or C and zinc deficiency [29] Allergies/sensitivities Chronic infection Sleep apnea
		"Crimson crescents" – bilateral reddening (a purplish red hue) of the pillars without any pain or sore throat	Chronic fatigue syndrome
		Warts on tonsils/pillars	HPV (human papillomavirus)
	Glossopharyngeal nerve (CN9) and vagus (CN10) examination: Assess movement of the pharynx while the patient says "ah" and evaluate for gag reflex (bilaterally). Listen to the voice for hoarseness or a nasal tone and observe for any difficulty swallowing (CN10 lesion)		
	Buccal mucosa	White spots	Oral thrush (*Candida*) – these can be scraped off – revealing red, raw (inflamed, bleeding) oral mucosa underneath. May also see squamous cell carcinoma, Koplik's spots (rubeola), or HIV (hairy leukoplakia) Worry more about hairy leukoplakia (precancerous) in those who smoke, chew tobacco, abuse alcohol, or have a history thereof
		Pigmented spots	Peutz-Jeghers syndrome, smokers' melanosis, malignant melanoma, Addison's disease, hemochromatosis
		Red spots: petechiae	Vitamin C, K, protein, and/or energy insufficiencies Thrombocytopenia Infectious mononucleosis, pyogenic granuloma, erythema migrans, Kaposi's sarcoma
		Xerostomia (dry mouth)	Zinc insufficiency
		Stomatopyrosis (painful inflamed mouth) and dysesthesia (burning mouth syndrome)	Iron, B12, folate, and/or magnesium insufficiency
		Pallor	Iron deficiency
		Ulcers/sores (aphthous ulcers [canker sores])	Vitamin B_{12}, folate insufficiency Allergies (including celiac disease) (More rarely seen with infection and cancer) Can recur with use of toothpaste containing sodium lauryl sulfate
	Gums	Gum hypertrophy, bleeding	Bioflavonoid and vitamin B_{12} insufficiency Poor brushing technique/use of a brush with hard bristles Vitamin C and D deficiency (with scurvy see petechiae (small red or purple spots caused by bleeding into the skin) on gums) Puberty, pregnancy Inflammatory bowel disease (IBD), uveitis, ankylosing spondylitis, peripheral arthritis, erythema nodosum [77] Leukemia Medications (phenytoin, cyclosporin A)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Gum recession Gingivitis Inflammation of the gum tissue Gingivitis with periodontitis (bacterial infection) is known as periodontal disease. In more advanced stages, larger gum pockets and teeth loosen and can fall out	Silica, calcium, CoQ_{10}, quercetin, antioxidant insufficiency Vitamin A and D, riboflavin, and niacin insufficiency (also see gingival tenderness with niacin deficiency) [78] Gingival inflammation significant predictor of cognitive decline [79] Oral inflammation and poor oral hygiene associated with hypertension in individuals <65 years of age [80] Strong links between chronic oral inflammation and a number of other health conditions (cardiovascular disease, stroke, diabetes, Alzheimer's and other dementias, and pancreatic cancer) [32, 78]
		Lead line A bluish-black line on the gums (~1 mm from the gum margin) that may indicate chronic lead poisoning. The line follows the contours of the gums and is absent where there are no teeth (it is produced by tartar-forming bacteria)	Lead or bismuth exposure
	Teeth	Long teeth	Gum recession
		Bruxism	Excess stress, allergies, parasites
		Tooth decay	Poor mineral absorption Vitamin C and B_{12}, fluoride, and phosphorus deficiency [29]
		Tooth discoloration with malposition and hypoplastic line across upper primary incisors (become yellow-brown in color)	Protein calorie malnutrition
		Mottled enamel, fluorosis	Excess fluoride, calcium insufficiency
		Tooth erosion	Excess consumption of fresh citrus or sugary sodas Bulimia (along posterior aspect of the teeth – particularly the incisors) GERD Swimming in chlorinated water (chronically) Frequent wine consumption (acids can erode the teeth)
	Dental materials Nickel and/or other metals used in restoration may lead to allergic reactions in some patients Mercury amalgams, root canals, implants, mixed noble- and base-metal crowns, partial dentures made of chrome cobalt, BPA-based resin fillings, night guards, and dentures may create oxidative stress in some patients Mercury amalgams in young adulthood may lead to increased risk of diabetes mellitus in later life [81]		
	Taste	**Nutrients involved in taste** [34, 58] *Vitamins:* A, E, riboflavin, niacin, pantothenic acid, pyridoxine, folate *Minerals:* Copper, iodine, iron, zinc Taste tests available for individual minerals (potassium, zinc, magnesium, copper, chromium, manganese, molybdenum, and selenium) may provide some initial information to guide physical exam and laboratory evaluation (note that these tests are generally considered less definitive than laboratory assays for these minerals, but are an affordable and rapid in-office assessment)	

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Dysgeusia Altered taste perception Differential diagnosis (Ddx): loss of smell, which can contribute to/cause loss of taste	Zinc and vitamin B_{12} insufficiency Diabetes, hypothyroidism, or other metabolic conditions Cancer treatment (chemotherapy and/or radiation), postoperatively and/or from certain medications such as azithyromycin [17], amlodipine, metronidazole, tetracycline groups, statins, and a number of thyroid medications [82]
		Loss of taste (general) Be sure to evaluate for loss of smell (which can contribute to/cause loss of taste)	Zinc insufficiency
		Loss of taste for meat	Incomplete protein digestion (most likely cause thereof is hypochlorhydria) Zinc deficiency Pepsin and protease insufficiency
	Intraoral inflammation	Redness of mucosa and/or gums	Vitamin C insufficiency [1]
	Bitter strips to evaluate supertaster status Place the control strip on the tongue first and then the bitter strip on the mouth and evaluate for taste Supertasters are homozygous for the allele that detects this taste. They have more fungiform papillae Women, Asians, and African Americans are more likely to be supertasters, and about 25% of all Americans are classified as supertasters. (Being a supertaster may have served an evolutionary advantage in avoiding potentially toxic plant alkaloids) Clinical significance: Supertasters tend to have a higher risk of colon cancer, consume more salt, and be leaner than the average population. They may be more resistant to bacterial sinus infections, and they tend to be pickier eaters Finally, supertasters may pass the zinc tally taste test, but still be deficient in zinc on later blood analyses Tasters are more likely to be non-smokers and not in the habit of drinking coffee or tea and more likely to find green vegetables bitter. Taster status is found more commonly in Native Americans, Inuits, and Australian or New Guinea aboriginals		
	Breath odor (halitosis)	Disorders of oral cavity	Niacin insufficiency [29] Retained food, stomatitis, glossitis, periodontal disease, poorly cleaned dentures, xerostomia (dry mouth – decreased saliva)
		Disorders of the nose and sinuses	Atrophic rhinitis, chronic sinusitis, nasal septal perforation, ozena (atrophic disease of nose and turbinates), nasal septal perforation (can be due to cocaine use), and retained foreign bodies
		Disorders of the tonsils and pharynx	Recurrent tonsillar and adenoid infections, pharyngitis
		Disorders of the digestive organs	Achalasia, GERD, empyema Dysbiosis, pancreatic enzymes, and/or hydrochloric acid insufficiency [58]
		Disorders of the lungs	Abscesses, bronchiectasis, pneumonia, empyema (is the collection of pus in a body cavity – in this case the lungs ("pleural empyema"))
	Fruity/ammoniacal odor	Systemic causes	Diabetic ketoacidosis (fruity smell), fetor hepaticus, and uremia (ammoniacal odor)
		Psychiatric conditions	Odor of bad breath perceived by the patient but not the physician/health provider. May be a hallucination. (Some patients will extend this to overall smells emanating from their body and will isolate themselves to avoid others smelling them)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Lymph glands (neck)	Lymphadenopathy (swollen glands)	Food allergies Infection Cancer
	Parotid gland	Enlargement	Thiamine deficiency [29] Protein insufficiency Bulimia
Tongue [34, 57]	The tongue is composed of skeletal muscle covered with mucosa. On the top (dorsum) of the tongue are three different types of taste buds/papillae: Filiform Fungiform (which cover the entire surface of the tongue) Circumvallate (posterior dorsum of the tongue in semicircular arrangement). In addition to containing the taste buds, these papillae also increase the surface area of the tongue Visualization: Have the patient say "Ah" while protruding (and then curling up) the tongue so as to visualize both the dorsum of the tongue and the sublingual surface. Gauze can be used to examine the far interior and lateral aspects (place on tip and grasp and pull with the aid of the gauze)		
	Color	Pale	Anemia
		Red *Candida* (beefy red with white coat); glossitis – various shades of coloration	Glossitis: B vitamin insufficiency (thiamine, riboflavin, niacin, pyridoxine, folate, B_{12}) Magenta (riboflavin insufficiency) Fiery red (niacin insufficiency) With hyperkeratotic appearance – vitamin A insufficiency [83] Note: in folate deficiency, glossitis is accompanied by normal proprioception, but in glossitis due to vitamin B_{12} deficiency/pernicious anemia, abnormal proprioception is seen Iron deficiency anemia Severe protein-calorie nutrition and malabsorption Alcoholism Oral estrogen – likely due to hormone-induced depletion of B vitamins [83] If *Candida* is the cause, may co-occur with iron and/or vitamin C deficiency
	Coat	Thin If occurs with atrophied taste buds "slick or smooth tongue" or atrophic glossitis	The tongue can often be sore (indicates atrophy). Vitamin B deficiencies, iron deficiency, alcoholism, severe protein-calorie malnutrition, malabsorption May occur with hypochlorhydria and/or small intestinal bacterial overgrowth (SIBO)
		White, cheesy discharge (atop beefy red tongue)	Candidiasis, GI flora imbalance, AIDS
		Thin coat with parched appearance	Dehydration
	Ridges/furrow	Fissured tongue (also known as "scrotal tongue")	Niacin deficiency and gut-triggered autoimmune issues thought to be possible causes as well May occur with psoriasis (along with geographic tongue) and Sjogren's syndrome [83]
	Swelling	Can often be seen with teeth marks on the lateral border of the tongue	Poor digestion, allergies, hypothyroidism, dysbiosis, amyloidosis, Down syndrome [29] Can also be seen with thickened speech, snoring, and sleep apnea

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Lesions	Geographic tongue A form of atrophic glossitis that has scattered smooth red areas of denuded papillae alternating with normal patches of the tongue – lending the map-like appearance that changes over time (migratory). Considered benign and self-limited in conventional medical circles	B Vitamin and zinc insufficiency Allergies May occur with psoriasis along with fissuring [83] and with chemical sensitivity [32] Celiac disorder
		Hairy black tongue – the "hair" is elongated papillae on the tongue dorsum	May follow antibiotic therapy, smoking, and exposure to bismuth exposure Use of charcoal at high doses in cases of poisoning/overdose can also lead to this condition
		Hairy leukoplakia – multiple white, warty, and painless plaques. These are usually located on the lateral aspect of the tongue (and can also be seen on the inner mucosa of the cheeks). The plaques each have hair-like projections. Ddx – *Candida*: In *Candida*, the white coat can be scraped off, which is not the case with hairy leukoplakia	Insufficiencies of Vitamin A, riboflavin, niacin, pyridoxine, folate, B_{12} precancerous, HIV/AIDS
		Tongue biting	If with history of syncope (fainting), suspect seizures (generalized tonic-clonic), especially when biting is on the sides (lateral portions) of the tongue
		Varicose veins on sublingual (underside of the tongue) veins. Referred to as "caviar tongue"	May be normal variant of age, but in some patients, may indicate a chronic increase in right-sided pressures (e.g., CHF)
	Movement	Tremors or involuntary movement	Hypoglossal (CN12) nerve defect
	Hypoglossal (CN12) examination: assess the patient's ability to articulate; inspect the tongue on resting and with protrusion		
Jaw	Jaw function – assess for temporomandibular joint (TMJ) dysfunction (it can limit/change food intake) Palpate the patient's jaw (also opening of ear canal) as they open and close their mouth. Feel and listen for audible clicks over the jaw. Assess for chewing and swallowing		
	Movement	Clicking and misalignment (and often reports of pain) due to TMD/TMJ or TMJD (temporomandibular disorder, temporomandibular joint disorder)	TMD/TMJD correlated with increased psychological stress and may be associated with abdominal obesity and a lower BMI in women [84] Headaches, allergies, depression, fatigue, degenerative arthritis, fibromyalgia, autoimmune disorders, sleep apnea, and gastrointestinal complaints were shown to be more prevalent in those suffering from TMJD [85] and in those with rheumatoid arthritis, ankylosing spondylitis, and primary Sjogren's syndrome [86]

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Chewing and swallowing	Important to assess for both chewing and swallowing in elderly 3 oz. water swallow test If this test is passed, thin liquids and other food consistencies can be recommended without further dysphagia assessment [88] Dysphagia risk assessment for the community-dwelling elderly (DRACE): A valid and reliable tool for detecting latent risk of chewing and swallowing disorders in the elderly community-dwelling population [89]	Those with chewing and swallowing difficulties had significantly lower vitamin A, E, and manganese levels, and those with chewing difficulties had significantly lower magnesium and vitamin E [87] Vagus nerve defect (CN10) could interfere with swallowing
Neck[31,34]	Lymphatic vessels are located throughout the body in all tissues and organs. Lymphatic vessels accompany blood vessels – which helps to locate the nodes in some regions of the body. Lymphatic vessels function to collect lymph (ECF) and carry it to venous circulation. In transit to the venous system, lymph passes through lymph nodes – which serve to filter lymph fluid. Microbes, malignant cells, and other debris in the lymph nodes can lead to enlargement and/or hardening of the lymph nodes. If this enlargement or hardening is significant enough, the nodes can be palpable, and the diagnosis of "peripheral lymphadenopathy" is made. Note that a normal adult has around 400–450 lymph nodes in the body, though only ~100 of these are palpable (in the arm and underarm (axilla), in the leg and in the head and neck)		
		Lymphadenopathy When palpating a lymph node, do so lightly and assess for: Size – >1 cm diameter (usually measured with calipers); considered significant and may be pathological (may see large nodes in intravenous (IV) drug users – often benign) Consistency – Rock hard suggestive of malignancy (though Hodgkin's lymphoma nodes are usually rubbery). Note that cysts, being fluid filled, are softer, and swollen nodes without malignancy (infection or allergies) will generally be softer Matting – individual nodes swell together to create larger nodes that may or may not be stuck to overlying skin or underlying tissue Tenderness – usually tender in inflammation, less often with cancer In general: Benign nodes are usually small, soft, non-tender, and discrete (not matted) Inflammatory nodes, tender, firm, and often matted. Cancerous nodes usually large, non-tender, matted, and rock hard. "Sentinel" nodes are nodes that, when enlarged or abnormal to palpation, signal a specific condition	Allergies, infection (systemic, may have generalized and chronic LA (lymphadenopathy); acute, may be isolated node(s) and resolve as the infection resolves), toxin exposure, Hodgkin's, lymphoma, leukemia, cancer, HIV, CT (connective tissue) disorders. Note that cysts and lipomas must be considered in the differential Significance by location: Occipital (kids, childhood infections; adults, rare (maybe with scalp infection)) Posterior cervical – dandruff Preauricular – conjunctivitis and lymphoma Submandibular, submental – dental or cancer of oral or nasal region Supraclavicular node enlargement on the left known as "Troisier's node" signifies spread of intra-abdominal or intrapelvic malignancies Supraclavicular node enlargement on the right – lung and breast cancers

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Venous distension along the carotid artery		Fluid status overload [1, 3] – may be due to heart failure, hypoalbuminemia, retention of salt and water, venous, or lymphatic stasis
	Parotid gland enlargement		Protein deficiency/bulimia (bilateral) [3] Thiamine deficiency [29] Cyst, tumor, or hyperparathyroidism [3]
	Range of motion	Decreased range of motion can affect ability to properly masticate food [3]	
Thyroid [31, 34]	With palpation, note size, consistency (soft, firm, rubbery, or hard), texture (diffuse or nodular), tenderness, tracheal deviation (seen with asymmetrical goiter), and enlarged lymph nodes [over the thyroid] Rubbery consistency is palpable with Hashimoto's thyroiditis, and hardness is noted with cancer The size of the thyroid varies with the supply of iodine in a diet (less iodine leading to larger glands). Note that women's thyroid glands are usually larger and easier to palpate than men's. And the right lobe of the thyroid is often a little larger than the left		
		Goiter	Iodine deficiency/excess Can occur with hypothyroid, euthyroid, or hyperthyroid status
		Nodules	Iodine deficiency Hashimoto's thyroiditis Thyroid adenoma, cyst, cancer
Chest	**Cardiac exam:** *Normal:* "Lub dub" (S1, S2, or first and second heart sounds produced by the closure of the AV valves (tricuspid and mitral) and then the pulmonic and aortic valves (S2)). This explains why S1 is heard more in the lower chest and S2 in the upper Listen for abnormalities of the sound of S1 and S2 over each of the valves and any additional sounds *Clinical significance:* Auscultation can be used to detect a wide range of cardiac conditions using careful techniques of listening for S1 and S2 over each of the valves, using specific positions or techniques to accentuate suspected abnormalities and listening for adventitious sounds **Pulmonary exam:** Perform both anteriorly (patient lying on back) and posteriorly (patient seated with arms crossed (spreads scapula to better examine the lungs)). Work from head down – comparing sides as you go (asking them to take a deep breath in each time you place your stethoscope on a new site) *Palpation* Tenderness (can occur with costochondritis – inflammation of the costal cartilage) *Percussion* Determines if the lungs are full of air/fluid/solid masses *Auscultation* Compare sides with patient breathing through the mouth		
	Cardiac [31, 34, 57]	Mitral valve prolapse (MVP) [31, 34, 57]	Magnesium, carnitine, potassium, calcium, and niacin insufficiency Dehydration, allergies, medications
		Palpitations, arrhythmia	Thiamine, magnesium, coenzyme Q_{10} (CoQ_{10}), vitamin K, and calcium deficiency [29] Potassium or magnesium deficiency/excess, calcium, or phosphorus deficiency [3]
		Cardiomegaly	Selenium, thiamine [29]
		Tachycardia	Thiamine [3], CoQ_{10} deficiency [29] Dehydration [3] Organic heart disease, severe pulmonary disease, respiratory insufficiency, excessive alcohol consumption, or drug toxicity

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Pulmonary inspection	Barrel chest	Thin elderly individuals Chronic obstructive pulmonary disease (COPD) such as emphysema
		Pigeon chest (bowed chest)	Rickets, Marfan syndrome Familial (normal)
		Funnel chest (hollow chest)	Can lead to arrhythmias or MVP
		Retraction of interspaces	Severe asthma, COPD
		Use of accessory muscles to breathe (sternocleidomastoid (SCM) and scalene) during inspiration and abdominal muscles in expiration. Normally the diaphragm is the only muscle used in breathing	Signifies COPD or respiratory muscle fatigue
		Reactive airways	Magnesium deficiency
	Respiratory rate and rhythm	Increases in respiratory rate lead to increases in caloric, and often fluid, requirements, and changes in respiratory rate can affect acid-base balance [3]	
		Pursed lip breathing	Emphysema (often the result of chronic cigarette smoking)
		Tachypnea (rapid breathing)	Physical exertion Heat stroke, shock, anxiety/panic attack Metabolic acidosis, diabetic ketoacidosis, pneumonia, cystic fibrosis, pulmonary embolism, heart failure, sepsis
		Bradypnea	Hypothyroidism Medications: sedatives/narcotics
		Apnea (absence of breathing 20 seconds while awake, 30 seconds while asleep)	Sleep apnea
	Peak expiratory flow	Measurement of air flowing out of the lungs See Fig. 39.17. Peak Expiratory Flow Rate Green, Yellow Zone and Red Zone – relative to peak flow	Asthma associated with a narrowed airway – using a peak flow meter gives information about how open the airways in the lung are (during an attack, the airways in the lungs slowly begin to narrow) Daily PFM readings for those with asthma are encouraged. This provides valuable information about the status of the airways and can help to determine triggers of asthma, how well an asthma management/treatment program is and when emergency medical care is needed. With an impending attack, the peak flow rates start to drop. This allows early changes in one's medication or routines to prevent worsening of asthma symptoms Decreased peak flow rates may be seen with EFA, magnesium insufficiency, with food/environmental allergy and if fewer methyl donors (folate, vitamin B_{12} insufficiency) available (as these are required for histamine metabolism) Prognostic: decreased peak expiratory flow rate predictive of increased mortality in those with COPD [90]
	Auscultation	Rales (crackles)	Associated with fluid in the alveoli (fluid overload), as seen in CHF

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Rhonchi (high pitched, continuous, clear with cough)	Obstruction
		Wheezes (high pitched, musical)	Due to narrowing of airways with chronic obstructive lung disease (including asthma). Hear on expiration
		Kussmaul (Deeper and more rapid breathing)	Diabetic ketoacidosis anion-gap acidosis "**MAKE UP a List**" [34]: **M**ethanol poisoning **A**spirin intoxication **K**etoacidosis **E**thylene glycol ingestion **U**remia **P**araldehyde administration **L**actic acidosis
Abdomen [21, 31, 34]	Generally, the 4-quadrant method is preferred as the 9-quadrant system often has organs occupying more than one quadrant Have the patient lie supine (on back) – pillow under the head and with knees bent (or pillow under) Ask if they need to void their bladder before having them lay down on the exam table Patient's arms should be at sides or folded over the chest. Ask the patient to point to any areas of pain and examine these last. While performing the examination, watch the patient's face for signs of discomfort. Make sure your hands and stethoscope are warm and your nails trimmed. If the patient is tense or ticklish, begin the palpation step with their hand under yours – you can then slip your hand under soon thereafter as they will usually calm quickly. As you carry out the four steps (inspection, auscultation, percussion, palpation), try to visualize the organs underneath		
	Inspection	Scars, bruising/ecchymosis	Sign of abdominal hemorrhage
		Distension	6 Fs: Fluid (ascites) Fat (obesity) Flatulence (gas) Fetus (pregnancy) Feces (constipation) Full-sized tumor (abnormal lesion) [16]
		Striae (stretch marks)	Considerable weight changes Pregnancy Cushing's syndrome can see pink-purple striae
		Scaphoid (sunken) – occurs with loss of subcutaneous fat	Insufficient caloric intake [3]
		Dilated veins	Hepatic cirrhosis obstruction inferior vena cava
		Rashes, lesions, nodules	Keratin and sebum can build up in the umbilicus – leading to a nodule which can be readily extracted Prognostic: Sister Mary Joseph Nodule – metastatic carcinoma of the umbilicus, usually from the stomach, colon ovary, or pancreas – often means only 10–11 months left of life
		Contour (rounded, protuberant, bulging flanks)	Protein deficiency [29] Gas Obesity Ascites (often accompanied by edema and hypoalbuminemia) [31]
		Symmetry	Asymmetry with enlarged organ or mass
		Caput medusae (abnormal venous networks on the abdominal wall	Portal hypertension (usually seen in those with cirrhosis)
		Ascites (accumulation of fluid in the peritoneal cavity) – bulging flanks, flank dullness	Liver disease (severe), cancer, CHF, pancreatitis

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Scratch test (Sergent's white line) Take the cap end of a pen and stroke it lightly across the abdomen (make about a 6-inch line) A normal response is to see a whitish line, which reddens within a few seconds. In adrenal insufficiency, the line remains white and may grow wider	If redness is delayed/absent when scratch near the umbilicus, evaluate for decreased adrenal function
	Auscultation	Follows inspection (prior to percussion and palpation) as these can alter the frequency of bowel sounds. This step of the examination is helpful in determining bowel motility (via the bowel sounds) and exploring vascular obstructions or abnormalities (such as bruits) Listen for bowel sounds using your stethoscope over all four quadrants. Bowel sounds usually occur on the order of 5–34 per minute. You may hear the stomach growling (prolonged gurgle of hyperperistalsis known as borborygmi). Listen for 2 minutes before deciding if absent If patient has high blood pressure, listen in epigastric region for bruits∗. (If arterial insufficiency is suspected in the legs, listen over the aorta, iliac arteries, and femoral arteries. And if the liver pathology is suspected, listen over the liver for hepatic bruits) ∗A bruit is caused by turbulent blood flow in an artery	
		Increased borborygmi	Diarrhea and in early small bowel obstruction
		Decreased borborygmi	Post-surgery, later stage bowel obstruction, paralytic ileus, peritonitis [3]
	Percussion	Helps to assess the amount and distribution of gas in the abdomen and to identify possible masses	
		Hepatomegaly	Protein deficiency or vitamin A excess Hepatitis Chronic alcohol abuse/cirrhosis, lymphadenopathy [31]
		Splenomegaly	Lymphadenopathy, infection (tropical diseases (malaria, typhoid)), HIV, jaundice, hepatocellular disease, cirrhosis, leukemias, lymphomas [31], hemolytic anemia
	Palpation	Tenderness to the left of the xiphoid at the fourth intercostal space	May be due to hiatal hernia syndrome
		Tender areas in the colon	Investigate for yeast overgrowth, dysbiosis, diverticulitis, colitis, cancer (particularly if accompanied by occult blood), and a variety of functional GI disorders Testing HCL levels may be indicated [57]
		Abdominal wall tenderness test (Carnett's test) [34, 91] Identify the area of maximal tenderness from palpation and apply enough pressure to the point to elicit a moderate amount of tenderness. Continue to apply pressure as the patient folds the arms on the chest and lifts the head and shoulders (partial sit-up). If this elicits increased tenderness at the site being palpated, it is a positive test (and thus peritonitis less likely)	Diabetic neuropathy elicits a positive test and will often occur with cutaneous hypersensitivity and weakness of the abdominal organs (producing bulging of the abdominal wall) In patients with chronic abdominal pain, a positive abdominal wall tenderness test decreases the probability that the pain has a visceral (i.e., organ-related) cause
		Hepatojugular reflex With patient in supine position, exert firm and sustained pressure on the lower liver edge (in and up toward the head at the lower right costal margin)	In CHF, will see filling of the neck veins – which characterizes a positive reflex test

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
Musculoskeletal [21, 26, 31]	Inspect – for joint swelling, tenderness, and deformity Palpate – for joint warmth, tenderness, and crepitus Investigate – range of motion (ROM) of joint Note that joint pain within the joint (articular disease) often manifests in swelling and tenderness surrounding the joint and often limits ROM with both passive and active movements, whereas pain outside the joint (extra-articular disease) causes swelling and tenderness which is localized to specific regions within the joint and does not affect all aspects of a joint's ROM Musculature and skeletal system are related to nutritional status. In developing countries, it can be seen with marasmus (energy deficiency) and kwashiorkor (protein and energy deficiency) with frank malnutrition, whereas in developed countries, the presentation is generally subtler, with lower body weight, muscle atrophy and loss of subcutaneous fat, weakness, and laboratory abnormalities (low albumin, increased creatinine excretion)		
	Skull	Delayed closure of fontanelles in infants or abnormal softening of bones in the skull (craniotabes), frontal, or parietal bossing (swelling or thickening of the front and sides of the head)	Vitamin D and calcium deficiency [3, 29]
	Head/face	Muscle wasting (temporal)	Protein and calorie insufficiency [1, 3]
	Torso	Beading of ribs (prominent knobs at the base of the costochondral joints (also known as Rachitic Rosary). These knobs create appearance of beads under the skin of the rib cage)	Rickets, with bowed legs, pain in spine, pelvis and legs, thickened wrists and ankles, projection of the breastbone, delayed growth, and muscle weakness, due to vitamin D deficiency
		Subperiosteal hemorrhages (of the femur)	Children with vitamin C deficiency
		Scoliosis A lateral curvature of the spine	Structural (with vertebral rotation or thoracic deformity) or functional (unequal leg length without vertebral rotation or thoracic deformity) Some evidence to suggest that scoliosis is associated with methylation defects (methylenetetrahydrofolate reductase (MTHFR)) [92]
		Kyphosis A rounded thoracic convexity Dowager's hump	Osteoporosis (adults) If in adolescents, consider Scheuermann's disease (seen in tall and underweight adolescents). There is a hereditary component to this disease
		Lordosis Accentuation of the normal lumbar curve	Can develop in compensation to protuberant abdomen (pregnancy or marked obesity) or in compensation for flexion deformities of the hip
	Legs	Bowing of legs and/or knock knees	Rickets (vitamin D deficiency)
		Muscle wasting gastrocnemius, buttocks	Insufficient protein and calorie intake Thiamine, vitamin C, phosphorus, and calcium deficiency [3]
		Low skeletal muscle mass lower leg	Independently associated with osteoarthritis of the knee in obese individuals [93]
		Weakness, pain in calf muscles	Thiamine deficiency
		Epiphyseal enlargement	Vitamin D deficiency (if painless) or vitamin C deficiency (if painful)
	Arm(s)	Arm muscle area – assesses total amount of muscle or protein in the body (uses triceps skinfold measure)	(See Fig. 39.18. Anthropometrics Flow Chart)
		Deltoid muscle wasting	Protein and calorie insufficiency [1]

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Spinal accessory (CN11) examination: Assess patient's ability to shrug shoulders and strength of sternocleidomastoid muscles with flexion as head turns against your hand [21]		
	Wrists and carpal joints	Ganglion (cystic, round, usually non-tender swelling along the tendon sheath on the dorsum of the wrist commonly). They can also develop elsewhere on hands, wrists, ankles, and feet	Not a known nutritional association. (Though homeopathic silica is often used to treat ganglion cysts.)
		Dupuytren contracture A fibrous thickening on the palm along the tendon of the fourth finger which keeps the finger partially flexed	Hereditary (in part), males over 40, dysglycemia, seizures (for reasons not yet understood) History of hand trauma, alcohol, and tobacco use may also predispose one to the condition
		Subluxation of the ulna	Chronic rheumatoid arthritis
		Epiphyseal enlargement	Deficiency of vitamin D (if painless) and of vitamin C (if painful)
		Grip strength Measure using a dynamometer and compare readings obtained to instrument's normative tables	Hand grip strength reflects nutrient status and accurately predicts postoperative complications (Lower hand grip strength indicates poorer nutrient status [particularly protein and vitamin D [29]] and increased risk of post-op complications) and may be indicative of presence of sarcopenia Recommended cut-off values for sarcopenia [94]: Caucasian: <20 kg in women <30 kg in men Asian: <18 kg in women <26 kg in men Prognostic: There is also evidence to suggest that in postmenopausal women, grip strength is positively related to normal bone mineral density and may help to identify women who could benefit from additional bone density evaluation [95] Predictive of risk of cardiovascular disease, cardiovascular death, and all-cause death (across both genders) [96] and was a stronger predictor of cardiovascular and all-cause mortality than systolic blood pressure [97] Grip strength (post-stroke) of the unaffected side considered an independent predictor for short-term functional improvements [98]
	Fingers	Swan neck deformity, Boutonniere deformity, ulnar deviation	Rheumatoid arthritis
		Heberden's nodes Nodules on the distal interphalangeal joints (due to bony overgrowth of the joint). They are usually hard and are painless Bouchard's nodes are located on the proximal interphalangeal joints and are less common	Osteoarthritis (consider allergy to nightshade vegetables) [29]
		Callus on the back of the hand	Bulimia (from using fingers to stimulate the gag reflex in order to vomit)

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Gout	Associated with increased protein (purine-rich foods such as red meat and sardines), alcohol, medications (diuretics, low-dose aspirin, cyclosporine, end-stage renal disease), and metabolic syndrome
		Skin cracks/splits	Zinc and EFA deficiency [29]
	Global symptoms	Bone/joint pain	Vitamin A, C, and D deficiency [3, 29] Infection Degenerative joint changes Tumor(s) Multiple myeloma
		Muscle spasms	Magnesium insufficiency (Carpopedal) calcium, magnesium insufficiency [29]
		Muscle tenderness bilaterally	Thiamine insufficiency [3]
		Decreased muscle tone (especially of hips and pelvis)	Vitamin D insufficiency
	Sarcopenia	Defined as the loss of muscle mass and strength that occur with advanced age [99]	Vitamin D insufficiency (and thus likely those with VDR polymorphism) and protein (and hence those with hypochlorhydria, pancreatic insufficiency, or leaky gut are at increased risk [32]) Antioxidant insufficiency (vitamins C and E, carotenoids, and selenium) is linked to increased risk of sarcopenia in older adults [100] Considered to be due to chronic low-grade inflammation driven by decreased physical activity, anabolic hormone, cytokines, oxidative stress, and adipokines (with obesity) [101]
Neurological [34]	**Mental status**	Confabulation (making up stories) and disorientation	May be due to Korsakoff's psychosis (deficiency of thiamine resulting from alcoholism) or Wernicke's encephalopathy (precipitates the brain damage that leads to Korsakoff's psychosis)
		Acute disorientation	Phosphorus and niacin insufficiency [29]
	Reflexes	Reflexes are involuntary contractions of the muscles which are induced by specific stimuli We will focus on muscle stretch reflexes, in which a brisk stretch of the muscle induces the reflex via muscle spindles to the spinal cord (which then sends the signal back to the muscle and causes the reflexive contraction) Examining reflexes: Have the patient seated on an examination table with their leg dangling and limbs hanging symmetrically Sharply tap (with a reflex hammer) on the point where the muscle inserts distally on the bone. On tapping the pointed end or blunt end can be used. The pointed end is better in smaller locations. Hold the hammer between the thumb and index finger so it swings freely within the hand Check reflexes bilaterally and compare. Use only enough force needed to generate a response. Can reinforce the knee reflex (i.e., accentuate if the reflex response is difficult to elicit) by asking the patient to clench their jaw and interlace their fingers Reflexes typically tested include the biceps, triceps, brachioradialis, abdominal, patellar, ankle, and plantar [3] Rate the reflex response according to the following scale: 0 = absent 1 = hypoactive (diminished) 2 = normal 3 = brisk (increased) 4 = hyperactive For the Babinski reflex, stroke the lateral aspect of the foot with the metal end of the reflex hammer. A normal response is the absence of a reflex response. If dorsiflexion (the toe goes up), it is a positive sign Asymmetry of reflexes more suggestive of pathology	

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Hypoactive (Achilles, patellar reflexes)	Hypothyroidism (Achilles) Nutrient deficiencies: Potassium [3] Thiamine, pyridoxine, vitamin B_{12}, or possibly with excess B_{12} (Achilles, patellar reflexes) Respiratory alkalosis [3]
		Hyperactive	CNS disease Calcium deficiency/hypocalcemia
		Positive Babinski sign	Parasites, drug/alcohol intoxication, post-seizure (or upper motor neuron disease – such as amyotrophic lateral sclerosis (ALS)), vitamin B_{12} deficiency [102] (Positive sign is normal to see in infants)
	Touch	Examine for ability to perceive touch by touching the skin lightly over different dermatomes with cotton wisp covering as many dermatomes as possible A dermatome is the area of the skin innervated by the sensory fibers of a single nerve root If a nerve root is damaged – there will be loss of sensation across the whole dermatome [31]	
		Monofilament testing Apply pressure on the plantar side of the foot until the monofilament buckles Hold for 1 second and release	If a patient cannot sense this pressure, they have loss of protective association (seen in diabetes) Prognostic: increased risk of foot ulceration and amputation
		Paresthesias Abnormal sensation with "pins and needles" (numbness, tingling, pricking sensation) due to damage to (or pressure on) the peripheral nerves	Thiamine, iodine, vitamin B_6, vitamin B_{12}, vitamin E, omega- 3 fatty acid, phosphorus insufficiency [29] Carpal tunnel syndrome, ulnar neuropathy, multiple sclerosis (MS), diabetes, hypothyroidism, alcoholic neuropathy, drug toxicity
	Temperature	Examine for ability to perceive temperature by touching the skin lightly over different dermatomes with tubes of warm/cold water or cold tuning fork and warm index finger of clinician (to discern difference) covering as many dermatomes as possible [31]	
	Pain	Examine for ability to perceive pain by touching the skin lightly over different dermatomes with sharp and dull object/stimuli (to discern difference) covering as many dermatomes as possible [31]	
	Sensation	Dermatomal testing discussed previously	
	Vibration	Test with a tuning fork (128 Hz) Strike the tuning fork forcefully against the heel of your palm and then apply the stem of the fork to the lateral malleolus (ankle bone) should perceive vibrations for ≥11 seconds (decreases by 2 seconds for every decade starting at 40 years) And ≥15 seconds (decreases by 2 seconds for every decade starting at 40 years) on the ulnar styloid	Decreased vibratory sense seen with exposure to heavy metals, neurotoxins [103] decreased antioxidant intake, methylation defects (riboflavin, B_6, folate, B_{12}) Thiamine, riboflavin, niacin, pantothenic acid, and B_{12} insufficiency Polyneuropathy of diabetes, Lyme disease, collagen vascular disease, allergy, and autoimmune conditions [3]
	Proprioception/ position sense [31]	Grasp the lateral aspect of the toe or index finger between the thumb and forefinger. Have the patient close his/her eyes and move the digit up and down – pausing to ask what orientation they perceive the digit to be in	Loss of proprioception with peripheral neuropathy Thiamine [29], vitamin B_{12} deficiency Diabetes, MS, history of stroke, severe brain disease

(continued)

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
	Neuropathy	Peripheral neuropathy Characterized by weakness, paresthesias, ataxia, decreased tendon reflexes, fine tactile sense, decreased vibratory sense, and (position sense)	EFA, vitamin E, thiamine, pyridoxine, vitamin B_{12} insufficiency, or excess pyridoxine [3, 29] Alcoholism (polyneuropathy) [36]
	Tremors [21, 31]	Resting (static) Tremor is most prominent at rest and may decrease or disappear with voluntary movement	Parkinson's disease Magnesium and pyridoxine insufficiency [29]
		Active tremors Postural: Active tremors appear when actively holding the affected part. It may worsen with intention. Essential tremor is the term used when it is a benign tremor. It is the most common movement disorder, and the etiology is unknown. Intention: The tremor is absent at rest, appears with activity, and worsens as one nears the target (e.g., picking up a mug)	Postural: hyperthyroidism, fatigue, anxiety, and also benign (familial) tremor Intention tremor: multiple sclerosis
	Balance	Romberg test – patient should stand with feet together and eyes open and then close both eyes for 60 seconds. Note that you will want to have an arm in front of and behind them to protect them from falling should they lose balance. Only very minimal swaying should occur unless ataxia (problems with coordination and nervous system function due to neurological lesion), cerebellar disorders, or an acoustic nerve lesion (CN8) is present	
		Positive Romberg	Diabetic neuropathy, Guillain-Barre, MS Ataxia Vascular injuries to the thalamus [36]
	Gait [36]	Walking is a very complex action that requires integration of many systems (motor, sensory, vestibular, and visual) so most abnormalities in the nervous system are visible in the gait. Look for symmetry versus asymmetry (muscle, joint, and pain disorders cause asymmetry, whereas abnormal limb control tends to be more symmetrical and due to central lesions) Disorders of the gait can be due to pain, joint immobility, muscle weakness, or abnormal control of the limbs Note that alcoholism/alcohol intoxication affects gait enormously (can lead to wide gait, poor tandem gait, and possibly leg ataxia)	
		Gait speed: Associated with increased survival in older adults, said to reflect health and functional status and to be a potentially useful clinical indicator of well-being [104] and survival [105] in older adults Measure via measured walk from standing start (over 8 feet [104] or 4 m [105] Patient to walk from start to finish at their usual speed "just as if… walking down the street to go to the store" [104] Time two walks and average May be less helpful for older adults who already report dependence in basic activities of daily living [105]	≤0.8 m/s associated with sarcopenia (other measures (of muscle mass and strength) need to be assessed to confirm/strengthen diagnosis [100] <0.6 increased likelihood of poor health/function >1.0 m/s associated with healthy aging [105]

Table 39.1 (continued)

Region examined	Nutrition-associated examination findings (and select examination/test techniques)		Nutritionally related cause/association
		Slow gait	Sarcopenia Depression Schizophrenia Prognostic: predictive of cognitive decline
		Rapid gait	Mania Hyperthyroidism
		Tandem gait	Schizophrenia, alcoholism [36]
		Wide gait	Thiamine and vitamin B_{12} insufficiency [29] Alcoholism
		Shorter stride length	Schizophrenia Cortical/basal ganglia disorders
		"Parkinsonian gait" Short steps (petit pas), reduced arm swing, stooped posture, anteropulsion/retropulsion, festination, postural instability	Parkinson's disease Depression (can resolve as depression resolves) Schizophrenia (mild Parkinsonian gait) Antipsychotic medications
		Ataxia Increased width of gait, arrhythmic steps, unsteadiness and impaired tandem gait, and loss of position sense	Cerebellar, pons or thalamus injury, possible cortical damage Alcohol or medications (benzodiazepines, anticonvulsants) Thiamine, vitamin E, vitamin B_{12}, and copper insufficiency [1, 29] Mitochondrial dysfunction, EFA imbalance, toxin burden [20]
		Antalgic gait	Degenerative joint disease (DJD), orthopedic injury
		Spastic gait with scissoring	Osteoarthritis, B_{12} deficiency, trauma, inflammation, tumor, demyelination disorder
		Abrupt onset of gait disturbance, selective disability, gait disturbance related to minor trauma	Psychogenic balance disorders
	Risk of falling	Stops walking when talking (difficulty performing both simultaneously confers increased risk of falling) Timed chair stands: times how long it takes for a patient to get up from a chair and sit again three times in a row (positive is >10 seconds) Get-up-and-go test: assesses mobility and predicts falls – positive is ≥12 seconds [106]	Polypharmacy (medications risk factor for falls in at least 30% of elderly exhibiting gait or balance disorders – especially psychiatric medications) Hypotension Positive get-up-and-go test with sarcopenia
	Coordination	Assessed by: Finger-to-nose test Rapid alternating movements Heel-to-shin tests	Cerebellar disease – clumsy/unsteady movement [21]

Anthropometrics				
Measure	**Examination/measurement method**	**Optimal**	**Excess/elevated**	**Deficient/depressed**
Stature/height	The simplest method to accurately measure height involves positioning the individual to be measured with their back against a flat vertical surface upon which a measuring stick or measuring tape has been affixed. Then a headboard is positioned at a right angle to the wall or vertical surface upon which their back rests and their stature can be obtained (ideally to the closest 1/8 of an inch) A stadiometer can also be used to measure height Some notes on ensuring accuracy with this measurement: If a wall is used, the baseboard should be minimal, and the individual being measured should be standing on a hard, uniform surface without carpet For those with difficulty walking or who have severe spinal curvature, measuring height by this method would be inaccurate, so their stature is best estimated from knee height (normative reference tables are published to interpret this measure) -Knee height correlates closely with stature An alternative method is to estimate stature from upper or lower arm length (though this is used less often) The knee and ankle of the left leg are typically measured (as the left leg was used by researchers in developing the equations used to determine normative values) The knee and ankle should be at a 90-degree angle to each other (verify this with a right triangle, square, or other device) The fixed blade of the sliding caliper is positioned under the heel of the left foot, and the moveable blade is placed on the anterior surface of the left thigh [26]	Used relatively (in other measures (such as body mass index and waist-to-height ratio)) and for growth chart assessment		
Length (*aka* recumbent length) Pediatrics	Obtained with subject lying down in face-up (supine) position. Usually limited in use for children ≤24 months of age or children who are unable to stand without assistance. Length forms the basis of growth charts up to 24 months of age, with height used in growth charts for children at 2 years and beyond To measure recumbent length accurately, a special measuring device is required, and two people are needed to accurately obtain the measurement. A stationary headboard and moveable footboard must be perpendicular to the backboard The length is measured from the foot board ("0" starts at the headboard), with the crown of the head held securely against the headboard, and a right angle made between the Frankfort horizontal plane and the backboard The soles of the feet are to be held firmly against the footboard at this time (toes pointing upward), and the child's shoulders and buttocks should be firmly touching the backboard. The length of the child can then be recorded to the nearest 1/8 of an inch. Make notes of any challenges or increased estimation based on the child moving about and not laying still during this procedure The rate of gain in length is indicative of nutritional adequacy [26]	Used relatively (in other measures (such as body mass index and waist-to-height ratio) and for growth chart assessment		

Measure	Examination/measurement method	Optimal	Excess/elevated	Deficient/depressed
Head circumference {Pediatrics} [26]	To perform this measurement, with the child seated in their caregiver's lap and the lower edge of a non-stretchable, but flexible, measuring tape positioned just above the eyebrows and ears around the occipital prominence of the head. The tape should be tight enough to compress the hair. The measurement should be read to the nearest 1/8 of an inch A duplicate reading is best to ensure an accurate reading	The measurement of head circumference is very important for screening in the first year of life, in particular. In the first 12 months of life, head circumference increases rapidly and slows by 36 months of age. Pediatric growth charts are used to evaluate head circumference for age as a means to monitor growth and development		
Weight [26]	Weight is one of the most important measurements in nutritional assessment. It is important in predicting caloric expenditure and in determining body composition Electronic scales are preferred over balance beam scales (for accuracy and they also are generally lighter weight, more portable, and easier to use and have a higher weight capacity (best when weighing obese clients)) Many models of electronic scales can connect into computer networks, and information on weight, body mass, and stature can be directly recorded into a client's electronic chart/record To weigh a child or adult correctly/accurately, ensure that both feet are firmly planted on the base of the scale (in the middle of the platform) without touching anything and with weight evenly distributed over both feet. Read the weight to within 0.2 lb. Any subsequent reading, if performed correctly, should agree within 0.2 lb. It is best to weigh both children and adults after voiding (after they have emptied the bladder) and dressed in an item of clothing of known weight, such as a gown There are diurnal variations in weight of about 2 lbs. in children and 5 lbs. in adults, so it is best to record the time that an individual was weighed and to weigh them subsequently at approximately the same time of the day Non-ambulatory persons require a bed scale or wheelchair scale. The individual is positioned into a weighing sling, which is then raised until the person is suspended over the bed A chair scale can also be used to obtain weight (which has the person sitting upright in their chair while leaning against a backrest). And finally, there are wheelchair scales (upon which the wheelchair is rolled) for obtaining a person's weight Note: Weight in adolescents more accurately reflects nutritional adequacy than height [17]	Optimal weight is 22.5–25 kg/m^2. The risk of death is lowest when the body mass index (BMI) is approximately 22.5–25.0 kg/m^2 For every 5 kg/m^2 increase in BMI, risk of death from all causes increases by 30%, from cardiovascular disease by 40%, from diabetic renal and hepatic diseases by 60–120%, and from neoplastic diseases by 10% Usual body weight (UBW) Variations from UBW strongly linked to nutritional risk and health complications Nutritional risk: >5% unexplained weight change in <1 month or >10% in 6 months Percent usual body weight [107] =*current body weight* ×100 usual body weight Percent weight (wt) change = *Present body weight – usual body weight* ×100 usual body weight or: % usual body weight – 100 = % change	Overweight A body weight in excess of some reference point The reference point is usually defined in terms of weight for height Possible for very muscular person to be overweight (though not commonly the case) BMI ≥25 kg/m^2 Obesity An excess amount of body fat relative to lean body mass usually expressed as a percentage of body weight that is adipose tissue BMI ≥30 kg/m^2 Those with a BMI in the 30–35 kg/m^2 range died 2–4 years earlier Those with a BMI in the 40–45 kg/m^2 range died 8–10 years earlier (comparable to the effect of cigarette smoking on lifespan)	Underweight Defined as a BMI <18.5 kg/m^2 With a BMI <22.5 kg/m^2 (not even underweight), the risk of death increases, especially for smoking-related diseases such as respiratory diseases and lung cancer

Measure	Examination/measurement method	Optimal	Excess/elevated	Deficient/depressed
Body mass index (BMI) (Quetelet index)	Because of the difficulty of determining body composition and the ease of measuring height and weight, BMI is used to screen for overweight and obesity in children, adolescents, and adults Correlates with underwater weighing and dual-energy X-ray absorptiometry (DEXA) BMI = (W/H [2]), which is weight in kilograms divided by height in meters (squared) Calculations or nomograms available for interpretation or classification and online calculators are available for metric and nonmetric calculation BMI differs with race/ethnicity, sex, age, and musculature (athletes with increased muscle mass may have elevated BMI measure in the absence of elevated total body fat). These differences must be considered in interpreting the BMI	Child and adolescent: 5th–85th percentile on growth chart (BMI for age percentile charts) [17] Adult [17]: 22.5–25 kg/m^2	Child and adolescent: Overweight 85th–95th percentile Obese: ≥ 95th percentile Adult [17]: Overweight: 25–29.9 kg/m^2 Obese: ≥30 kg/m^2	Child and adolescent: <5th percentile Adult: Underweight<18.5 kg/m^2 BMI <23 in older adults (>65 y.o.) confers an increased risk of mortality [17]
Growth charts	Growth charts are used to assess the growth and development of infants, children, and adolescents (up to 20 years of age) They are based on growth data obtained from large numbers of healthy infants, children, and adolescents and are an important tool in assessing nutritional status, general well-being and growth, and development of individuals up to 20 years of age (For infants/young children less than 2 years of age, they are known as the growth standard (as opposed to a *growth reference* – which determines what is/exists and is comprised of data from all kids, not just healthy individuals) Note that growth reference data is all that we have available for the 2–20 years of age growth charts Growth charts are a helpful tool to monitor nutritional status in those undergoing medical treatment – allowing adjustments in nutritional intake (enteral or parenteral) to be made in a timely and effective manner These charts have historically been used to screen for malnutrition but are increasingly being used to screen for overweight/obesity now There are two sets of growth charts for both male and female: Birth – 24 months of age and 2–20 years of age There are growth charts that give percentile curves for: Weight-for-age Length-for-age Weight-for-length Head circumference-for-age			
Waist circumference (WC) [107]	Where fat is distributed in the body may have a greater impact on health than total amount of fat in the body To measure: Have the patient remove any outer clothing covering the abdomen and waist and place the measuring tape on bare skin Obtain the measurement by measuring the distance around the narrowest area of the waist (between the lowest rib and the iliac crest) The person being measured should stand erectly with the abdomen relaxed, arms at side, and feet together The tape should be snug against the skin but not to the point where the skin is compressed Take the measurement after the end of a normal expiration Repeat 1–2 times to ensure accuracy and record to the nearest 0.1 inch If the BMI >30, assuming central adiposity, WC is not necessary to perform [26] Waist circumference may be used to evaluate success of weight loss treatment Little predictive value in people with BMI ≥35 kg/m^2 May not apply with height <60 inches (5 ft.) Ethnic variation (Asian descent – WC > BMI for predicting disease risk) Ethnic variation – generally predictive for racial and ethnic groups in North America – those of Asian descent – WC > BMI for predicting disease risk Fat accumulation in the abdomen is linked to increased risk of type II diabetes and obesity-related diseases in general Recommended to be used as part of routine physical exam	Increased waist circumference is an independent risk factor for disease [17] Male: High risk >40 inches Female: High risk >35 inches May not be a useful measure with height in excess of 60 inches or with BMI ≥35		

Measure	Examination/measurement method	Optimal	Excess/elevated	Deficient/depressed
Waist-to-hip ratio[17]	=Waist/hip circumference Abdominal fat is comprised of: Subcutaneous fat Visceral fat – Research that visceral fat (fat around a number of abdominal organs (such as the stomach, liver, and spleen)) is most strongly correlated with morbidity and mortality Retroperitoneal fat (retroperitoneal fat = outside of and posterior to peritoneal cavity (which lines the surface of the abdominopelvic wall and contains most of the organs)) Most accurate measure of abdominal fat is via MRI or CT – but costly and less practical, so WHR is used to estimate abdominal adiposity (Hip measurement is taken at the widest part of the buttocks (i.e., hip circumference at largest point. The anatomic landmark for this is the greater trochanter.))	Preferred ratio is to have the waist circumference less than the hip circumference (so the ratio <1 (due to the increased risk for hypertension with higher waist circumferences)) Optimal/ideal: <0.8 female <0.9 male	Increased abdominal fat is an independent risk factor for morbidity (sickness) and mortality World Health Organization (WHO): >9 in men >0.85 in women Benchmark for metabolic syndrome (predicts all cause and CVD mortality) [17]	
Waist-to-height ratio (WHtR)	WHtR = Waist circumference divided by height A measure of the distribution of adipose tissue [17] More sensitive than BMI as early warning of health risks and also considered to be more sensitive than the waist circumference in several different populations (due in part to the fact that it includes a measure of stature) [108] It is easier to measure/calculate than BMI and more affordable (no scale is required, just measuring tape for waist circumference and height [108] More accurate in adolescents and across different ethnicities WHtR > WC > BMI for detecting cardiometabolic risk across both genders [109, 110, 111, 112] The WHtR counteracts differences across ethnicities that the waist circumference and WHR cannot (such as the fact that health risks for Asians are increased with smaller levels of visceral fat than for Caucasians). With the average height of Asians being less than Caucasians, the WHtR can account for this WC and WHtR are superior to BMI in predicting diabetes and CVD risk (BMI does not assess the accumulation of visceral/abdominal fat) [109]	WHtR = 0.5 "Keep your waist circumference to less than half of your height" [109] General age-related ranges: 0.43–0.5 adults less than 40 y.o. 0.5–0.6 adults 40–50 y.o. ≤0.6 adults over 50 y.o [17].	(Apple and pear shapes) Overweight: F: 0.49–0.54 M: 0.53–0.58 Obese: F: 0.54–0.58 M: 0.58–0.63 Very obese: F: >0.58 M: >0.63 Higher values of WHtR relate to increased risk of metabolic syndrome and to obesity-related cardiovascular conditions [17, 108]	(Chile shape) Slim: F: 0.35–0.42 M: 0.35–0.43 Underweight: F: <0.35 M: <0.35
Body composition analysis – there are several methods for determining body composition [17, 26] Densitometry Underwater weighing Air displacement plethysmography Total body water Total body potassium Neutron activation analysis Creatinine excretion 3-Methylhistidine Electrical conductance Bioelectrical impedance analysis (BIA) Infrared interactance Ultrasound Computed tomography (CT) Magnetic resonance imaging (MRI) Dual-energy X-ray absorptiometry The most accurate and widely used will be discussed in more depth in this table hereafter				

Measure	Examination/measurement method	Optimal	Excess/elevated	Deficient/depressed
Skinfold thickness [26, 107]	Most widely used method of estimating percent body fat As these measures assume subcutaneous fat comprises 50% of the total body fat, and the measures require considerable skill to perform correctly, they are not considered the most accurate method of determining percentage body fat. However, they do have some advantages: Estimates energy reserves (fat and protein) in subcutaneous tissue Measurements can be easily and quickly obtained Done accurately, measures can correlate well with hydrostatic weighing Inexpensive and portable equipment (vs. hydrostatic weighing) Typical sites measured include: Chest Triceps Subscapular Midaxillary Suprailiac Abdomen Thigh Medial Calf Calculations and/or nomograms are used to determine body fat percentage from one or more specific skinfold sites (sites chosen for measurement/calculation vary by gender and age) In hospitalized patients, the sum of: Triceps and subscapular skinfold thicknesses (measured recumbently) are used as indicator of body's energy reserves	Normative tables, equations, and nomograms available for interpretation [26]		
Arm muscle area (AMA) [26]	Arm muscle area is used to assess total amount of muscle in the body (uses triceps skinfold (TSF) measure and mid-arm circumference (MAC) for calculation/determination) Limitations with accurately measuring MAC and TSF limit use of this measure AMA is correlated with creatinine excretion (children) and total body muscle mass (adults)	Normative tables, equation, and nomograms available for interpretation		

Measure	Examination/measurement method	Optimal	Excess/elevated	Deficient/depressed
Bioelectrical impedance analysis (BIA) [17, 26]	Electrical current passed through the body to determine fat vs. fat-free mass. This current is harmless and cannot be felt by the subject Principle: The current is opposed by nonconducting tissues (fat and cell membranes) and transmitted by electrolytes in water (in fat-free tissues mainly) Opposition to alternating current (AC) = "Impedance" Accuracy – comparable to skinfold measurements (may be better) Particularly helpful in assessing body composition in those with edema or in patients who have had an amputation Weaknesses: assumes normal hydration With the weakness of dehydration skewing results, it is advised to have subjects drink plenty of water and refrain from exercising heavily for 4–6 hours and from consuming alcohol and/or taking diuretics for 24 hours prior to the test Depending on the device used, a BIA machine may measure any/all of the following: Weight Percent total fat Fat mass and fat-free mass Muscle mass Bone mass BMR Metabolic age Visceral fat rating BMI Physique rating For more specifics on these measures and their interpretations, consult the guide(s) of the specific machine(s) that you will use for BIA testing	For more specifics on these measures and their interpretations, consult the guide(s) of the specific machine(s) that you will use for BIA testing BIA skeletal muscle mass (whole body) measure can be used to screen for sarcopenia [94] (in conjunction with handgrip strength and gait speed) <8.87–10.76 kg/m^2 men <6.42–6.76 kg/m^2 women		
Air displacement plethysmography (BOD-POD) [17, 26]	Body density is measured as a means to estimate body fat and fat-free mass. The BOD-POD device is considered to be an accurate method for determining body composition Patient enters a capsule/pod wearing tight-fitting swimsuit and cap to minimize measurement error It is relatively quick, easy, and affordable to test/obtain results and is preferred for children, the elderly, and those with disabilities over underwater weighing As it does not rely on body water content for determining body density and composition, it has potential utility in those with hydration imbalances and in adults with end-stage renal disease			
Dual-energy X-ray absorptiometry (DEXA) [17]	Measures fat, bone mineral, and fat-free soft tissue Used in hospital setting Considered easy to use. Patient needs to remain still for accurate measure so can be a problem for those with chronic pain and the elderly Affected by hydration status and thickness of tissues Emits low-level radiation			

Measure	Examination/measurement method	Optimal	Excess/elevated	Deficient/depressed
Measuring energy expenditure [26]	Measuring energy expenditure Direct calorimetry Indirect calorimetry Doubly labeled water Bicarbonate urea Estimating energy expenditure (REE) Harris-Benedict equation World Health Organization (WHO) NIH University of Vermont Mifflin St. Jeor Estimating energy expenditure – major determinant is fat-free mass (determine 70–80% of variance in REE, with the remaining 20–30% due to genetics). Note that the WHO equations do not include stature (it was not found to significantly improve the predictive ability of the equations) The resting energy expenditure equations must be increased to account for total energy expenditure, and this is achieved by multiplying the REE by an activity factor. In theory, REE includes the thermic effect of food (TEF) and total energy expenditure (TEE); however, in most clinical settings, allowance for additional energy needs from the TEF is not given In cases of disease, injury, and surgery, an additional factor can be included to estimate the 24-hour energy expenditure of these patients. The Estimated Energy Requirement (EER) developed by the National Academy of Sciences is defined as "average dietary intake that is predicted to maintain energy balance in a healthy person of defined age, gender, weight, height and level of physical activity consistent with good health." These equations apply only to people with healthy weight. For overweight, use the TEE equations			
Nutrition screening questionnaires				
Mini Nutritional Assessment [26] (MNA and MNA-SF)	Designed to efficiently identify elderly patients at nutritional risk who may then need a more extensive nutritional assessment The full MNA can be completed in 10–15 minutes The short form (MNA-SF) can be completed in less than 5 minutes			
Malnutrition Universal Screening Tool (MUST) [26]	Designed to identify adults who are malnourished, at risk of malnutrition, underweight, or obese It evaluates BMI, history of unintentional weight loss, and the presence of decreased food intake due to illness Can be completed in 3–5 minutes

Using a Peak Flow Meter (PFM),

- Set the sliding pointer on the meter to zero
- Hold the PFM by the handle
- Stand erect
- Remove chewing gum or food from mouth
- Take a full deep breath and seal both lips and tongue around the mouthpiece
- Exhale as quickly and as forcefully as you can
- Note the number where the sliding pointer stopped
- Reset the sliding pointer to zero
- Repeat 3 times
- If any coughing occurs in this process, repeat
- Record the highest reading of the 3 in a graph or log (This is the *peak flow.*)
- Use daily – ideally around the same time each day
- If a new meter is needed, be sure to determine peak flow for that meter

Peak Flow Zone	Clinical Meaning	Action to take
Green	***Go Zone*** – 80-100% of peak flow Zone to be in every day Indication that air is moving freely through the large airways	None
Yellow	***Caution Zone*** – 50-80% of peak flow Clue that large airways are starting to narrow May be symptomatic (coughing, fatigued, short of breath, tightening of chest	Talk to doctor- medication change/increase and/or other intervention may be needed
Red	***STOP Zone*** – <50% of peak flow Indication of severe narrowing of large airways – MEDICAL EMERGENCY May have coughing, wheezing, short of breath. May be difficult to walk & talk	Take rescue medication and call the doctor

Predicted average peak expiratory flow (L/mins):

Age (yrs)	Height					
	65″		70″		75″	
30	489	617	502	637	513	655
40	483	620	496	641	507	659

Fig. 39.17 Peak expiratory flow rate (PEFR) technique

39.2 Conclusion

In this chapter, we have covered an array of physical signs and cues that signal nutritional and medical imbalances, disorders, and diseases. By integrating this knowledge into practice, the dietitian/nutritionist or medical provider may benefit from the words of William Osler, a Canadian physician who emphasized the importance of the history and physical exam in making an accurate diagnosis:

> Learn to see, learn to hear, learn to feel, learn to smell and know that by practice alone can you become experts. [113]

Indeed, learning the language of the body takes time and presence. The more examinations one performs, the more the examiner builds a repertoire of knowledge and also an embodied sense of what is normal. This sense then allows one's antennae to more accurately pick up something abnormal [114]. It is no wonder that Sir Arthur Conan Doyle, the creator of iconic fictional detective and astute observer Sherlock Holmes, was a physician [115]!

The physical exam offers a unique opportunity to truly relate to a patient in a more intuitive and sensory manner, to connect with them through a kind of ritual that can initiate a patient-provider bond. Verghese entreats the examiner to perform the exam with skill and consideration so as to not violate the sacredness thereof and the transformation that this ritual can incite [13]. Furthermore, he and his colleagues introduce a conceptual framework for the utility of the physical exam organized into seven themes [116].

1. Diagnostic accuracy: Well-performed technique, practiced over time increases diagnostic accuracy.
2. Ongoing care and prognosis: Physical exam findings can guide therapy and prognostic assessments.
3. Patient contact: The physical exam can improve the patient-provider relationship through the ritual and touch that it involves.
4. Accessibility: Rapid assessment (often with minimal equipment) is possible with the physical exam
5. Pedagogic value: Teaches clinical reasoning and bedside manner and can also be used in patient education.

6. Cost: The physical exam may be more cost-effective than comparable technological tests.
7. Patient safety: Many physical examination procedures offer lower risk assessment than corresponding technological evaluations.

They contend that the physical exam may offer healing not only to the patient but to many pressing issues in healthcare today, such as misdiagnoses, escalating costs, decline in the provider-patient relationship, and provider burnout.

This chapter provides the knowledge needed to recognize and interpret a wide variety of abnormal findings. From what has been covered here, you may notice that a patient who presents with keratosis pilaris, fissuring eczema, ridging and missing lunulae of the nails, a tendency toward paronychia, thinning of the hair, photophobia, and a reduced sense of smell and taste may be suffering from deficiencies of zinc and possibly protein. With your counsel, the patient does a trial switch from a vegan diet to one with high-quality animal protein daily, and within a few months, partial lunulae are present on all of their nails, and, within 6 months, the lunulae are fully intact and accompanied by changes to the health of their skin and hair. These changes reflect to the examiner that their zinc and protein status are improving and with it, a return of greater health overall.

Lest we not touch on one important point before closing: in an era where dietitians, nutritionists, and healthcare providers are besieged with pressures and growing amounts of data to create and sift through, a little fun may be welcome, and physical diagnosis, and the satisfaction of arriving at a diagnosis solely (or largely) with one's wits and senses, while connecting more with one's patient [34], may be just what the doctor ordered.

40.1 Introduction

The skilled IFMNT practitioner understands that developing a clear picture of a client's current life circumstance is imperative to helping the client implement desired functional nutritional and lifestyle prescriptions for the long term. Optimizing lifestyle change is the fundamental intervention of the integrative functional medicine approach. Initiating and sustaining that transformative change is dependent on many factors, including how the IFMNT practitioner establishes the therapeutic relationship and maintains knowledge of critical factors in the social milieu. Knowing how to obtain a comprehensive assessment of modifiable lifestyle factors in an insightful, educational, and compassionate manner can have lasting impact on the achievement and maintenance of health goals.

The detailed metabolic and physiologic pathways for nutritional influences on health and disease outcomes have been previously discussed in this textbook. The study of the science behind physiologic mechanisms and biochemical pathways is the science of medicine. Knowing how to engage the patient and how to ask questions is the art of medicine. So, how does the practitioner translate knowledge into action for the patient? What tools are available for assessment? For education and interventions? For ongoing support? What personal interaction skills are necessary for the practitioner? How do we assess the client's readiness to change? How do we support lifelong changes? Each area is discussed in (▶ Chaps. 6 and 9).

We begin by establishing a mutually beneficial dialogue with the client to understand where they are in their life at this moment. The bottom of the IFM Matrix tool emphasizes the role of current lifestyle areas as root factors influencing the complex interconnecting physiologic and biochemical factors of the Matrix above it. These areas represent the ongoing modifiable triggers and mediators of biologic function. As a teaching tool, the practitioner can explain how these five primary "roots" of the Functional Matrix "tree of symptoms" act as major influences on current health. The Matrix provides an excellent visual to explain complex phenomena in a simple manner (◘ Fig. 40.1).

At the center of these modifiable lifestyle factors is nutrition assessment, the purview of ▶ Chap. 9 on IFMNT NIBLETS. The four other important areas to assess, in a nonjudgmental and compassionate fashion, are past and current exercise and movement, sleep and restoration habits, stress levels and their perception (including resilience levels), as well as relationships and beliefs. Detailed physiological impacts of these areas on biochemical pathways have been previously discussed (see Part I, Section 2: ▶ Chaps. 7 and 8). In addition, as part of implementing any kind of program, it is valuable for the practitioner to know how to assess the client's readiness to change.

Most practitioners are very comfortable asking about exercise and sleep issues and have had training in asking basic stress and relationship questions, but many are not yet comfortable, nor have the tools, to help a client explore their deeper belief systems and underlying spiritual values. It is often that these very important underlying and unspoken codes are the "back story" that unconsciously governs sabotaging behavior. Positive beliefs and spiritual connections can be harnessed to engage not just immediate change but for transformative, inspirational, lifelong benefit.

40.2 Gathering Lifestyle Data: The Big Picture

40.2.1 Establishing the Therapeutic Relationship

For the practitioner, understanding in detail where the patient stands regarding current levels of stress and overwhelm can help direct priorities and frame realistic expectations for the client's current capabilities. In addition, interest from the clinician can serve to markedly assist in developing trust from the patient who feels heard. When the client has been validated for their obstacles and challenges and sees that the practitioner is interested in finding workable solutions to those challenges, they are then more willing to trust the clinician's guidance, want to actively cooperate, and are more likely to persevere in the face of stumbling blocks. In order to get optimal outcomes, the client must be mentally, emotionally, and physically capable of implementing the requested changes to their diet and lifestyle.

By evaluating each of the subject areas, the practitioner can prioritize and provide support tools to help the client implement change and move beyond limiting beliefs. If the practitioner doesn't understand the current circumstances and capabilities of the client, there is likely to be frustration and disillusionment on both sides, as well as wasted time and resources, no matter how brilliant a diagnostician is. There is no use telling a client to go on an elimination diet when they are in the midst of remodeling their kitchen or are drowning in stress from spending their hours in traffic driving kids to sports practice with no time for self-care. Meeting the client where they are is imperative.

> "Meeting the client where they are is imperative."

Identifying obstacles and opportunities in each area allows for individualized support tools to be recommended [see below] and can have profound impact on outcomes. For example, one patient may be a former athlete whose belief system is easily engaged in focusing on exercise as a leverage point, whereas another may be very committed to their faith practice, whose tenets may be used to support changes in eating habits. It's critical for the practitioner to help clients see new avenues for change, often from years of entrenched, unhealthy patterns. The lifestyle factors section on the Adult Intake Questionnaire [Male or Female] (▶ Chap. 46) is an

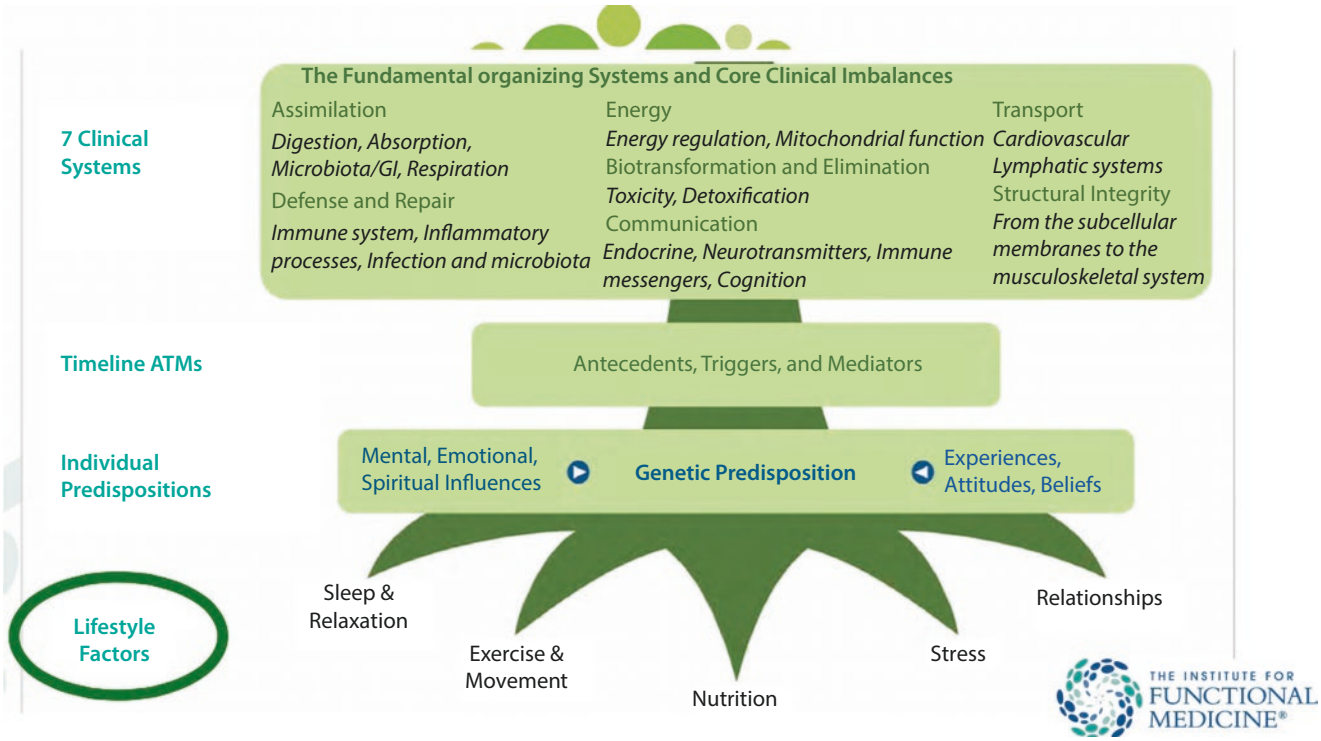

Fig. 40.1 Modified IFM tree. (Used with permission from The Institute for Functional Medicine ©2015)

excellent starting tool for basic assessments, pointing the practitioner to areas that may require more in-depth assessment with other questionnaires.

40.3 Gathering Oneself

The IFM acronym "GOTOIT" [1] is an organizational framework pneumonic that refers not only to gathering information and data on the client but to gathering one's self as a practitioner.

"GOTOIT"
- *G*ather
- *O*rganize
- *T*ell
- *O*rder
- *I*nitiate
- *T*rack

We must ask ourselves, "How well do I do as a practitioner regarding daily meditation or mindfulness-prayer practices, movement, rest, and restoration?" Does the clinician have a support system? What kind of personal growth and ongoing psychotherapeutic work has been done? Burnout is extremely common among today's physicians and nurses [2], affecting the clinician's ability to be present. The practitioner's energetic state can markedly influence the patient's receptivity. Calm, present, mindful clinicians, following their own advice, are much more likely to inspire confidence and participation by the client [3]. ▶ Chapter 46 has an assessment questionnaire, "Walk the Talk," specifically designed for practitioners to look at themselves. In this arena, the ancient wisdom teaching of "know thyself" connected to the biblical command of "physician heal thyself." (▶ Chap. 6) Both speak volumes!

Since studies have shown that 60–80% of office visits for physical complaints are, in reality, related to personal psychosocial stressors [4], the clinician must cultivate both internal personal resources and external network of resources for referral to the appropriate support mechanisms, such as psychotherapists, social workers, support groups, domestic abuse shelters, trainers, nutritionists, bodyworkers, lifestyle coaches, acupuncturists, chiropractors, biologic dentists, crisis centers, as well as clinical subspecialists. It takes a village, and creating health is a team sport!

40.4 Utilizing Assessment Questionnaire Tools

40.4.1 Benefits for Practitioners

Collecting lifestyle data can be done both with direct questioning and indirectly by using any of several different questionnaires and assessment tools. As direct questioning in all these different areas at one sitting is a daunting task, the use of questionnaire materials ahead of time can allow for the gathering of much data with minimal time. Many useful questionnaires are available through organizations (such as the IFM Toolkit, available on the IFM website, and referred to henceforth as "Toolkit") [5] as well as online resources.

Practitioners can initially utilize the answers on a modifiable intake form, such as the comprehensive Adult Medical Intake Questionnaire [male or female] found in the IFM Toolkit. Each lifestyle area is addressed with basic questions to help begin a dialogue. While reviewing the questionnaires with the client on intake, the opportunity often arises to segue directly into brainstorming of ideas for improvement or changes that can be made. Multiple examples are listed throughout this chapter and provide an opportunity to have a back-and-forth dialogue about what is possible.

For more in-depth and illuminative information, areas of concern can be investigated with additional self-administered questionnaires such as the sleep questionnaire, the DASS [Depression Anxiety Stress Scale] questionnaire or an exercise assessment, or self-care questionnaire (Appendix A2). The practitioner can easily uncover areas of concern while noticing opportunities for leveraging behaviors and beliefs to expand on what is already working. The questionnaires can additionally help triage the client's ongoing needs to the appropriate practitioner. For example, a busy physician may not have the time or expertise to counsel a client on an exercise prescription, but they recognize the need to refer to the lifestyle coach or to refer another client for counseling because of abuse issues.

40.4.2 Benefit for Clients

The benefit for the client from filling out these detailed questionnaires is that the process itself can have educational and therapeutic value. They may wonder why they're being asked about how they were born or whether they had ear infections while growing up. They may ask how answering that question will help them now. A question regarding whether a client was breastfed helps them to begin to understand the connection between early life nutrition and later outcomes such as autoimmune and gut function. It is often an eye-opening experience for the client to begin to see just how many layers of stress they have been dealing with, or how little time they have for self-care, or how having lots of antibiotics as a child may be impacting their health now. We may often be the first to ask about histories of childhood abuse, and they will be relieved and grateful. Many have new insights into what is really underlying their health issues and begin connecting dots from the past to be able to make the necessary changes moving forward. The questions themselves prepare the client to be more receptive to solutions the practitioner can provide.

40.4.3 Insights and Change

Questionnaire-induced insights may bring about shifts even before the practitioner meets with them. For example, after filling out a DASS, the client may purposefully seek to cut down on watching stressful television or the amount of alcohol they consume, or they may realize just how much their job is impacting their health and begin contemplating a change. Filling out the exercise questionnaire often gets them moving a little more before they come in for their visit. Answering questions about stress factors from the past, such as the Adverse Childhood Events (ACE) score can be illuminating. These questions can help a client to see and realize just how important current strategies and tools to help modulate the lifelong impact of those events become. An opportunity arises for discussing resiliency tools and strategies. The ACE questionnaire tool and resources can be found at the Centers for Disease Control and Prevention website (► cdc.gov) or for the layperson at ► ACEsTooHigh.com.

It is particularly valuable to focus on *whatever* a patient is doing right and build on the positives rather than focusing on the negatives. The use of the word "why" as in "Why aren't you exercising?" should be avoided as it creates defensiveness. Instead, when exploring obstacles and challenges, use a phrase such as, "Tell me about…." For example, "Tell me about what gets in the way of exercising or movement for you."

40.4.4 Storytelling and Healing

Just the act of telling their story to an attentive listener and being witnessed has therapeutic value for the patient and has been documented as a healing tool in and of itself [6]. Unfortunately, because of the time limitations within the conventional medical model, few clients have had an opportunity to tell their histories in a comprehensive way and to discuss their current lifestyle challenges in-depth. As the client is watching, the practitioner can draw arrows from the lower half of the Matrix, illustrating connections from lifestyle factors to the functional metabolic disturbances above – an excellent, concrete teaching strategy.

Once the client's information is gathered, the attentive and compassionate practitioner tells the patient's story back to them, organized in such a way that a path to healing can be illuminated through the modifiable factors, inspiring hope and confidence. Reiterating the client's history in this way lets them know they have been heard and often elicits astonished appreciation and a willingness to eagerly move forward. Not uncommonly, a sense of great relief and well-being happens for the client without the practitioner actually "doing" anything. Thus, with a thorough and caring intake assessment, done well, a therapeutic relationship begins.

40.5 How to Ask Questions: Establishing the Therapeutic Relationship

» The consciousness in which you gather your information is just as significant as the information you gather.
– Monique Class, RN, MSN, IFMCP

When gathering lifestyle information, it is important to ask questions with empathy in a nonjudgmental and neutral way, as many of these areas are sensitive or may elicit guilt or shame response from the client's perceived lack of control or failure to have previously implemented changes. Focusing on what is already working and expanding those areas can often be more useful than just focusing on what a client is not doing "right." Again, one of the most important things a clinician can do to improve their credibility with clients is to assess and address each of these areas in themselves [7–9].

The following are eight practices that are found to promote healing relationships, outlined in an excellent article by psychologists Churchill and Schenck on "Healing Skills in Medical Practice" [10]. They are well worth printing out for clinicians to remind themselves how to create the most positive interactions.

1. *Do the little things*: Introduce yourself and your team, greet everyone, shake hands, smile, sit down, make eye contact, give your undivided attention, be human, and be personable.
2. *Take time and listen*: Be still, be quiet, be interested, and be present.
3. *Be open*: Be vulnerable, be brave, face the pain, and look for the unspoken.
4. *Find something to like, to love*: Take the risk, stretch yourself and your world, and think of your family.
5. *Remove barriers*: Practice humility, pay attention to power and its differentials, create bridges, be safe, and make welcoming spaces.
6. *Let the patient explain*: Listen for what and how they understand, listen for fear and anger, and listen for expectations and hopes.
7. *Share authority*: Offer guidance, get permission to take the lead, support patients' efforts to heal themselves, and be confident.
8. *Be committed and trustworthy*: Do not abandon, invest in trust, be faithful, and be thankful.

40.6 Assessing Exercise/Movement

40.6.1 Exercise: Assessing the Big Picture

It is well established that adequate and regular exercise has a great number of health benefits impacting every area of metabolism and physiology, as elucidated in earlier chapters. A person need not be familiar with intricate beneficial biochemical cellular impacts to intuitively understand that they feel better when moving. There are those clients who are already engaged in an excellent exercise regime and may not require much motivation, but unfortunately, the majority of clients present struggling to incorporate "exercise" into their lives. Currently 70% of the average American adult's time is sedentary, while the remaining 30% is only light activity [11]. The data is clear that chronic sitting is as deadly as smoking. Encouraging clients to replace any sedentary time with sleeping, standing, walking, or moderate physical activity has been shown to reduce morbidity and mortality [12].

So, what are the challenges faced by so many of us in implementing a regular exercise program? This is where the compassionate inquiry skills of the IFMNT practitioner are beneficial. For example, for many women in particular, "exercise" is a dirty word, something else added to the "should" list of too many things to do already, when they are exhausted, not well or don't enjoy it. Having tools to help assess and reframe their beliefs from the idea of more "work" or a "have-to" into one of compassionate self-care can be valuable. Identifying and engaging in opportunities to increase movement throughout the day, no matter if formal exercise or not, can be useful.

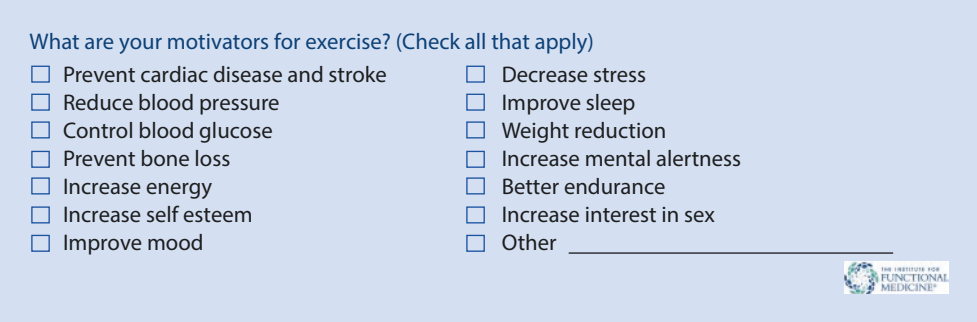
40.6.2 Questions to Ask: Exercise and Movement

Beyond the questions on the Adult Intake Questionnaire, the IFM Exercise History and Activities of Daily Living questionnaires are excellent tools to help develop a comprehensive assessment of overall daily movement, including formal exercise and general activity levels, enjoyability, and perceived roadblocks. Yet for some, filling out the extended Exercise History Questionnaire can sometimes feel overwhelming and shaming when inadequacies in this area are revealed.

It is always best to initially frame these questions in terms of "what are the motivations for and perceived benefits of the client's long-term health goals?" For example, start with: "Would you like better sleep, mood, weight loss, brain function, cardiovascular health, cancer prevention?" Beginning with the end in mind helps create a bridge for incremental change (see Fig. 40.2).

A comprehensive exercise intake assessment includes "FITT" questions about frequency, intensity level, type of exercise, and time done and covers cardiovascular activities, strengthening, stretching, and balance. Other pertinent areas to assess are:

- What types of activities do they prefer? Formal or informal?
- What do they like most about exercising?
- What do they like least?
- Do they prefer solo, partner, or group activities?
- Do they have a membership at any facility that includes movement?
- Do they have any of their own equipment?
- What obstacles do they have? Time constraints? Financial? Transport?
- What are some possible solutions?
- Best time of day?
- When do they have the most energy and time?
- What are their goals regarding balance, flexibility, fitness, and body composition?
- What kind of injuries or physical limitations with joint or musculoskeletal pain do they have?



What are your motivators for exercise? (Check all that apply)

- ☐ Prevent cardiac disease and stroke
- ☐ Reduce blood pressure
- ☐ Control blood glucose
- ☐ Prevent bone loss
- ☐ Increase energy
- ☐ Increase self esteem
- ☐ Improve mood
- ☐ Decrease stress
- ☐ Improve sleep
- ☐ Weight reduction
- ☐ Increase mental alertness
- ☐ Better endurance
- ☐ Increase interest in sex
- ☐ Other _____

THE INSTITUTE FOR FUNCTIONAL MEDICINE

Fig. 40.2 Motivators for exercise. (Used with permission from The Institute for Functional Medicine ©2015)

- What kind of medical conditions such as neurologic issues, breathing issues, balance, congestive heart failure, or angina limit their activities?

It is often helpful to walk a client through their day from morning to bedtime to help reveal where the obstacles and opportunities lie. Encouraging the patient to substitute any movement for screen time can be beneficial for every aspect of health [13, 14].

Explain at a metaphorical level that movement is about "taking the next right step" and "moving forward" in life. Literal movement is a concrete external manifestation of the internal changes the client wants to make. Movement can be reframed as a form of prayer or meditation, e.g. taking time to be mindful of each step, of the neighbor's gardens, and of the changing seasons or while mentally rehearsing a favorite spiritual verse or poem, dedicating themselves to a higher good. "My body is my temple and the home to my soul" is a wonderful mantra to repeat while walking.

If a client is feeling "stuck" in old patterns and hates the concept of "exercise," this attitude can be reframed into an opportunity to literally "create more movement" in their life. A simple strategy to encourage moving beyond inertia is to suggest putting tennis shoes and sweats right by the bed, getting up first thing without thinking, putting them on, and walking 10 minutes in one direction out the door and 10 minutes back. No gym required.

Additional strategies include asking, "Do you feel safe walking in your neighborhood? Do you have a friend you can go with?" For some, the opportunity to have "walk and talk" therapy time with a good friend or buddies cycling together can provide the motivation to get out and going. Having a client setting a goal of only watching their favorite rerun while on the treadmill, balance ball, or mini trampoline can provide incentive. Make it fun by encouraging the use of favorite dance music from the time a person was in his/her teens and 20s as a way to engage the joyful, high energy spirit that naturally makes the body want to move.

For the more sedentary or ill client who is having difficulty moving, utilizing the Activities of Daily Living Questionnaire is a gentler introduction. It provides not only a realistic assessment of physical capability but also an opportunity to suggest simple measures that can be incorporated to enhance what movement is already naturally occurring day to day. For example, chores can be arranged so a person can alternate downstairs and upstairs tasks, purposefully making as many round trips as able. Using breath and mindfulness techniques at the same time can help keep the person present to the miracle of movement.

For those with severe fibromyalgia, chronic fatigue syndrome, or other debilitating illness, an excellent functional impact questionnaire that includes activity can be found online at ► Myalgia.com or ► FIQR.info. These questionnaires can be downloaded, or better yet, online electronic calculators used, to make it very fast and easy to assess and follow a client's progress over time. The Toolkit handout of Lifestyle Modification for Chronic Pain and Fibromyalgia Syndromes can be supportive.

Inquire about the patient's experience with tai chi, Pilates, and yoga (which can be done at all intensity levels from restorative to intense) as all are good choices for core strengthening, flexibility, and balance. Many people can't stand the thought of a gym, whereas others find it energizing and improving of their self-esteem, but transportation and membership cost can be an obstacle [15]. Dancing, hiking, gardening, and yard work are all ways to move aerobically without a gym. Of course, running, cycling, weights, swimming, martial arts, and aerobics classes are excellent modalities. A balance ball is a very inexpensive tool to utilize for sitting both at home and work. Help clients look for lower cost resources such as a YMCA or recreation center and classes such as senior "SilverSneakers" or chair yoga classes for the over-65 crowd. "Pickleball" is the new rage for all ages, especially found in senior communities, combining tennis, badminton, and table tennis, all elements for multigenerational fun. Dance is an excellent form of exercise, from Zumba to ballroom dancing, country and western to Argentine tango, ballet to barre, involving balance and flexibility as well as aerobic activity. Dance classes can provide a social milieu as well. Encourage at least one activity a week in community for the importance of social connection.

40.6.3 Assessing Movement at Home

Unfortunately, given all the "convenience" appliances and foods of this day and age, people are moving far less and sitting more both at home and at work. They work in order to

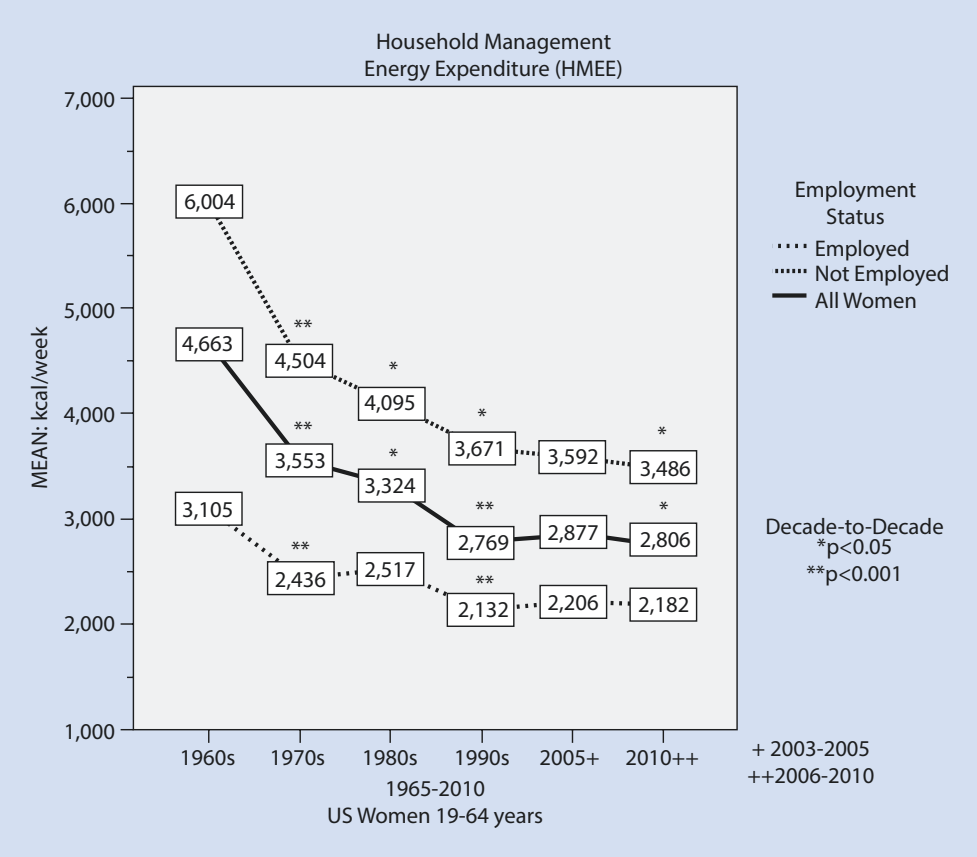


Fig. 40.3 Household energy expenditure. Depicts the decade to decade change in household management energy expenditure per week (HMEE/week) for all women and by employment status. (Reprinted from Archer et al. [16]. With permission from Creative Commons License)

pay for those conveniences and then pay more to go to the gym to workout. Yet, too often the thought of going to the gym or standing and preparing a real meal becomes exhausting for a burned-out working individual, especially with children. Commonly, many are recuperating from stressful days through sedentary time involved with watching television, sitting at a computer, or using handheld devices while eating a prepackaged microwaved meal. Unfortunately, these activities have become the sole source of "restorative" activities for a vast majority of the American population. Yet, for each additional hour of television watched per day, there is an 11% increase in all-cause mortality [14].

For those who are already quite sedentary, examine their written exercise intake or use the verbal interview to discover how much movement they are already engaged in with housework or yard work. Expanding on those areas can be useful ways to begin to increase caloric expenditure. Everyday chores can be a source of burning extra calories. The average 1950s housewife was burning 1000–3000 more calories a week with sweeping, doing laundry and walking to the local market, chopping and preparing daily meals, etc. [16]. Suggest listening to good music or podcasts while engaging the whole family in chopping vegetables, making meals and hand-washing dishes or while mindfully standing and ironing, turning those humdrum chores into activities of pleasure rather than boring repetitive tasks. Encouraging singing along loudly and dancing while sweeping, vacuuming, going up and down the stairs multiple times to carry laundry, making the bed, and bending and moving while cleaning can turn mundane "have to's" into fun and playful opportunities to burn calories. Putting the kids in a stroller and going out for a walk after dinner is a time-honored way to substitute TV time for moving family time (Fig. 40.3).

Additionally, we are burning less calories from maintaining temperature regulation compared to even 40 years ago because of HVAC systems keeping the temperature at steady states so our bodies don't have to. Keeping indoor temperatures cooler has been shown to expend more calories from thermogenesis as well as exercising in the cold [17–20]. Shivering and sweating are simple ways to increase caloric expenditure whether moving bodies indoors or out. Have everyone turn thermostats down in winter and up in summer.

40.6.4 Assessing Movement at Work

One can assess if the client's job is stationary/sitting or if it naturally involves movement, such as being a nurse or retail worker required to spend most of their shifts on their feet. A number of wearable devices are now available, such as the

Fitbit, and many smartphones can track movements and provide positive feedback to the client to encourage incrementally increasing their goals [see Toolkit for a list of personal device options]. Engaging their competitive spirit with co-workers can also be motivating.

Portable standing desktop stations and chairs that raise from sitting to standing are available that can encourage the client to frequently change positions. Balance-ball chairs actively engage core muscles while sitting. Devices, such as a stationary pedal for underneath the desk, are engaging and easy. Utilizing simple at-work stretching exercises for desk sitting and setting a timer to remind to stand every 15–20 minutes can be useful. Getting up frequently to go to the water cooler or taking stairs instead of an elevator can easily add to a daily step count. Helping the patient to think creatively can assist them in their goals.

40.6.5 Resources to Motivate and Track Exercise

Once an assessment is made of the current activity level and the challenges and opportunities outlined, it is much easier to utilize a tool such as the IFM Exercise Prescription, which reiterates the FITT model of desired frequency, intensity, type, and time. High-intensity interval training [HIIT] such as the "7-minute workout" (many versions available online) has become a popular, efficient, and effective use of time for cardiovascular fitness. Again, the client is much more likely to have interest and be compliant if the practitioner is also practicing what they are preaching [12]. Tracking over time can be done with a form such as the IFM Exercise Goals and Tracking Journal, both found in the Toolkit.

Two excellent handouts for motivation which also can be found in the Toolkit include "The Power of Movement: Living an Active Lifestyle" and "Tips to Incorporate Mindful Daily Movement." Suggest a TV moratorium for 4 weeks and see how much time is freed up for all forms of self-care!

40.7 Assessing Sleep and Restorative Activities

40.7.1 Restorative Activities: The Big Picture

More than a third of US adults don't get enough quality sleep. According to recent data from the CDC, 50–70 million adults in the United States have chronic sleep and wakefulness disorders [21]. Sleep difficulties are associated with all chronic diseases, mental disorders, health-risk behaviors, and the underlying limitations of daily functioning, injury, and mortality. Insomnia is a known independent risk factor for depression and other psychiatric disorders. Most patients with mood disorders experience insomnia. Conversely, one-third to one-half of patients with chronic sleep problems have mood disorders leading to a vicious cycle [22].

Recent data on all causes of mortality in the United States show sleep apnea to be a major cofactor for many chronic diseases. Although sleep apnea affects more than 22 million Americans, 80% of cases are undiagnosed. Sleep deprivation contributes to many health challenges including metabolic syndrome, cardiovascular disease, inflammation, neuropsychiatric disorders, and type 2 diabetes, along with impaired memory [23–25]. Sleep disorders may also trigger immune system abnormalities, inducing autoantibody production and autoimmune disease: SLE, RA, etc. [26] (▶ Chap. 35).

Thus, screening for insomnia, narcolepsy symptoms, snoring/sleep apnea, and restless leg syndrome is paramount. Appropriate strategies to improve sleep quality can be implemented, and the need for further diagnostic testing such as a sleep study at an overnight sleep center can be recommended. Fortunately, home sleep study equipment is now available through a number of different vendors which may be less expensive, less disruptive, and more amenable to encouraging a client to be proactive in addressing their issues than going to a sleep center. For many with mild-to-moderate obstructive sleep apnea, a special dental appliance, created by a dentist trained in this area, can be an economical option in lieu of a CPAP machine, improving compliance.

40.7.2 Screening Questions for Sleep Apnea

Important screening questions to identify sleep disturbance pathology include:

- On average, how many hours of sleep do you get in a 24-hour period?
- Do you snore?
- During the past 30 days, for about how many days did you find yourself unintentionally falling asleep during the day?
- During the past 30 days, have you ever nodded off or fallen asleep, for even just a brief moment, while driving?

40.7.3 Questions to Assess Sleep Habits

A more extensive sleep questionnaire can include questions about sleep environment, including light, sound, temperature, pets etc., including the use of electronic devices and sources of EMFs that may interfere with sleep. Physiologic changes in the brain have been documented from electromagnetic fields generated by cell phones, electronic appliances, and household electrical meters positioned near bedrooms. These have been shown to either produce or exacerbate a wide spectrum of neuropsychiatric effects including depression [27].

Questions include:

- What time do you go to bed? What time to you wake up?
- Are you watching the news or stimulating TV before bed?
- Are you on your laptop or electronic device before bed?

- On average how long does it take you to fall asleep?
- How many times do you wake up? Why? Going to bathroom? Hot flashes? Mind racing?
- Are you able to fall back asleep?
- Are you refreshed when you wake up?
- Are there pets in the bedroom?
- Does your spouse snore?
- Is there a TV in the bedroom?
- Do sounds and/or lights wake you easily?
- How much alcohol and caffeine do you typically drink per day?

It can be useful to help the client to take time for a bedtime routine, beginning an hour prior to bed, as a form of enjoyable deep self-care, rather than another "have to." Consider putting on calming music and taking time for a hot Epsom salt bath with essential oils such as lavender and frankincense (known to have calming effects on the nervous system). Everyone needs time for good oral hygiene, and women in particular often need extra time to mindfully take care of their skin, face, and hair with nontoxic cleansers. Reading a good book, stretching, journaling, and utilizing meditation, prayer, and gratitude can be very simple mindful ways to peacefully wind down, bringing a sense of contentment and closure to an otherwise very hectic day. Counsel patients that bedtime begins an hour before sleep with routine preparations that may include bathing and story time for themselves, no different than the parent has a routine with their children!

40.7.4 Other Restorative Activities

Leading-edge science on neuroplasticity has shown many benefits of tools like mindfulness meditation, gentle yoga, tai chi, gratitude, and journaling practices in rewiring the circuitry leading to chronic activation of the hypothalamus-pituitary-adrenal (HPA) axis. It is important to ask, "Besides sleep, what other type of restorative activity do you engage in? How do you express yourself creatively? What brings you joy? Makes you laugh?" Many clients will get blank looks or even well up with tears when asked these questions, as they realize they have no answers. Particularly women, who are wrapped up in meeting their families and children's needs, find themselves last on their list.

As discussed in previous chapters, meditation and mindfulness-based stress reduction techniques are ancient practices revealed by modern-day technologies to significantly impact learning and memory, emotional regulation, perspective, cognitive restructuring and learning, immune function, and HPA axis regulation. It is known to increase brain-derived neurotrophic factor (BDNF), stimulate the prefrontal cortex, and facilitate neurogenesis. It has been shown to be one of the most cost-effective intervention techniques for improving quality of life, particularly in chronic health conditions [28–31]. Other meditative and restorative practices can be knitting or other needlework, fishing, hiking, gardening, tinkering with tools, and cooking. When mindful concentration is brought to the moment, no matter the activity, it has the capacity to rest the mind, body, and spirit, shifting physiology. Bringing mindfulness and breath focus, to whatever pursuit engaged in, can significantly reduce levels of distress for clinician and client alike.

Laughter is truly the best medicine and yet is something that is frequently lacking. We know it raises endorphins, lowers stress hormones, and modulates immune function, helping to mitigate the impact of stress [32, 33]. Ask, "what makes you laugh, and how often?" One suggestion could be that if they are going to watch TV, choose only something benign, like a cooking or auto show, or something funny that will make them laugh. Pets can also be a great resource in this area. Seeking out humor on purpose, especially during times of stress, can help alleviate its intensity.

Questions for Restorative Activities:

- What is your favorite way to relax?
- What do you do that is fun? Joyful? Playful?
- What makes you laugh? And how often?
- How do you express yourself creatively?
- What did you do for fun as a kid?

40.8 Stress and Resilience

40.8.1 Stress and Resilience: Assessing the Big Picture

We live in a highly stressed culture, rapidly moving from one activity to the next, focused on maximum productivity, minimal downtime with much hidden as well as overt violence. Our society doesn't value space, emptiness, silence, and nature, unfortunately to the detriment of our long-term health. Stress is a word that can have many different connotations for the client along with many different sources. Patients are usually focused on the external sources of stress such as work, finances, family life, and poor health, which may be both acute and chronic. Many people utilize sugar, alcohol, or TV and excessive electronics to manage their stress level, which inputs often only further exacerbate the total stressful load. Adequate sleep and restorative activities as discussed above can contribute significantly to building resilience from stress, as can other activities, which are outlined below.

For the clinician, it is imperative to understand the sources of the patient's stress, the current perceptions of their impact, and their level of resilience and coping strategies in order to target appropriate interventions. Does the patient have a strong internal locus of control with established resiliency factors such as optimism, perseverance, and a social support system, or are they focused on an external locus, blaming others, having chronic negative self-thoughts and feelings of hopelessness? How an individual responds to stress is extremely variable and has genetic, learned and environmental components whose internal physiologic and metabolic consequences are extensively discussed in Parts II and IV of this textbook. From a functional medicine standpoint, the practitioner aims to support the client by alleviating the

total body burden of external stressors impacting the internal sources, offering them tools to help ameliorate both sides of the equation.

Unfortunately for many seeking functional medicine evaluations, the largest sources of stress are their chronic health issues, unresolved or worsened, often after years of seeking help from many different specialists with little improvement. They may be disillusioned, angry, and skeptical. Failure to resolve root causes of health issues has impacted their finances, relationships, self-esteem, level of anxiety, and depression and kept them in a downward spiral of hopelessness. Channeling anger and hopelessness into community and action can be important ways to transform those stressors.

Assessing how much stress a person feels on a daily/weekly/yearly basis can also be useful in understanding what testing to order and interventions to recommend. Every single physiologic node of the Matrix is impacted: hormones and neurotransmitters, inflammation, microbiome, etc. For example, depending on the presentation, the clinician may want to run a diurnal salivary cortisol test to see the impact on the HPA axis, or in another with severe IBS, a stool test to assess effect on the microbiome and intestinal permeability.

Focusing on implementing simple external coping strategies can be one of the most effective interventions. Often the least expensive and time-honored prescriptions are ones of community, laughter, downtime, adequate sleep, or mindful breathwork and meditation – all shown to benefit the internal physiology. Physically writing a prescription for self-care on a prescription pad and telling the client to put it on their bathroom mirror or refrigerator where they can see it every day can be an effective measure to engage their self-compassion and compliance.

40.8.2 Tools for Assessment of Stress and Self-Care

Excellent preliminary intake questions encompassing the common stress sources are found in the IFM Adult Intake Questionnaire and the Self-Care Assessment Questionnaire, both found in the Toolkit. These questions gently raise awareness in a nonjudgmental way and give the client insight into possibilities for change. Emphasize that there are no wrong or right answers. For more in-depth and insightful assessments, the DASS and ACE questionnaires (discussed below) can be essential tools for evaluating dimensions of emotional distress and root causes of chronic illness. All practitioners should be familiar with them.

40.8.3 Stress: Important Questions to Ask

A simple way to begin a conversation is: "On a scale of 1–10, with 10 being the highest amount of stress, where do you feel you are running on average today? For the last month? For the last year? What are your major sources of stress and can you tell me more?" Asking about work, family, social relationships, intimate relationships, children, financial stressors, and health are all important to get an overall picture of challenges and strengths.

What about their work life? What kind of work do they do? Are they satisfied with it? How are their relationships with co-workers or bosses? How much pressure do they feel and is there adequate time and support to get the work done they need? What kind of commute do they have? Driving in traffic can often be one of the biggest sources of chronic low-grade stress. Using tools such as listening to interesting podcasts, fun or inspirational music and books on tape while commuting, rather than cacophonous talk radio or stressful news, can be helpful.

Ask about their social life. Friends. Their significant other. Who takes care of the children if both parents work? What other health issues are other family members dealing with? Teenagers? Elderly parents? Are there major financial or legal stressors? For many working women, childcare issues and lack of time for self-care contribute to feelings of being majorly overwhelmed. For stay-at-home moms, acknowledge that raising children and caring for a home is a full-time job with its own set of stressors, not to be devalued. Men often shoulder their burdens internally and in isolation. In a culture that frowns upon asking for help, they tend to be minimizers on questionnaires and may require subtler questioning.

It may be helpful to ask whether there are ongoing issues such as alcoholism, addiction, or abuse. Does the person feel safe in their home? With their partner? In their neighborhood? One in every three women and one in every four men have been victim of violence in their lifetime, most often from an intimate partner [34]. These questions cannot be ignored.

40.8.4 Abuse and Neglect

Unfortunately, far too many of us, practitioners and patients alike, did not grow up in optimum circumstances, and some traumas can have lifelong health impacts if not acknowledged and addressed. Ask what things were like growing up. How stressed were their parents? What behaviors and coping skills were modeled? Were they allowed to speak their voice and offered comfort and appropriate support, or did dysfunction, verbal and physical abuse, neglect, and other forms of violence predominate? Did they grow up in an alcoholic family system? All practitioners should be familiar with administering the CDC's Adverse Childhood Events [ACEs] Study and scale, which looks at ten different types of childhood trauma, to understand the sobering long-term implications for personal and public health.

The ACE is an extremely useful tool for helping patients to understand how early childhood trauma can have long-term health impacts and can help to dissipate some of the shame and silence often associated with these events. Unfortunately, shame and guilt are extremely toxic emotions to the nervous and immune systems. Silence often leads to the perpetuation of violence and abuse from one generation to the next, no matter the socioeconomic status. Findings of the ACE study show:

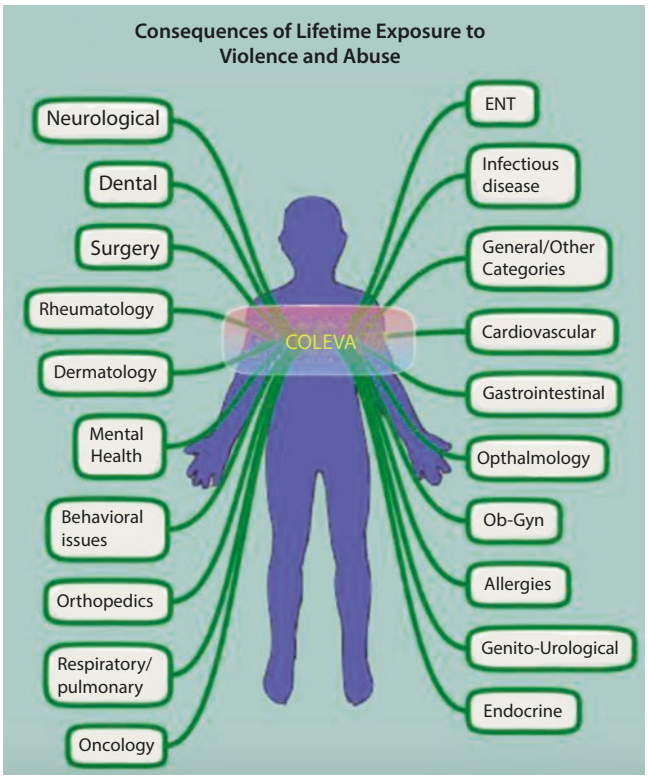

Fig. 40.4 Consequences of lifetime exposure to violence and abuse. (Based on data from Academy on Violence & Abuse (► AVAHealth.org). Exposure to Violence and Abuse (COLEVA). (Retrieved from: ► https://www.avahealth.org/resources/ava_publications/ava_publications_new.html)

Childhood trauma is very common, even in employed white middle-class, college-educated people. There is a direct link between childhood trauma and adult onset of chronic disease, including heart disease, lung cancer, diabetes, and many autoimmune diseases, as well as depression, violence, being a victim of violence, suicide, and a host of other mental health issues. People usually experience more than one type of violence, rarely is it only sexual or verbal abuse. More types of trauma increased the risk of health, social, and emotional problems [34].

Another excellent interactive resource for understanding the documented impacts of violence and chronic childhood stress on all organ systems is from the COLEVA project: Consequences of Lifetime Exposure to Violence and Abuse, a project of the Academy on Violence and Abuse (► avahealth.org) shown in Fig. 40.4.

Whichever stressors are uncovered, the clinician can impart the positive, hopeful findings of neuroplasticity, including the possibility of rewiring the brain, to change PTSD and stress responses by cultivating resiliency tools such as mindfulness-based stress reduction (MBSR), mind-body breathwork, EMDR, HeartMath, and other therapeutic modalities. All clinicians should be familiar with the attributes of resiliency detailed below for themselves as well as patients and must have a network of resources to which they can refer, such as crisis hotlines, psychologists, 12-step recovery groups, and licensed social workers familiar with how to support the client, who may be revealing this information for the first time to a healthcare practitioner.

40.8.5 Assessing Anxiety and Depression

Anxiety and depression are some of the most common symptoms presented by clients as ongoing sources of chronic distress. While there are many different depression and anxiety assessment tools, including the Beck Depression Inventory, Hamilton Anxiety Depression Scale, and GAD-7, the use of the Depression Anxiety Stress Scale [DASS] developed by Lovington and Lovington in Australia adds sensing of the third axis of physiologic stress separated from anxiety and depression symptoms (see ► Chap. 29).

» The DASS is a 42-item questionnaire which includes three self-report scales designed to measure the negative emotional states of depression, anxiety and stress. Each of the three scales contains 14 items, divided into subscales of two to five items with similar content. The Depression scale assesses dysphoria, hopelessness, devaluation of life, self-deprecation, lack of interest/involvement, anhedonia, and inertia. The Anxiety scale assesses autonomic arousal, skeletal muscle effects, situational anxiety, and subjective experience of anxious affect. The Stress scale (items) is sensitive to levels of chronic non-specific arousal. It assesses difficulty relaxing, nervous arousal, and being easily upset/agitated, irritable/over-reactive and impatient. Respondents are asked to use four-point severity/frequency scales to rate the extent to which they have experienced each state over the past week [35]. The questionnaire, along with its interpretive guide, can be accessed through the Psychology Foundation of Australia website or can be found in the IFM Toolkit.

40.8.6 Basic Questions to Assess Stress Levels

- How stressed do you feel on a scale of 1–10?
- What are the major sources of your stress?
- How are things going for you at home? With work? With relationships? With finances?
- How much is your health contributing to your stress levels?
- Did you feel safe growing up?
- Do you feel safe at home now?
- Physical, emotional, and sexual abuse are unfortunately very common – is this an area for us to discuss?
- What "courageous conversation" are you not having about an issue that's bothering you?
- Is the level of anxiety or depression, grief, or sadness you feel impacting your quality of life?

40.8.7 Assessing Resilience

Studies show that recovery is possible from even extreme trauma and stressors, both past and future [36, 37]. The following list, adapted from the work of psychotherapist Elizabeth Scott, MS, explains how qualities found in resilient individuals can be purposefully cultivated and include [38]:

1. Developing a positive attitude – learning to view life's difficulties as challenges to overcome, rather than fears to be avoided, moving from self-pity and blame to positive self-talk and taking responsibility.
2. Developing emotional awareness – asking "Why are you upset?" "What needs to change?" Journal to express feelings.
3. Developing an internal locus of control – even if we can't control an external situation, we can control how we respond.
4. Cultivate optimism by maximizing strengths and minimizing weaknesses.
5. Rally social support and tap into community resources.
6. Maintain a sense of humor.
7. Exercise and get adequate rest.
8. Get in touch with spiritual side, in whatever form is meaningful.
9. Perseverance and determination not to give up.

Many resources from books, DVDs, personal devices, and apps are available to help clients cultivate resiliency and learn techniques to retrain emotional and physiologic reactivity. Perhaps some of the best-studied tools include those from the HeartMath Institute (► HeartMath.org), which have created many biofeedback programs focusing on heart rate variability and coherence for both personal and professional use. The Monroe Institute (► MonroeInstitute.org) offers many modalities focusing on using Hemi-Sync binaural sound technology to entrain brain waves into relaxed states. QEEG neurofeedback harnesses the power of the brain's electromagnetic fields to restore calm; both personal devices such as Muse and professional devices are available. Many apps can be downloaded to help learn mindfulness and mediation including Headspace, Calm, Insight Timer, and others. Well-known investigators and research pioneers in the fields of meditation, mindfulness, and trauma recovery have audio. A number of spiritual leaders, from all traditions, have online broadcasts that are easily downloaded to a portable device.

Ask your clients "How do you manage your stressors?" and explore what are their resources for support: Family? Friends? Community? Church? Pets? Nature? Exercise? Meditation? Prayer? Silence? Have they sought counseling? Support groups? When is the last time they had a vacation or long weekend? How are they sleeping? Do they get some exercise? How often do they laugh? What tools do they use to relax and have fun or express themselves? As discussed above, some of the most powerful and insightful question you can ask is: "What do you do that is fun, joyful, creative, or playful?" It is amazing how many clients will get tearful when you ask these questions when they recognize they don't have an answer.

Twelve-step programs, such as AA and Al-Anon, Overeaters Anonymous, etc., offer inexpensive and incredibly valuable support tools that provide a day-to-day plan for getting through the most difficult of circumstances. All practitioners should be familiar with them and are encouraged to attend open meetings to learn more. Remembering that joy, fun, humor, and creativity even in the midst of severe external circumstances can be what carry people through. They are potent healing modalities. Build on whatever they are doing well, look for positives, and expand them.

40.8.8 Resources for Assessing and Addressing Stress and Resilience

The Toolkit offers resources to share with clients on an array of topics, including:

- Relaxation response
- Strategies for transforming stress
- Mindfulness for sleep disorders and anxiety
- Integrated guide to visualization and imagery
- Meditation-getting started
- IFM gratitude journal
- Breathing techniques to soothe the soul, restoration prescription
- Cultivating self-awareness and mindfulness
- Restoration activities
- Health benefits of napping
- Tips to incorporate mindful movement daily

Other modalities to raise sympathetic tone may include bodywork such as massage, lymphatic therapy, craniosacral work, acupuncture, and laughter.

40.9 Assessing Relationships and Beliefs

40.9.1 Relationships and Beliefs: The Big Picture

Of critical importance for the practitioner to assess is the client's current state of relationships, whether at home, with extended family and friends, pets, work, and community, and including their support systems and beliefs. These factors are the "back story" which underlie and can either completely undermine or be the lynchpin for positive change. Those wishing to make significant lifestyle changes that deviate from the norm of their friends and family may encounter major obstacles in obtaining support or be directly undermined. At the same time, many feel isolated from a community or are far from family or perhaps they are purposely disengaged from a dysfunctional family system and need a source of community to support their goals. Unlike small communities and extended generations, where skills were passed from one generation to another, today's highly mobile

and distant lifestyle can make many feel isolated and alone. Pets and animals can be an important source of comfort, relaxation, affection, and attachment for many. They may often be an incredibly important primary relationship in a person's life, whose well-being is tied to their own (► Chap. 6).

Beliefs encompass not only belief in themselves and their ability to make the required lifestyle changes but also the person's belief in whether they feel connected to something larger than themselves – a religious or spiritual source of sustenance, no matter the particulars. Developing knowledge of the client's stage of readiness to change, from pre-contemplative to ready to take action, can focus the efforts of clinician and client alike. By having an understanding of these forms of connectivity, along with the obstacles and opportunities presented, the clinician can help inform and guide the utilization of positive forces and known benefits of social networks in supporting the health goals of their patients.

40.9.2 Relationships, Social Networks, and Health Outcomes

Many studies have shown that a person's habits and state of health are closely tied to their relationships with family and community of friends. Family ties and social networks can markedly impact longevity and quality of life [39]. The famous Roseto study of an Italian-American community, published in the early 1960s, showed rates of death from heart disease were unexpectedly lower than surrounding neighborhoods, even though the theoretical cardiovascular risks from smoking and poor diets were the same. The factors that seemed to play the important role in longevity were close intergenerational family ties with a strong social network of like-minded values [40]. A recent study concluded that family aids most in longevity, as marriage bonds were found to be more important than friends in terms of survival [41]. However, what about overall health, weight, obesity, and nutritional and lifestyle choices? How do family and friends impact these factors?

A pivotal longitudinal study by Christakis, published in 2007, looked at the spread of obesity between friends and family and revealed that it is the network of friends, particularly the ones with the closest and strongest ties, which had the most powerful influence on gaining weight or not. Christakis concludes, "The spread of obesity in social networks appears to be a factor in the obesity epidemic. Yet the relevance of social influence also suggests that it may be possible to harness this same force to slow the spread of obesity. Network phenomena might be exploited to spread positive health behaviors, in part because people's perceptions of their own risk of illness may depend on the people around them… People are connected, and so their health is connected" [42].

It is the social support, advocacy, accountability, and supportive influences found in *groups*, not necessarily the directives of what a person is actually being told to do, that create the anticipated behavioral change. These factors have been utilized for a number of years in the layperson setting of peer support groups, ranging from divorce and grief support groups to Weight Watchers, smoking cessation, Alcoholics Anonymous, and other similar 12-step programs, and have shown the power of a collective consciousness in creating positive outcomes.

The IFMNT practitioner can harness this phenomenon to great advantage with the opportunity to do learning and group visits, also known as shared medical appointments (SMAs), which have been shown to enhance individual patient experience, improve population health, and reduce the cost of healthcare, three cofactors upon which some models of reimbursement are now based [43–46]. Coined the "Triple Aim" of improved "care, health, and cost," stakeholders have recently acknowledged the necessity of upgrading to the "Quadruple Aim," adding the fourth component of "provider satisfaction," as rates of physician, nursing, and clinical staff burnout are significantly high. Healthcare clinicians and staff, appropriately trained in the necessary group facilitation skills based on a team model of shared responsibilities, can significantly benefit from this group model, with overall improved personal and professional satisfaction [47, 48].

The SMA/group care model has been successfully implemented in many primary care settings and includes improved outcomes in diabetic and cardiovascular care, prenatal care, cancer, autoimmune, asthma, diabetes, ulcerative colitis, multiple sclerosis, HIV, pain management, menopause, insomnia, and stress [49–51]. An excellent review, published by Massachusetts General Hospital in 2012 for the hospital and outpatient clinic setting, outlines a practical framework for implementing the three basic goals of SMAs:

1. Access to medical care visits
2. Education for patients on their medical condition or disease
3. Enhancement of self-management skills for lifestyle and behavioral change, to promote self-management at home and consistency in follow-through on medical recommendations [51] (see ◘ Fig. 40.5)

An additional excellent resource for implementing group visits, focused specifically on the practitioner of functional medicine, has been developed by family practice physician Shilpa Saxena, MD, IFMCP and can be found through her website.

Ideally, impacting population health for the better begins with impacting prenatal and postnatal health. An excellent example of how relationships developed in early prenatal care, utilizing a group visit model, can be used to great advantage to achieve the Quadruple Aim, is reviewed in Strickland's 2016 article, "Centering Pregnancy: Meeting the Quadruple Aim in Prenatal Care" [52]. Originally developed in the early 1990s by certified nurse-midwife Sharon Rising and championed by the Centering Pregnancy Health Institute [CHI] to great advantage, "Centering Pregnancy is a group prenatal care model that engages pregnant women in their care, [resulting] in promising health and system outcomes…this innovative care model deliver[s] the Quadruple Aim of improved patient experience, quality of care, cost containment, and provider satisfaction" [53]. Strickland's article outlines how women involved in supporting one another through pregnancy and postnatal care had significantly

Types of Groups			
Main Focus of the Group	**ACCESS** To improve access to medical care and address direct medical needs	**EDUCATION** To improve health education and teaching skills for self management	**BEHAVIORAL CHANGE** To promote and enhance strategies for lifestyle and behavioral change
Examples of Groups by Focus	• Shared medical appointments • Group medical clinics, veterans administration hospital	• Diabetes self-management education groups by CDE diabetes nurse educators • Health coaching	• Medical group visits • Group psychotherapy • Patient peer-to-peer support groups

Fig. 40.5 Types of group visits or shared medical appointments. (Reprinted from with permission from Putting Group Visits into Practice- A Practical Guide to Implementation and Maintenance of Group Visits at Massachusetts General Hospital, Jan 2012. Retrieved from: ► http://www.massgeneral.org/stoecklecenter/assets/pdf/group_visit_guide.pdf)

reduced episodes of preterm birth, increased healthy birth weights, and markedly improved rates of breastfeeding, all known factors in long-term cost and health outcomes for later life. In addition, markedly improved clinician personal and professional satisfaction was a measured outcome in several studies referenced, bringing back a sense of hope, meaning, and rededication to their vocations [54].

40.9.3 Beliefs

Beliefs encompass everything from a person's thoughts about themselves and their capabilities, to their place in the world, to their connection to a spiritual source greater than themselves. Belief systems can be powerfully engaged to help the client make needed changes toward their health goals. Determining if a client has a sense of an internal locus of control in which they believe in themselves, versus an external locus, feeling chronically buffeted by outside forces over which they feel helpless, can direct the clinician in the language and resources necessary to engage and inspire that client. Ask what are they passionate about? What moves them? Is there an area they feel strongly about? How do they feel about their ability to implement and sustain necessary changes? What can help or hinder them?

40.9.4 Spirituality and Religion

Spirituality is the point of connection for the entire Patient's Story. Asking in a nonjudgmental, non-directed way whether or not a client has a regular spiritual or meditative practice can open a dialogue to engage God, truth, or a higher power as a personal resource for positive behavioral change. As discussed by Saguil et al., "The medical literature has become replete with articles purporting positive links between spirituality and such diverse conditions as cardiovascular disease, COPD, cancer, cirrhosis, rheumatoid arthritis, leukemia, AIDS, depression, adolescent risk behaviors, anxiety, and pain. In addition, multiple studies have reported that increasing levels of spirituality correlate with decreasing levels of medical utilization, healthcare costs, and death" [54].

In 2012, Dr. Harold Koenig of Duke University's Department of Spirituality and Medicine published an exhaustive review of more than 1200 papers on prayer, health outcomes, and longevity [54]. Other studies have shown even that most physicians believe in medical miracles [55]. The data is clear that a regular spiritual or meditation practice is associated with improved well-being and outcomes and that all practitioners should ask their patients about spiritual needs. Indeed, the Joint Commission on Accreditation and the Association of American Medical Colleges have directed all health institutions and medical schools to implement a short spiritual assessment as part of the medical history, to help caregivers deliver compassionate and appropriate care [56].

Although religious beliefs and practices play a large role in many people's lives, those who find themselves a-religious may feel a strong sense of spiritual connection through animals or nature or feel drawn to the embodied spirituality of yoga or tai chi practices or martial arts.

Engaging larger values in serving a greater cause can help motivate new behaviors. For various reasons, a client may have a hard time believing they can make changes for themselves, yet they would be willing to take steps to be of benefit others such as animals or planet or family or their children or grandchildren. For example, many people are aware of large issues such as terrorism or wars but feel powerless or hopeless to do anything about it. Helping them see how day-to-day choices, e.g., by becoming mindful of their spending habits and which foods they choose, are personal ways of impacting forces much greater than themselves. Some can be motivated to engage in frequenting a local community garden or farmer's market as a way to get exercise and healthy food, to spend quality time with family and community, and to know they are contributing to supporting local and organic economies.

Engaging their "inner child" can be a tool to use to help motivate. "If your adult-self were watching your child-self stay up late, not eat, punish yourself with negative words and thoughts, how would you re-parent yourself?" Supporting a client in awakening compassion, not blame toward their pre-

vious choices, helps to overcome shame and guilt and creates a hopeful path forward.

The Rev. Rick Warren, along with functional medicine leader Mark Hyman, MD, showed exactly the benefit of engaging small groups and beliefs utilizing "Food + Fitness + Faith + Focus + Friends" in their combined effort called "The Daniel Plan." Small prayer groups already found at the church were engaged in lifestyle changes grounded in biblical principles to help the entire congregation get on board. Regarding positive outcomes, as Dr. Hyman likes to joke, "A New England Jew meets a born-again Christian and an entire church loses 10 tons along the way!" Jewish Community Centers have utilized this concept to help create centers of service and community that include everything from childcare resources to mental health and counseling to exercise and religious study, as has the YMCA. Whether in Hare Krishna, Buddhist temples, or Muslim mosques, faith, fitness, and fellowship can go together. Some churches are educating their communities about the detrimental environmental and health consequences of genetically modified foods by using the adage that GMO stands for "God Move Over"!

As outlined in detail above, no matter what faith, or none, mindfulness meditation is a powerful tool that has shown extraordinary ability to create new neural pathways and can be combined with any daily activity, faith or healing practice. For example, the Christian concept of centering prayer uses mindfulness techniques and a repeated sacred word as points of focus. Fishing or knitting both use active forms of mindfulness. Respectfully exploring the importance of a patient's spiritual beliefs gives permission to actively engage this most powerful resource of healing.

40.9.5 Questions to Ask About Relationships and Beliefs

The practitioner should approach relationship and beliefs assessments in a nonjudgmental, non-threatening manner (without injecting their own beliefs unless asked) and using open-ended questions such as:

- How are things going at home with your spouse/partner?
- With your co-workers and boss?
- With your children/parents?
- With extended family?
- Do you have pets to whom you are connected?
- Do you feel safe and supported at home?
- Do you have close friends who know what is going on with you?
- Do you feel you have someone to talk to in times of need and to share triumphs?
- How supportive are your close friends and family of your health goals?
- Do you feel like your life has purpose and meaning?
- Do you have a regular spiritual or faith practice that is meaningful to you?
- What kind of extended support system do you have?
- Do you see a counselor or therapist?
- Any support groups to which you belong?
- Do you have a sense of belonging?
- Is there any activity you are engaged in that makes you feel part of a community?
- Do you have silence in your life?
- What wishes do you have for yourself, what do you value most about yourself and your work?
- What makes you feel most alive?
- Do you believe there is a higher purpose in the health challenges you have suffered?

The IFM Adult Intake Questionnaire [male/female] includes a section in which similar questions are easily covered, including stress assessments and relationships together and can be an initial resource to investigate areas of concern.

Finding a higher purpose and meaning in their health journey may be one of the key factors that can help inspire hope and enable clients to become willing to move through the necessary steps of readiness to change. Particularly for those who have been very sick and isolated for a long time, finding meaning in their suffering can be a source of hope for healing. Viktor Frankl, the famed psychotherapist, Nazi concentration camp survivor, and author of the classic, "*Man's Search for Meaning*," began a powerful psychotherapeutic approach, logotherapy, which arose out of his horrific experience [57]. He realized that those prisoners who were able to find a higher purpose or meaning in their suffering were much more likely to survive the bleak and dangerous hopelessness of the concentration camp than those who felt there was nothing to live for. For himself, it was imperative to do everything he could to survive, so he could be a witness to the horrors he experienced.

Can you help your client to be able to share his or her own process of healing? To take the tools and information they will be learning and turn around their experience to reach out and to help others out of their suffering? For all people, young or old, with devastating anxiety and/or depression, cancer or CFS, gastrointestinal and autoimmune issues, or neurologic disorders, all conditions being suffered by hundreds of thousands of their peers – what if they can become a voice for greater change as their challenges are turned around to be a beacon of light for so many others on similar paths? No matter who, telling their story through the lens of the hero's/heroine's journey can be a powerful tool for inspiration, enabling long-lasting health and well-being.

40.10 Assessing Readiness to Change

40.10.1 The Nature of Change

» Change is not just about integrating new ideas.... It's about transforming old ones! –Monique Class, MSN, IFMCP [58]

Change and transformation are the underlying mechanisms for improving lifestyle. So, what is change and how is it different from transformation? What can we do to foster change in patients (and ourselves)? Why is change difficult? What are

stages that we should recognize? Where do patients get stuck? Where do practitioners get stuck? Why is it important to talk about spirituality with our patients to foster change, transformation, and healing? These are all important questions for practitioners to grasp when engaging their clients to make changes for optimal health outcomes.

We want to be able to encourage "change," which is a goal-oriented, past or future action and is measurable. At the same time, we would like to inspire "transformation," which can be defined as a significant alteration in behaviors due to insight from the subconscious mind and which is more likely to help sustain change for the long run.

Understanding the stages of change and where the patient is on their journey can be helpful to direct the appropriate education, inspiration, and interventions, to help a person meet their health goals. Prochaska, in his seminal work "*Changing for Good*," outlines the stages that occur not necessarily in a linear fashion, but more akin to moving up and down a spiral: the five stages include [59]:

1. Pre-contemplation: I don't even know or don't want to know that I need to do something.
2. Contemplation: I need to do something in the next 6 months.
3. Preparation: I am going to do something in the next month.
4. Action: I am actively pursuing changes.
5. Maintenance: I am continuing to have new behaviors ongoing.

The IFM Adult Questionnaire has an abbreviated version addressing these stages as part of the intake, assessing how willing and ready a person is to make changes in their diet, nutrients, fitness, tracking, sleep, etc. utilizing a scale of 1–5. If a patient is still in the pre-contemplative stage, they may require further education or questioning about their beliefs, values, social support, and perceived benefits to help move them forward, versus someone who is seeking out a practitioner purposefully because they are ready to take action. Ongoing maintenance is often a more difficult area and one that is influenced by all of the factors discussed above, including relationships, beliefs, social support, and barriers such as transport and cost.

40.10.2 Smart Goal-Setting

Once opportunities for change have been identified in each area, encouraging the client to set attainable goals in each area of lifestyle factors can be very helpful. Start with one simple goal in each area and add incrementally. Having the client write down their goals, using the SMART technique of naming a specific goal, that is measurable, action-oriented, realistic and timely can markedly improve engagement. A specific goal answers the questions who when, what, where and why. For example, "I will ride my bike three times a week for 15 minutes in the neighborhood, to help with stress relief and improve my metabolism." A measurable goal answers the question of "how?" As in, "I can keep track of my mediation time with my Headspace or Calm app, and work on adding an additional minute each week, until I've reached 30 minutes per day." Or, "I can write three gratitudes in my journal for what I have done well that day" (Fig. 40.6)

SMART Goal Component	Example
Specific State the desired outcome as explicitly as possible, and target a specific area for improvement. This is the "who, what, where, when, which, and why" of your goal.	I will walk at least five days per week in the evenings to help me reduce my waist size (in inches).
Measurable Identify the ways in which you will track your progress, and be as specific as possible. This is the "how" of your goal.	I will meditate for 30 minutes a day five times a week in order to lower my stress levels and blood pressure.
Action-oriented Start with small, achievable goals that are easily outlined into specific steps that will enable you to complete the goal. Then, as you meet those smaller goals, work up to intermediate goals and goals that are more difficult to achieve.	I will make an effort to move my body for at least 15 minutes three days a week, increasing my time each week by five minutes until I reach 30 minutes per day. I will add an extra day every two to four weeks until I reach 30-60 minutes for five days a week.
Realistic Create a goal that you are both willing and able to accomplish.	I will begin my bedtime ritual one hour before bedtime, which will help me fall asleep faster each night.
Timely Set a deadline or time for achieving your goal to help keep you motivated. THE INSTITUTE FOR FUNCTIONAL MEDICINE®	Over the next month, I will start eating breakfast every day. For the first week, I will make breakfast (or prepare it ahead the night before) twice per week. In the second week, I will make breakfast three times per week. In the third week, I will make breakfast five times per week. In the fourth week, I will make breakfast every day.

Fig. 40.6 Smart goal-setting. (Used with permission from The Institute for Functional Medicine ©2015)

40.11 Conclusion

As practitioners, by doing an in-depth, compassionate, and insightful assessment of all lifestyle factors, we can help inspire transformative change in the five fundamental modifiable lifestyle areas: nutrition, exercise and movement, stress and resilience, sleep and restoration, and relationships and beliefs. Gathering oneself as a practitioner, being present and mindful, and knowing how and what questions to ask, including the use of targeted questionnaires, can efficiently and compassionately engage the client in a therapeutic relationship.

Supporting transformative change by utilizing nonjudgmental questioning techniques and encouraging statements, such as "Your body has a remarkable ability to heal itself from the cellular to the spiritual levels. Everything we consume at all levels of body, mind and spirit become us, so changing and transforming what you are consuming, at all levels, helps to change and transform the body and your health," can be very empowering. And, we can ask, how can they take their suffering, their challenges, their learning, and their opportunities for transformation and find meaning?

Acknowledging the client by retelling their story with empathetic statements like, "Wow Mr. Jones, I can see you have really suffered and are feeling very frustrated and angered by how your complaints have been previously marginalized or trivialized, you have amazing fortitude to get you here! Let us see how we can help you find and build increasing sources of resilience to help you turn around," gives hope and engenders partnership and cooperation to encourage lifelong, positive lifestyle change.

41.1 Introduction

Integrative and functional medical nutrition therapy is done within the context of therapeutic and healing partnerships. The purpose of such a relationship is to help the patient heal by identifying the influences and underlying mechanisms that initiated and continue to mediate the patient's illness. It is an equal investment of focus by both the dietitian/nutritionist and the patient to work together to identify where to apply the leverage of change – may it be nutritional or related to sleep, relationships, or stress management. Connection, rapport building, deep listening, reflection, presence, humility, vulnerability, compassion trust, and gratitude are all essential for healing to occur [1].

There are four essential components in integrative and functional medicine nutrition therapy (IFMNT), and they can be used by all healthcare professionals applying the functional medicine approach:

1. Listening to the patient story on the initial intake
2. Evaluating, prioritizing, and focusing on the patient's modifiable lifestyle factors
3. Organizing the patient's clinical imbalances by underlying causes into a systems biology matrix framework
4. Creating a therapeutic and healing partnership between the dietitian/nutritionist and patient to provide practical evidence-based interventions with timely monitoring and evaluation [2]

After gathering and working through the patient's history and laboratory findings; organizing the subjective and objective data on the functional medicine timeline and matrix; retelling the story back to the patient and acknowledging their goals, antecedents, triggers, and mediators; and identifying the clinical imbalances in the organization of physiological systems of the matrix, the dietitian/nutritionist comes to the most critical aspect of the encounter: intervention.

A completed matrix facilitates the review of common pathways, mechanisms, and mediators of disease and helps the nutrition expert select points of leverage for nutritional and lifestyle interventions. The nutrition practitioner may also find an opportunity to refer the patient to another healthcare practitioner for their medical expertise. For example, one might send a patient for vision evaluation if one complains of strained eye/poor vision or send a male patient to a physician specializing in bioidentical hormones if he has very low testosterone and cardiovascular or cognitive decline. However, even with the matrix as an aid to synthesizing and prioritizing information, it can be very useful to consider the impact of each variable at five different levels:

1. Whole body (the "macro" level)
2. Organ system
3. Metabolic or cellular
4. Subcellular/mitochondrial
5. Subcellular/gene expression [3]

It is important for the nutrition practitioner to identify therapies based on their potential impact on the most central imbalances of the particular patient. Evaluating interventions that are available at each of these five levels can help to identify a reasonably thorough set of strategies from which to choose. The following list incorporates only a few examples of various types of interventions within these five different levels.

1. *Whole-body interventions:* The human organism is a complex adaptive system with countless points of access. Therefore, interventions at one level will affect points of activity in other areas as well. For example, improving the patient's sleep will beneficially influence the immune response and melatonin levels, along with decreasing oxidative stress. Exercise reduces stress, improves insulin sensitivity, and improves detoxification. Reducing stress can reduce cortisol levels, improve sleep, improve emotional well-being, and reduce the risk of heart disease. Changing an individual's nutrition plan can have myriad effects on health, from reducing inflammation to reversing coronary artery disease or insulin resistance to even impacting cognitive decline.
2. *Organ system interventions:* These interventions are used more frequently in the acute presentation of illness and, in most cases, would require a referral to a non-nutrition professional. Examples include draining lesions; repairing lacerations; reducing fractures, pneumothoraces, hernias, or obstructions; or removing a stone to reestablish whole-organ function. There are many interventions that improve organ function. For example, continuous positive airway pressure (CPAP) machines improve inspiratory flow rate sleep quality and decrease daytime sleepiness and oxidative stress in individuals with obstructive sleep apnea syndrome (OSAS), thereby improving metabolic functions and cognition [4]. There is also evidence that effective management of OSAS not only has positive impacts on the individual but also infers positive benefits to their partners' sleep and daytime functioning [5].
3. *Metabolic or cellular interventions:* Cellular health can be addressed by ensuring the adequacy of MAPDOM status – minerals and fiber, antioxidants/phytonutrients, proteins, vitamins, fatty acids, and methylation factors in the diet or, if necessary, from supplementation. An individual's metabolic enzyme polymorphisms can profoundly affect his or her nutrient requirements. For example, adding conjugated linoleic acid (CLA) to the diet can affect body weight, alter the peroxisome proliferator-activated receptor (PPAR) system, and modulate the inflammatory response. However, in a person who is insulin resistant and/or has diabetes, adding CLA may induce hyperinsulinemia, which is detrimental. Altering the types and proportions of carbohydrates in the diet may reduce insulin secretion, increase insulin sensitivity, and essentially alter metabolism in the insulin-resistant patient.
4. *Subcellular/mitochondrial interventions:* There are several examples of mitochondrial nutrient-support interventions. Inadequate iron intake causes oxidants to leak

from the mitochondria, damaging mitochondrial function and mitochondrial DNA. Making sure there is sufficient iron helps to mitigate this concern. Ensuring sufficient antioxidants and cofactors for the at-risk individual must be considered in each part of the matrix. Carnitine, for example, is required as a carrier for the transport of fatty acids from the cytosol into the mitochondria and in improving the efficiency of beta oxidation of fatty acids and resultant ATP production. In patients who have lost significant weight, carnitine undernutrition can result in fatty acids undergoing omega oxidation, a far less efficient form of metabolism. Patients with low carnitine may also respond to riboflavin supplementation.

5. *Subcellular/gene expression interventions:* Many compounds interact at the gene level to alter cellular response, thereby affecting health and healing. Any intervention that alters NF-κB entering the nucleus, binding to DNA, and activating genes that encode inflammatory modulators such as IL-6 (and thus CRP), cyclooxygenase 2, IL-1, lipoxygenase, inducible nitric oxide synthase, TNF-alpha, or a number of adhesion molecules will impact many disease conditions. There are several ways to alter the environmental triggers or NF-κB, including altering emotional stress, exercising, lowering oxidative stress, and consuming adequate phytonutrients, antioxidants, alpha-lipoic acid, EPA, DHA, and GLA. Vitamin D has key roles in controlling gene expression, inflammation, bone metabolism, calcium homeostasis, endocrine and cardiovascular physiology, and healing [3].

   Once the nutritional professional has ample experience using this model along with improved pattern-recognition skills, it will often lessen the need for extensive laboratory assessments. However, there will always be certain clinically perplexing cases that simply cannot be assessed without objective data, and, for most patients, there may be an irreducible minimum of laboratory assessments required to accumulate information. For example, in the clinical workup of patients with Alzheimer's disease, heavy metal toxicity, infection, or mold exposure may play an important role [6, 7]. Heavy metal body burden or mold toxicity cannot be sensibly assessed without laboratory studies. In such cases, it becomes critical for the nutrition practitioner to develop a network of capable, collaborative healthcare practitioners with whom to co-manage challenging patients and to whom referrals can be made for therapies outside the nutritional professional's own expertise. This will enrich patient care and strengthen the nutritionist/dietitian-patient relationship.

No two patients are treated identically in functional medicine, but some advice is applicable to nearly every patient. The following lifestyle recommendations also meet the criterion of helping to normalize and have a large impact on multiple systems, working as whole-body interventions and thus providing a foundation of health.

41.2 Initial Interventions

41.2.1 Food

Food is not only nutrition; it also plays a significant role in cultural and personal identity, along with shaping and expressing social relations. The nutrition professional should consider these factors while personalizing a nutrition plan for the patient. It is also crucial to consider family history, history of diseases and chronic conditions, physical activity, allergies and food intolerances, access to food, epigenetic markers, and food preferences.

This is an era when diets can be a lot like religion, and there are proponents of each food culture – from paleo to vegan or vegetarian. It is crucial that the nutrition practitioner has insights into the latest "diet trends," along with critically differentiating between an effective therapeutic food plan tailored for the patient utilizing evidence-based research and whatever diets are popular at the moment. In current times, the dietitian/nutritionist has a plethora of therapeutic diets to work with based on the patient's needs. Examples of therapeutic diets are Specific Carbohydrate Diet (SCD); fasting; the ketogenic plan; intermittent fasting; time-restricted feeding, low-glycemic plan; elimination food plans; low-histamine diet; the Dietary Approaches to Stop Hypertension (DASH) diet; gluten-free or casein-free diets; the Gut and Psychology Syndrome (GAPS) diet; fermentable oligosaccharide, disaccharide, monosaccharide, and polyol (FODMAPs) diet; a Mediterranean food plan; and the Zone diet. The nutritionist/dietitian also needs to be aware of the different effects of nutrients according to our genetic constitution (nutrigenetics) and how nutrients may affect gene expression (nutrigenomics). Dietary advice that is specific to individuals with a particular genotype is more effective at preventing chronic diseases than general recommendations about diet. The next chapter will go into the details about each of these therapeutic diets.

Personalized and precision medicine and nutrition can be considered as occurring at three levels: (1) conventional nutrition based on general guidelines for population groups by age, gender, and social determinants; (2) individualized nutrition that adds phenotypic information about the person's current nutritional status (e.g., anthropometry, biochemical and metabolic analysis, physical activity); and (3) genotype-directed nutrition based on rare or common gene variation. Research and appropriate translation into medical practice and dietary recommendations must be based on a solid foundation of scientific knowledge and practical solutions that the patient is able to follow and comply [8].

1. *Removal of processed foods: high-glycemic-index foods, high-fructose corn syrup, and trans or partially hydrogenated fats*

   The Western-style diet, also known as the meat-sweet diet or standard American diet, is characterized by an overavailability and overconsumption of food, along with high intakes of high-sugar desserts, sweetened drinks,

high-fat foods, refined grains, red meat, and high-fat dairy products. The heat processing of these foods involves high levels of dietary advanced glycation end products (dAGEs). The National Health and Nutrition Examination Survey (NHANES) showed that 68.3% of those studied were considered overweight (BMI ≥25) and 33.9% were obese (BMI ≥30) [9]. Chronically increased intake of these foods correlates with higher concentration of fasting insulin, C-peptide, leptin, tissue-type plasminogen activator antigen (tPA), C-reactive protein (CRP), E-selectin (sSELE), intercellular adhesion molecule 1 (sICAM-1), vascular cell adhesion molecule 1 (sVCAM-1), and interleukin 6 (IL-6). This affects multiple metabolic functions, causing oxidative stress, a higher osteoporosis risk, and chronic kidney disease [10–12]. In general, processed foods impact each and every clinical imbalance in the matrix, causing changes in digestion and absorption, impairing insulin regulation, leading to immune system activation and vasculature to causing hormone biotransformation.

2. *Consumption of whole-food meals at regular intervals*
Epidemiological studies have shown that regular consumption of whole foods is associated with health promotion and reduced risks of developing several chronic diseases, as well as all-cause mortality. The underlying physiological mechanisms behind the protective effects of whole foods can most likely be ascribed to a concerted action of a wide variety of phytochemicals, phenolic compounds, carotenoids, vitamin E, sterols, and dietary fiber [13]. Plants are the only source of these nutrients, whereas animals are essentially devoid of them [14].

What Can You Do to Reduce High-AGE Foods in Your Diet?

- Eat more raw or steamed fruits and vegetables and eat meat less often for damage control. Fruits and vegetables are high in antioxidants and have anti-aging properties.
- Limit the amount of grilled, fried, or broiled foods in your diet.
- Lower the flame to low on a gas grill.
- Use "wet" cooking methods, such as stewing, boiling, braising, slow-cooking, or steaming, often because dry-heat cooking methods create more AGEs than moist ones. For example, a chicken breast broiled for 15 minutes contains more than five times as many AGEs as the same food boiled for 1 hour.
- Trim visible fat from meat before cooking at high temperatures. Cook with less fat.
- When you do grill, use acidic marinades including lemon juice and vinegar, which are thought to help to fight AGEs.
- Don't eat the browned or charred portions of cooked meats and cheeses.
- After cooking, cut off any portions of food that were charred.
- Emphasize whole grains such as oatmeal, brown rice, beans, quinoa, and whole grain or bean/lentil pasta over meat when making meal choices.
- Limit your intake of processed foods, which are often pasteurized at high temperatures.

Phytochemicals are a large group of chemical compounds naturally occurring in plants, fruits, vegetables, legumes, whole grains, nuts, seeds, fungi, herbs, and spices, conferring aroma, flavor, texture, and color. These compounds have been developed over thousands of years of evolution to defend organisms from the effects of free radicals, fungi, bacteria, and viruses. One would wonder as to why these phytochemicals have beneficial effects on humans if they are produced to protect plants. Humans have been ingesting plants as part of their diet throughout their evolutionary history, and our neurons have conserved many of the same signaling pathways that first evolved in insects and other herbivores that preceded humans in evolution. Examples include pathways that signal via SIRT1, AMPK, and Nrf2. Activation of one or more of these signaling pathways that evolved to defend cells against potentially toxic phytochemicals appears to be a major reason why ingestion of phytochemicals can protect us against injury and disease [15].

Phytochemicals can be classified into several major groups based on their chemical structure: alkaloids, sulfur-containing phytochemicals, terpenoids, and polyphenols [16]. Apart from imparting flavor, color, and texture, these phytochemicals perform a slew of functions – they decrease oxidative stress and neutralize free radicals, act as anti-inflammatory and antibacterial agents, reduce carcinogenic activity via inhibiting tumor growth, detoxify carcinogens, and slow down the progression of such degenerative diseases as osteoporosis, macular degeneration, and cataracts [14].

Phytochemicals have beneficial or stimulatory effects on animal cells, though they can be toxic when consumed in high amounts. The beneficial effects are an example of "hormesis." When cells and organisms are challenged with mild stress by some of the noxious phytochemicals present in the plants, they respond adaptively in ways that help them withstand more severe stress. Hormetic phytochemicals such as resveratrol, sulforaphane, curcumin, catechins, allicin, and hypericin are reported to activate adaptive stress response signaling pathways that increase cellular resistance to injury and disease [15].

Alkaloids from *Piper nigrum* (black pepper) exhibit anti-inflammatory activity via activating the Nrf pathway. The activation of Nrf2 has been shown to be a key step in the cellular response against several common diseases, including inflammation, aging, diabetes, cardiovascular disease, acute pulmonary injury, neurodegenerative diseases, and cancer [17]. Glycoalkaloids produced by eggplants (α-solamargine and α-solasonine), potatoes (α-chaconine and α-solanine), and tomatoes (α-tomatine) or their hydrolysis products (mono-, di-, and trisaccharide derivatives and the aglycones

solasodine, solanidine, and tomatidine) have been shown to inhibit the growth of cancer cells in culture (in vitro), as well as tumor growth in vivo. In experimental studies, α-tomatine also contributed to protective immunity elicited by a malaria vaccine candidate [18].

Organosulfur compounds such as allicin, ajoene, and isothiocyanates have shown antibacterial activity against both gram-negative and gram-positive bacteria. Allicin is an organosulfur compound obtained from garlic when it is crushed, which causes the enzyme alliinase to convert alliin into allicin. This transformation occurs only in crushed plants; in intact plants, alliin and alliinase are kept in different cell compartments, coming into contact only when the cloves are broken. Allicin has also shown antibacterial activity against *P. aeruginosa*, *S. epidermidis*, *Burkholderia cepacia*, *S. agalactiae*, MRSA, and oral pathogens causing periodontitis and caries [16].

Terpenoids are a group of substances that occur in nearly every natural food. Their main subclasses discussed as beneficial to maintain and improve health are monoterpenes (like limonene, carvone, or carveol), diterpenes (including the retinoids), tetraterpenes (which include all different carotenoids like α- and β-carotene, lutein, lycopene, zeaxanthin, and cryptoxanthin), and terpenoid chromanols [19].

Tocotrienols and tocopherols (vitamin E) are terpenoid chromanols and tocotrienols that possess the ability to stimulate the killing of cancer cells selectively through apoptosis in order to reduce cancer cell proliferation, while leaving normal cells unaffected. One of the mechanisms by which tocotrienols are thought to suppress cancer is related to the isoprenoid side chain. Isoprenoids, along with selenium, have been shown to suppress the initiation, growth, and progression of prostate and other cancers. They are commonly found in almonds, peanuts, and walnuts, which may explain why diets rich in these foods such as the Mediterranean diet have consistently been shown to reduce the incidence of cancer. Much of the broad involvement of vitamin E in human metabolism is due to its role as the body's primary lipid-soluble antioxidant. Tocopherols and tocotrienols are part of the body's highly effective defense system, without which life could not exist. This defense system consists of a network of antioxidants, interacting with and supporting each other. Antioxidants such as vitamin C, coenzyme Q10, and glutathione are needed for effective recycling of tocopherols and tocotrienols. The unique power of both tocopherols and tocotrienols is their ability to break the chain reaction of lipid peroxidation by neutralizing peroxyl radicals to prevent the spread of free radical damage in cell membranes. Vitamin E is a generic term for at least eight structurally related molecules: α-tocopherol (αT), β-tocopherol, γ-tocotrienol (γTE), and δ-tocotrienol. Among them, αT is the predominant form of vitamin E in plasma and tissues and is the form that has drawn most attention in the past. Combinations of different forms of vitamin E may be superior to each alone [20].

Polyphenols are one of the largest secondary plant metabolites ubiquitously present in fruits and vegetables considered an integral part of the human diet. Polyphenols are classified as flavonoids and non-flavonoids, based on their chemical structure. Flavonoid-type polyphenols are divided into different subclasses: anthocyanins, anthocyanidins, flavones, flavanols, catechins, isoflavones, flavanones, and flavonols. Non-flavonoids are comprised of stilbenes, phenolic acids, lignans, and hydroxycinnamic acids [21].

Polyphenols have been studied for their potential involvement in many areas, including cardiovascular, diabetes, cancer, neurodegenerative conditions, inflammation, and microbial diseases. Their protective activity was firstly attributed to their free radical scavenger, antioxidant, and metal chelator properties and later on to their ability to inhibit or reduce different enzymes. The best studied stilbene is resveratrol, found in grapes and grape products, for its role in activation of sirtuin enzymes that increase longevity, reduction of TNF-α and TGF-β, and induction of neurotrophic factors such as brain-derived neurotrophic factor (BDNF) [22, 23]. The richest sources of lignans are flaxseed and sesame seeds, while minor sources are cereals, lentils, fruits (pears, prunes), and vegetables (garlic, asparagus, carrots) [22]. Sesamin, a lipid-soluble lignin, has shown to potentiate TNF-α-induced apoptosis, inhibit proliferation of a wide variety of tumor cells, and downregulate NF-κB activation induced by various inflammatory stimuli and carcinogens [24].

Fibers found in whole plant foods powerfully support the gastrointestinal, cardiovascular, and immune systems through multiple mechanisms and will be discussed further in this chapter. Yet more than 90% of adults and children in the United States do not get the minimum recommended amount of dietary fiber [14].

41.2.2 Whole Food Versus Specific Dietary Nutrient

Consumption of whole foods is strongly associated with reduced risk of chronic diseases. It is therefore reasonable for scientists to identify the bioactive compounds responsible and hope to find the "magic pill" to prevent chronic diseases. The critical question then is whether a purified phytochemical has the same health benefit as the phytochemical present in whole food or a combination of foods [25]. Summaries, which mostly represent meta-analyses, show no long-term benefit for vitamin supplements (Collin C) if no dietary and interventional changes are made. Dietary supplements do not have the same health benefits as a diet rich in whole grains, legumes, nuts, seeds, fruits and vegetables, because, taken alone, the individual antioxidants studied in clinical trials do not appear to have consistent preventive effects. Constituents delivered by foods taken directly from their biological environment have different effects from those formulated through technologic processing. The isolated pure compound either loses its bioactivity or may not behave the same way as the compound in whole foods [25, 26].

For example, numerous studies have shown that the risk of cancer is inversely related to the consumption of green and

yellow vegetables and fruits. As beta-carotene is present in abundance in these vegetables and fruits, it has been extensively investigated as a possible cancer-preventive agent. However, the role of carotenoids as anticancer supplements has recently been questioned as a result of several clinical studies. In one study, the incidence of non-melanoma skin cancer was unchanged in patients receiving a beta-carotene supplement. In other studies, smokers gained no benefit from supplemental beta-carotene with respect to lung cancer [25].

Vitamin C supplementation also has been shown to lower the incidence of cancer and heart disease. A Cornell University study reported that phytochemical extracts from fruit have strong antioxidant and antiproliferative effects and proposed that the combination of phytochemicals in fruits and vegetables is critical to powerful antioxidant and anticancer activity. For example, the total antioxidant activity of phytochemicals in 1 g of apples with skin is equivalent to 83.3 mol vitamin C equivalents – that is, the antioxidant value of 100 g of apples is equivalent to 1500 mg of vitamin C. This is much higher than the total antioxidant activity of 0.057 mg of vitamin C (the amount of vitamin C in 1 g of apples with skin). In other words, vitamin C in apples contributed only <0.4% of total antioxidant activity. Thus, most of the antioxidant activity came from phytochemicals, not from the vitamin C. The natural combination of phytochemicals in fruit and vegetables is responsible for their potent antioxidant activity [27].

In another study, researchers compared the efficacy of lycopene supplementation with consumption of tomato products on intermediate cardiovascular risk factors, including oxidative stress, inflammation, endothelial function, blood pressure, and lipid metabolism. Tomato intake provided more favorable results on cardiovascular risk endpoints than did lycopene supplementation [28].

In short, the effect of the whole food is more powerful than the effect of a specific dietary nutrient. However, public confusion proliferates on this issue, incurring huge monetary and social costs [29]. It is important that the nutrition practitioner emphatically relays this message to their patients. Practitioners have often seen new patients coming to their first visit with a bagful of supplements. With all the information available on the Internet and individuals and companies claiming benefits of these supplements, a desperate patient might buy these supplements without correct guidance. Helping patients to understand the importance of whole foods then becomes one of the important objectives of nutrition education during that visit or subsequent visits, whichever seems apt for the practitioner.

41.2.3 Meal Timings and Intervals

We are increasingly moving away from regular meals as more meals are being eaten outside the home and family meals have been eroded by hectic schedules. The prevalence of irregular meal patterns is greater among adolescents than it was during previous decades. Irregular snacking has become more common in children and may have contributed to both the increasing prevalence of obesity in children as well as dyslipidemia in adolescents during the past few decades.

In a study conducted at Queen's Medical Centre in the United Kingdom, irregular meal frequency disturbed energy metabolism in healthy lean women, leading to a lower postprandial energy expenditure, higher degree of insulin resistance, or lower postprandial insulin sensitivity and higher fasting lipid profiles, thereby indicating a deleterious effect on these cardiovascular disease risk factors [30]. A more evenly spaced pattern of three meals per day with no snacks was more strongly associated with a lower prevalence of overweight and obesity and a nutritionally higher-quality diet [31]. Meanwhile, prolonged intervals between meals and skipping meals may trigger migraines and hypoglycemia in some individuals.

Physiological responses to what and how much we eat represent the foundation for translational as well as basic science aimed at preventing and treating metabolic diseases, including obesity and diabetes. However, the timing of food consumption independent of total caloric intake and macronutrient quality has emerged as a critical factor in maintaining metabolic health. Panda states that when healthy adults eat identical and isocaloric meals at breakfast, lunch, or dinner, the postprandial glucose rise is lowest after breakfast and highest after dinner, as if the dinner were twice the size of the breakfast. In addition, when healthy adults are given a constant glucose infusion over 24 hours, blood glucose rises at night and falls around dawn. This is likely because melatonin inhibits insulin release from pancreatic islets through the melatonin receptor and the evening rise in melatonin likely causes hyperglycemia. This indicates that in addition to what and how much we eat, *when we eat* helps determine the physiological response to nutrient availability [32, 33].

Almost every cell in the body has a circadian clock machinery, each with an approximately 24-hour period. Circadian rhythms are an integral part of physiology that seems to be essential for health. The circadian system is a master integrator of both the internal state of the organism and the organism's interaction with nutrition and ambient light. The suprachiasmatic nucleus (SCN) in the hypothalamus acts as a master clock to coordinate independent oscillators throughout the body and determine the period of the organism. Unlike peripheral oscillators, the SCN is composed of a network of neurons with intricate intercellular communication to produce robust outputs through both neural and humoral cues. In addition to this internal regulation, the SCN also receives external input, such as light, to help an organism coordinate with their environment. Nutrient consumption also has a large influence on biological rhythms, but it has a more direct effect on peripheral oscillators than the SCN. Together, light and nutrients coordinate internal biological rhythms with the environment.

The erratic lifestyle associated with modern society – aberrant eating and sleep patterns, inappropriate light exposure, jet lag, and shift work – contributes to circadian rhythm

disruption. This disruption compromises multiple levels of physiology, metabolism, and inflammation and increases the risk for noninfectious chronic diseases such as metabolic disorder, diabetes, cardiovascular disease, dental caries, and cancer [34]. Light at night suppresses sleep and promotes extended wakefulness, thereby allowing ingestive behavior to continue late into the night. Therefore, room lighting (or darkness) is critical during sleep. It is important to keep bedrooms as dark as possible and avoid blue light before sleep. Conversely, maintaining a consistent daily eating and fasting rhythm and sleeping in a dark room maintains normal circadian physiology and can prevent or mitigate several of these chronic diseases [35, 36].

41.2.4 Increased Intake of Vegetables with Moderate Fruit Intake

Fruits and vegetables are rich sources of a variety of nutrients, including trace minerals, vitamins, and dietary fibers, along with other classes of biologically active compounds. These phytochemicals can have complementary and overlapping mechanisms of action, including modulation of cholesterol synthesis, reduction of platelet aggregation, detoxification enzymes, stimulation of the immune system and hormone metabolism, reduction of blood pressure, promote brain health and antibacterial, antioxidant, and antiviral effects [37].

41.2.4.1 Antioxidant Activity

The antioxidant defense system has both enzymatic and nonenzymatic components that prevent radical formation, eliminate damaged molecules, repair oxidative damage, remove radicals before damage can occur, and prevent mutations. Phytochemicals from fruit and vegetables can induce the expression of endogenous antioxidant enzymes along with metalloenzymes. For example, mitochondrial superoxide dismutase is a manganese-containing enzyme, and adequate consumption of vegetables and fruit can provide the necessary manganese [15]. Nonenzymatic components of the antioxidant defense system interrupt the free radical-initiated chain reaction of oxidation or scavenge and disable free radicals before they react with cellular components. Typically, the antioxidants vitamins C and E and beta-carotene have received the most attention. Two-week administration of carrot and tomato juices (330 mL/d) and spinach powder (10 g/d), added separately to a low-carotenoid diet, decreased endogenous lymphocyte DNA strand breaks and reduced DNA-based oxidation in 23 healthy men [38].

41.2.4.2 Modulation of Detoxification Enzymes

Detoxification, or drug-metabolizing, enzymes are essential for the biotransformation of many important endogenous compounds and xenobiotics. Phase I enzymes, such as cytochrome P450 (CYP)-dependent monooxygenase, catalyze oxidation, reduction, and hydroxylation reactions and convert hydrophobic compounds to reactive intermediate metabolites in preparation for their reaction with water-soluble moieties to improve excretion. Phase II enzymes – such as glucuronosyltransferases, sulfotransferases, and glutathione transferases – catalyze these conjugation reactions.

Numerous constituents of plant foods, including isothiocyanates, flavonoids, and allyl sulfides, are potent modulators of the CYP monooxygenases. However, the effects of some of these phytochemicals on CYPs are complex. They have the capacity to inhibit certain enzymes at high concentrations of the compound or to activate moderately the same enzyme at lower concentrations, while others may be competitive inhibitors of CYPs. Even when present at low concentrations and in combination with other compounds, their actions can be significant.

The capacity to conjugate metabolically activated intermediates and excrete them from the body is critical in protecting against many potential mutagens, and efforts have focused on determining how vegetable and fruit constituents can influence the phase II conjugating enzymes. In a series of small studies where individuals were supplemented with 300 g of brussels sprouts, the results showed the capacity of this cruciferous vegetable to affect specific glutathione transferase isoenzymes and increase plasma concentrations of glutathione transferase. Induction of these enzyme systems is rapid, and enzymatic activity rises and plateaus within 5 days of continued daily ingestion of a food with inducing capacity. Similarly, the enzyme activities drop rapidly when the food is removed from the diet.

Xenobiotics share many of the same metabolic pathways with drugs, relying on the same enzyme systems for their biotransformation. For example, compounds in cruciferous vegetables can alter drug metabolism by both inhibiting and inducing certain CYPs and possibly by inducing select conjugating enzymes. Lampe mentions a study in which feeding individuals a diet of cruciferous vegetables enhanced their ability to metabolize phenacetin and antipyrine (a pain-relieving drug) oxidatively. Consuming a diet containing brussels sprouts and cabbage for 1 week could also influence select conjugating enzyme systems, stimulating the conjugation of acetaminophen with glucuronide but not with sulfate.

41.2.4.3 Stimulation of the Immune System

Nutrients and other constituents of fruit and vegetables have the potential to affect almost all aspects of the immune system. Several of the vitamins associated with diets high in fruit and vegetables have been shown to improve immune status. Del Corno and his colleagues demonstrated the immune-protective role of polyphenol metabolites to human dendritic cells in markedly impairing the production of proinflammatory cytokines and chemokines in response to bacterial application and its role in the prevention of acute and chronic inflammatory diseases [39, 40].

41.2.4.4 Decreased Platelet Aggregation

Blood platelet aggregation is fundamental to a wide range of physiologic processes – e.g., normal blood coagulation, thrombosis, atherosclerosis, and tumor formation and metastasis. Activated platelets adhere to altered blood vessel walls, where they aggregate and promote the release of mitogenic factors that stimulate endothelial cell proliferation. A subsequent cascade of events leads ultimately to occluded vessels.

Lampe's article mentions two studies showing reductions in platelet aggregation of 16.4% and 58% with 9 g and 10 g of fresh garlic cloves, respectively. The antiplatelet effects are attributed to the allyl propyl disulfide, diallyl disulfide, and other sulfur compounds contained in the essential oil.

Mitogenic factors released by platelets, such as platelet-derived growth factor (PDGF), are thought to be important in the initiation and progression of atherosclerotic lesions and to respond to alterations in diet. High consumption of carotenoid-rich vegetables (carrots and spinach) and soy foods (tofu and textured soy protein) increased concentrations of serum PDGF in study participants, thereby demonstrating the anti-atherogenic role of carotenoids [38, 41].

41.2.4.5 Alterations of Cholesterol Metabolism

Isolated dietary fibers from vegetable and fruit sources, particularly pectins, have hypocholesterolemic action. The addition of pectin and fiber-containing foods in experimental diets lowered plasma cholesterol to varying degrees – a variety of vegetables (570 g/d) and fresh apples (600 g/d) by 4%, fresh carrots (200 g/d) by 11%, apples (350–400 g/d) by 8–11%, and prunes (100 g/d) by 5%. The reductions in cholesterol are probably due to different mechanisms specific to the type of fiber source and to different dietary fiber intake amounts. On the basis of the physiologic effects observed in humans, possible mechanisms include (1) increased excretion of fecal bile acids and neutral steroids; (2) altered ratios of primary to secondary bile acids; (3) increased fecal cholesterol and fatty acid excretion; (4) and indirect effects, such as high-fiber foods replacing fat- and cholesterol-containing foods in the diet [38].

41.2.4.6 Modulation of Steroid Hormone Concentrations and Hormone Metabolism

A vegetarian diet is associated with lower circulating concentrations of sex steroid hormones, increased fecal excretion of estrogens, and different hormonal profiles than those observed with consumption of an omnivorous diet. In the past, much of the response to such a diet has been attributed to the physiologic effects of dietary fiber. However, other constituents of vegetables and fruit also may influence metabolism of endogenous steroid hormones.

Effects of indole-3-carbinol (I3C), a constituent of cruciferous vegetables, on estrogen metabolism have been observed in men and women. In men, 500 mg I3C/d (equivalent to 300–500 g of cabbage) for 7 days increased estrone 2-hydroxylation from 29% to 46%. A randomized clinical trial compared the effects of 400 mg I3C, 20 g of cellulose, and placebo daily on 2-hydroxylation of estrogen in women. The mean ratio of 2-hydroxyestrone to estriol, a measure of 2-hydroxylation, increased 1.6-fold in the first month and remained at that level for the 3 months of the study, while no change from baseline was observed in the cellulose or placebo group [38].

It has been hypothesized that shifting the metabolism of 17β-estradiol toward 2OHE1, and away from 16OHE1, could decrease the risk of estrogen-sensitive cancers, such as breast cancer. Reding and her colleagues demonstrated that fruit consumption, specifically banana and citrus fruits, was positively associated with 2- OHE_1 concentrations and not associated with 16α-OHE_1, thereby suggesting that breast tissue exposure to estrogen metabolites may be influenced by diet [42].

41.2.4.7 Antibacterial and Antiviral Activity

Plants have developed sophisticated active defense systems against pathogens, one being the production of antibiotic compounds. Cranberry juice has long been advocated as a treatment for urinary tract infections in women. In a double-blind, randomized, placebo-controlled trial, Avorn et al. showed that 300 mL of cranberry juice per day for 6 months can influence bacterial flora in the urinary tract.

The protective effects of vegetables and fruit observed in epidemiologic studies are not observed with pharmacologic doses of plant foods or their constituents, but with intakes constituting part of a usual diet. Research on the effects of pharmacologic doses of individual plant food constituents may identify particular uses for selected compounds. However, it is unlikely that any one compound will be a magic bullet preventing a whole range of chronic diseases, and humans will still continue to eat food to nourish body and soul, so we must remain committed to consuming a variety of vegetables and fruit as part of a whole-food diet [38].

41.2.5 Consumption of Organically Raised and Locally Grown Foods whenever Possible, with Low-Fat Animal Products (Low-Fat Dairy and Poultry) in Moderation

Numerous studies have compared organic and conventional food production, in relation to both their nutritional value and their content of chemical residues. Reganold looked at 15 reviews or meta-analyses of the scientific literature comparing the nutrition of organic and conventional foods that were published in the preceding 15 years. Twelve of these studies found some evidence of organic food being more nutritious (for instance, having higher concentrations of vitamin C, total antioxidants and total omega-3 fatty acids, and omega-3 to omega-6 ratios). Whether or not these are nutritionally

meaningful differences continues to be debated. The rest of the three studies concluded that there were no consistent nutritional differences between organic and conventional foods.

Organic farming systems produce lower yields compared with conventional agriculture. However, they are more profitable and environmentally friendly, and they deliver equally or more nutritious foods that contain less (or no) pesticide residues, compared with conventional farming.

Studies have found that children who eat conventionally produced foods have significantly higher levels of organophosphate pesticide metabolites in their urine than children who eat organically produced foods [43]. In 2012, the American Academy of Pediatrics reported that an organic diet reduces children's exposure to pesticides and provided resources for parents seeking guidance on which foods tend to have the highest pesticide residues [44].

Organic livestock are fed with organically produced feed that is free of pesticides and animal byproducts, and therefore it is supposed that there should be lower accumulation of chemical residues. An intriguing study by Hernandez and his colleagues found pollutants in both conventional and organic meat. This group examined 76 samples of organic and conventional beef, chicken, and lamb for 33 carcinogenic pollutants that are commonly found in nonorganic meat. They found pollutants not only in the conventional samples but also in the organic samples. In fact, the difference in the level of pollutants between both was minimal. Of the samples, they found that lamb – both nonorganic and organic – had the highest level of pesticides, with the organic samples actually containing more pollutants than the nonorganic. Both kinds of chicken had the lowest levels [45]. Another study found that conventional chicken and pork had a 33% higher risk for contamination with antibiotic-resistant bacteria compared to organic alternatives [43]. In short, the organic meat was far from being devoid of persistent organic pollutants.

A large meta-analysis by Dominika and colleagues iterated that there was a difference in the composition and quality of fat between conventional and organic meat, with organic meat having more unsaturated fat, including anti-inflammatory omega-3 s [46].

These studies demonstrate that environmental contamination by POPs is ubiquitous and human exposure is difficult to avoid. Even consumers who choose to consume organic food, which is theoretically healthier with better composition of fatty acids, have exposure rates to fat-soluble pollutants that can become even higher than those of consumers who eat conventional food. There needs to be a consistent effort to minimize environmental toxic pollutants and consume animal products in moderation [45, 47].

41.2.6 Increased Intake of Fiber

The World Health Organization (WHO) and Food and Agriculture Organization (FAO) state that dietary fiber is a polysaccharide with 10 or more monomeric units which is not hydrolyzed by endogenous hormones in the small intestine. Dietary fiber and whole grains contain a unique blend of bioactive components including resistant starches, vitamins, minerals, phytochemicals, and antioxidants. Dietary fiber is indigestible in the human small intestine but digested completely or partially fermented in the large intestine. It is examined in two groups: water-soluble and water-insoluble organic compounds.

Based upon their digestibility in the gastrointestinal (GI) tract, they are divided into two basic groups: nonstructural, nonfibrous polysaccharides or simple carbohydrates (starch, simple sugars, and fructans) and structural, non-starch polysaccharides (NSP) or complex carbohydrates that are resistant to digestion in the small intestine and require bacterial fermentation located in the large intestine (cellulose, hemicellulose, lignin, pectin, and beta-glucans). NSP can be further subdivided into the two general groups of soluble and insoluble.

Soluble fiber (pectins, gums, inulin-type fructans, and some hemicelluloses) dissolves in water, forming viscous gels, bypasses the digestion of the small intestine, and is easily fermented by the microflora of the large intestine. Insoluble fibers (lignin, cellulose, and some hemicelluloses) are not water-soluble and do not form gels, so their fermentation is severely limited [48, 49].

41.2.6.1 Health Benefits of Fiber

Cardiovascular

High levels of dietary fiber intake are associated with lower rates of coronary heart disease, stroke, and peripheral vascular disease, as well as lowering such major risk factors as hypertension, diabetes, obesity, and dyslipidemia.

The probable mechanisms behind dietary fiber and cardiovascular disease prevention may be as follows: First, soluble fibers have been shown to increase the rate of bile excretion, therefore reducing serum total and LDL cholesterol. Second, dietary fiber affects the ability to regulate energy intake, thus enhancing weight loss or maintenance of a healthier body weight. Third, short-chain fatty acid production, especially propionate, has been shown to inhibit cholesterol synthesis. Fourth, dietary fiber has been shown to lower risk of type 2 diabetes, either through glycemic control or reduced energy intake. Fifth, fiber has been shown to decrease proinflammatory cytokines such as interleukin-18, which may have an effect on plaque stability. Sixth, increased consumption of dietary fiber has been shown to decrease circulating levels of C-reactive protein (CRP), a marker of inflammation and a predictor for coronary heart disease.

Obesity

Dietary fiber's ability to decrease body weight or mitigate weight gain could be attributed due to several factors. First, fiber may significantly decrease energy intake. Second, soluble fiber, when fermented in the large intestine, produces glucagon-like peptide (GLP-1) and peptide YY (PYY). Both

these gut hormones play a role in inducing satiety. Third, dietary fiber may decrease diet metabolizable energy, which is gross energy minus the energy lost in the feces, urine, and combustible gases. Also, as dietary fiber intake increases, the intake of simple carbohydrates tends to decrease. Both soluble and insoluble fiber may lead to weight loss.

Diabetes

Although other risk factors such as obesity, lack of physical activity, and smoking are precursors for type two diabetes, dietary factors also seem to play a significant role. Type 2 diabetes results from decreased insulin sensitivity and hyperglycemia. Several explanations have been proposed to understand the physiology behind the relationship between glycemic index and diabetes. First, simple carbohydrates are high in glycemic index and produce higher blood glucose levels. This chronic hyperglycemia may lead to the dysfunction of beta cells in the pancreas, thus decreasing insulin release. Second, because of the high glycemic load, tissues such as skeletal muscle, liver, and adipose become resistant to insulin.

There is an inverse relationship between dietary fiber and diabetes, independent of age and body weight. The mechanisms behind insoluble fiber are more peripheral and not limited to nutrient absorption. First, an accelerated secretion of glucose-dependent insulinotropic polypeptide (GIP) is observed directly after the ingestion of an insoluble fiber. GIP is an incretin hormone that stimulates postprandial insulin release. Second, insoluble fiber can result in a reduced appetite and food intake, and this may lead to a decreased caloric intake and BMI. Third, short-chain fatty acids, via fermentation, have been shown to reduce postprandial glucose response in insulin-sensitive tissues.

Gastrointestinal Conditions

Dietary fibers affect the entire gastrointestinal tract from the mouth to the anus. Soluble fibers usually delay gastric emptying, while insoluble fibers tend to decrease gastric transit time. In the small intestine, fibers can reveal responses of a wide variety of gastrointestinal hormones that serve as incretins to stimulate insulin release and affect appetite. They can bind bile acids, impede micelle formation, and thereby increase fecal excretion of cholesterol and bile acids. They are also effective in increasing total fecal volume and promoting regular bowel movements. In the colon, soluble fibers increase microbiota mass, with some acting as prebiotics to promote health-promoting bacteria bifidobacterium and lactobacilli.

Guar gum and other soluble fibers are associated with low levels of gastric acid production, which may protect from GERD. Evidence strongly indicates that high fiber intake is associated with lower prevalence of duodenal ulcer disease than lower fiber intake. Judicious use of soluble fibers may offer benefits to individuals who are in remission from ulcerative colitis. Inulin as a prebiotic has the ability to stimulate the growth of bifidobacterium while restricting the growth of potential pathogenic bacterial species such as *E. coli*, *Salmonella*, and *Listeria*. This could be beneficial in such disorders as ulcerative colitis and *C. difficile* infections. In one study, inulin decreased the risk of colon cancer by reducing colorectal cell proliferation, decreasing interleukin-2 release, and decreasing exposure to genotoxins.

Cancer

Cancer continues to be one of the top health concerns of populations worldwide. Insoluble fiber found in whole grains has direct effects in the colon by promoting laxation, decreasing transit time, and binding substances such as bile acids and carcinogens. Soluble fiber is acted upon by the gut microbiota, and the utilization results in changes to the numbers and types of bacteria and, more importantly, changes to their metabolic activities in terms of the formation of tumor promoters, genotoxins, and carcinogens.

Selective prebiotic fiber sources – such as resistant starches, inulin, and some oligosaccharides – act as a selective substrate for bacteria that produce specific short-chain fatty acids and can lower the intestinal pH and prevent the growth of pathogenic bacteria. They increase the number of bifidobacteria in the colon, and this and the reduced intestinal pH have a direct impact on carcinogenesis in the large intestine. The SCFA butyrate has shown to increase apoptosis of colonic tumor cell lines.

Immune System

Soluble fibers such as inulin and other oligofructoses stimulate growth of bifidobacteria and lactobacilli in the colon. These bacteria generate short-chain fatty acids and stimulate the immune system. Some of the other health benefits of these bacteria include protection from intestinal infection; activation of intestinal function; assistance in digestion and absorption, especially of calcium; lowering of intestinal pH for formation of acids after assimilation of carbohydrates; reduction of the number of potentially harmful bacteria; production of vitamins and antioxidants; bulking activity and production of fecal matter; and potential reduction in the risk for colorectal cancer [48].

41.2.7 Removal of Potential or Documented Allergens and Excessive Alcohol

One of the most powerful tools for a whole-body intervention is identifying food triggers, food allergens, and intolerances. This becomes an integral part of a nutritionist/dietitian's 5-R approach (see Table 41.1). Identification of food allergies is done through IgE testing for foods, whereas to identify non-IgE-related food sensitivities, there are a plethora of tests in the market. If the patient has monetary restrictions, a well-structured elimination plan focusing on MAPDOMs offers the patient the opportunity to experience a much healthier approach to eating. Many common ailments tend to resolve once the individual focuses on more plant-based and organic foods.

Table 41.1 Integrative 5-R approach

Interventions	Definition	Food	Dietary supplements	Lifestyle	Referrals
Remove	Remove stressors Remove what harms This step focuses on eliminating pathogenic bacteria, viruses, fungi, parasites, and other environmentally derived toxic substances from the gastrointestinal tract Eliminate or reduce ongoing toxic exposures in the home and/or workplace	Remove foods and beverages that are likely to contain toxins, food allergens, or antigenic challenges Elimination diets Top 10 antigens FODMAP Remove processed foods containing dyes or chemicals Avoid highly processed foods Avoid foods cooked at high temperatures – these are high in advanced glycated end products (AGEs) Eliminate refined flours Eliminate soda and sugary beverages Limit/ eliminate alcohol	Antimicrobial Anti-parasites Oil of oregano, olive leaf extract, garlic extract, berberine, undecylenic acid, grapefruit seed extract, monolaurin, mastic gum, caprylic acid, wormwood extract, clove extract, black walnut hull, artemisinin, cinnamon bark, pau d'arco inner bark extract, rosemary leaf extract, thyme oil, apple cider vinegar Chelating agents: modified citrus pectin, chlorella, activated charcoal Energetics: bioenergetic therapies (cancer – Rad-Tox from Apex)	Eliminate toxic elements and chemicals from food and environment Mold remediation HEPA filters Toxic relationships EMF Fix irregular sleep patterns: regularize sleep as per circadian rhythms Eliminate Teflon pans, plastic containers Smoking cessation	DC/DO/NUCA-C1/C2/ Correct structural stress Medical specialties – gastroenterology Reduction of hiatal hernia – osteopathic, chiropractic, or visceral manipulation Allergy and immunology, infectious disease, ILADS, Lyme- literate practitioner Functional medicine psychiatrist Referral for IV chelation
Replace	The second clinical site: Replace factors that may be lacking or limited	Optimize nutrition through whole foods Correct nutritional deficiencies Apple cider vinegar Papaya, pineapple	Digestive enzymes, betaine HCl, zinc for HCl production, lipotropic factors, pancreatic enzymes, diamine oxidase, DPP IV proteases Swedish bitters Gentian Prokinetics such as D-limonene ginger iberogast, Chinese herbs (TJ 43)	Mindful eating Chewing food Eating meals at regular timings Clean filtered water Sleep hygiene helps with melatonin production – important for digestive support HEPA/ULPA filters to reduce dust, molds, volatile organic compounds Indoor plants	Meyer's cocktail, Vitamin C Acupuncture

(continued)

Table 41.1 (continued)

Interventions	Definition	Food	Dietary supplements	Lifestyle	Referrals
Reinoculate	Reintroduction of desirable bacteria, or "probiotics," into the intestine to reestablish microfloral balance	Butyrate in food: pasture butter/ buttermilk/SCFA Prebiotic foods: Asparagus Bananas Burdock root Chicory Chia seeds Fruit Garlic Leeks Onions Peas Sunchokes Probiotic foods: Buttermilk Jeruk Khimchi Kombucha Miso Nato Olives Raw pickles Sauerkraut Antibiotic-free animal produce	Butyrate inulin, larch- arabinogalactans, psyllium modified citrus pectin Probiotics *Saccharomyces boulardii* *Lactobacillus* species – *reuteri*, *casei*, *rhamnosus*, *acidophilus* *Streptococcus* species *Bifidobacterium* species: *infantis*, *lactis*, *longum*, *bifidum*	Sleep Emotional resilience Anger management Avoid negative self-talk Meditation, practicing loving kindness	Medical specialist for prescribing butyrate enemas, fecal transplantation
Repair	Provide nutritional support for regeneration and healing of the gastrointestinal mucosa	Whole-food nutrition Raw spinach, cabbage, okra, aloe vera Avoid highly processed foods Avoid high-temperature cooking processes – high advanced glycated end products	Glutamine N-acetyl glucosamine Fiber for SCFA (both soluble and insoluble) butyrate colostrum aloe, artemisia, boswellia, curcumin, geranium, licorice/ DG, marshmallow, quercetin, rutin, slippery elm Essential fatty acids Antioxidants: Vitamins C, A, and E, CoQ10 Liposomal glutathione Pro-resolvins Alpha lipoic acid Zinc picolinate/ carnosine Gamma oryzanol N-acetyl cysteine	Prayer/grace before meals Quiet environment Avoid microwave Forgiveness in relationships	Medical specialist for IV glutathione Psychotherapist Chiropractor Physical therapy

Table 41.1 (continued)

Interventions	Definition	Food	Dietary supplements	Lifestyle	Referrals
Rebalance	Modify attitude, diet, and lifestyle to promote healthier living	Whole clean foods appropriate for the individual Eat no later than 2–3 hours before bedtime Meal spacing Eating at regular intervals	As needed for maintenance Melatonin 5HTP GABA Adrenal support Magnesium Fiber Pro-resolvins Fatty acids Phosphatidylserine Ashwagandha	Healthy mind/healthy body/mindful eating Practice gratitude Movement Purpose Dinacharya: practice of daily routine as per Ayurveda HeartMath Acupuncture Massage Prayer Meditation Regular exercise Laughter: What makes you laugh? Steam/sauna Hydrotherapy Dry skin brushing	Yoga therapy Chiropractor Craniosacral practitioner Music therapy Water therapy Art Chakra balancing Guided imagery Hypnosis

The elimination diet excludes saturated and trans fats, empty calories, sugars, additives, hormones, and antibiotics in food along with toxic chemicals and xenobiotics. Alcohol needs to be eliminated, as ethanol depletes intestinal integrity and causes gut dysbiosis. Butyrate, a fermentation by-product of gut microbiota, is also negatively altered following chronic alcohol consumption [50].

With this one therapeutic modality, the dietitian/nutritionist can reduce food antigenicity and inflammatory reactions, improve gut permeability, rebalance Th1 and Th2 cytokines, rebuild the brush border, and improve digestion and absorption. Implementation is simple but may not be easy for patients and their families. Some improvements stem from the reduction of the antigenic load at the level of the gut and the resultant T-helper cell Th1 vs. Th2 immune shifting. While the simple sensitivities may take hours to days to improve, immune system rebalancing may take weeks to decrease and eliminate antigens from the gut and show improved symptoms on a clinical scale.

No one likes to change dietary habits, but it is an essential part of the management of chronically ill patients. It is important to emphasize the importance of complete adherence to the plan. When patients are prescribed an elimination diet, they will typically start "negotiating" the terms, including alcohol. It is here where motivational interviewing skills will serve both the practitioner and the patient.

Elimination of dietary triggers helps with most chronic conditions, including mental health issues. A paper published by Karakula et al. reviews the relationship between gut microbiota, intestinal permeability, and dietary antigens in the etiopathology of schizophrenia [51]. Studies on the role of ketogenic diet in mental health have been on a rise [52, 53].

41.2.8 Adequate Intake of Fatty Acids

Fatty acids are constituents of cell membranes, act as an energy source, and have biological activities that act to influence tissue, metabolism, and function, along with responsiveness to hormonal and other signals. The biological activities may be grouped as regulation of membrane structure and function; transcription factor activity; regulation of intracellular signaling pathways and gene expression; and regulation of the production of bioactive lipid mediators. Fatty acids influence health and well-being, and aberrations in their profiles influence metabolic conditions such as cardiovascular diseases, neurovascular diseases, type 2 diabetes, inflammatory diseases, and cancer.

Different foods contain different amounts of fat and different types of fatty acids, and these may be affected by processing, storage, and cooking methods. Humans eating a varied diet will consume many different types of fatty acid each day. The pattern of fatty acid consumption varies from meal to meal, from day to day, and from season to season. Aging, geographical location, and cultural and religious practices also impact fatty acid intake. Fatty acids can be synthesized in the human body, either from non-lipid precursors such as glucose or from other fatty acids; exceptions to this are the so-called essential fatty acids, which must come from the diet.

41.2.8.1 Effects of Saturated Fatty Acids

Palm oil, coconut oil, cocoa butter, and animal-derived fats such as lard, tallow, and butter are rich sources of saturated fatty acids. The amounts of individual saturated fatty acids

present vary among these sources. Many plant oils contain a significant amount of saturated fatty acids, particularly palmitic acid, as do fish and fish oils. Dairy fats contain some odd-chain saturated fatty acids. Saturated fatty acids are also synthesized de novo in humans, the precursor being acetyl-CoA, produced from carbohydrate or amino acid metabolism. Processed and refined carbohydrates, when consumed in excess, are also converted to fatty acids.

Saturated fatty acids influence cell signaling in many cell types through their roles in phospholipid, sphingolipid, ganglioside, and lipid raft structure and in covalent modification of proteins. Through effects on regulation of transcription factors involved in lipid metabolism and in inflammation (NF-κB), saturated fatty acids influence cholesterol, fatty acid, and triacylglycerol biosynthesis; lipoprotein assembly, secretion and clearance, and metabolism; and inflammatory processes. Hence, they play important roles in normal cellular and tissue metabolism and function but also influence factors involved in determining risk of cardiometabolic and other inflammatory diseases [54].

Based on the recent controversy with saturated fats, one could easily assume that the "butter/bacon is back" movement has won and that reducing saturated fat is no longer important for heart health. A few recently published studies conclude that there is no association between intake of saturated fats and cardiovascular risk [55, 56]. One of these studies was a meta-analysis of observational studies reporting associations of saturated fat with all-cause mortality, cardiovascular mortality, and stroke (de Souza). The researchers concluded that saturated fats are not associated with those outcomes. The other popular study was the Minnesota Coronary Experiment (MCE), a randomized control trial conducted with 9423 men and women [56]. The researchers concluded that replacing saturated fat in the diet with polyunsaturated fats had no impact on mortality, even though it reduced cholesterol. While these studies and arguments seem compelling, the vast majority of the research still links saturated fat intake with increased risk for cardiovascular risk. Critiques of the above meta-analysis show that the researchers based their conclusions on selective data and ignored the data that showed replacing saturated fat with high-quality carbohydrates – fruits, vegetables, and whole grains – reduced the risk of cardiovascular disease [57, 58].

41.2.8.2 Effects of MUFAs

Oleic acid is the most prevalent monounsaturated fatty acid (MUFA) in the human diet. Plant oils and animal-derived fats such as lard, tallow, and butter are good sources of oleic acid. Olive oil is an especially rich source, with oleic acid typically contributing about 70% of fatty acids present. In low-erucic acid rapeseed oil (aka canola oil), which is genetically engineered, oleic acid typically makes up about 60% of fatty acids. Palmitoleic acid is found in low amounts in many plants oils and animal fats, and it is quite abundant in macadamia oil and in fatty fish and fish oils. Both palmitoleic and oleic acids can be synthesized de novo in humans.

Cell membrane phospholipids contain some palmitoleic acid and significant proportions of oleic acid. Replacing saturated fatty acids with oleic acid has a small cholesterol- and LDL cholesterol-lowering effect with an inconsistent effect on HDL cholesterol. Oleic acid also renders LDL fairly resistant to oxidation and limits the formation of pro-atherogenic oxidized LDL. Although oleic acid is often called "anti-inflammatory," its effects on inflammatory processes are modest, and it seems likely that any anti-inflammatory effects of olive oil are due to polyphenolic substances rather than oleic acid. Oleic acid seems to improve glucose control and insulin sensitivity along with a small lowering effect on blood pressure.

Effects of oleic acid are observed when it is used to replace saturated fatty acids in the diet, and it is likely that these effects are due to partial removal of the deleterious biological effect of saturated fatty acids rather than to any specific molecular or cellular action of oleic acid. However, some studies show effects of oleic acid on transcription factors involved in lipid homeostasis. The effects seen when saturated fatty acids are replaced with oleic acid would be expected to lower risk of cardiovascular disease [54].

In terms of preventing cardiovascular events, the Prevención con Dieta Mediterránea (PREDIMED) study reported that a 4.8-year intervention with a Mediterranean diet that included extra-virgin olive oil – a source of oleic acid – reduced myocardial infarction, stroke, and cardiovascular death by 30% compared with the control diet [59].

Over the past decade, palmitoleic acid – found in macadamia nuts, avocado, and sea buckthorn – has received significant interest due to its description as a "lipokine." A lipokine is a lipid messenger released from adipose tissue having effects on other tissues such as the skeletal muscle, by increasing insulin sensitivity, and in the liver, where it reduces fat accumulation.

In conclusion, the two major dietary MUFAs appear to have a cardioprotective and anti-inflammatory role, especially when substituted for saturated fatty acids [54].

41.2.8.3 Effects of Omega-6 PUFAs

Linoleic acid is the most prevalent omega-6 (n-6) polyunsaturated fatty acids (PUFAs) in the human diet. Many nuts, seeds, and oils contain high proportions of linoleic acid. For example, linoleic acid comprises 75% of fatty acids in safflower oil and around 50–55% in corn oil, soybean oil, sunflower oil, and cottonseed oil. It also makes a significant contribution to vegetable oils that are rich in oleic acid (rapeseed, peanut, and olive oils) or palmitic acid (palm oil). Some seeds and seed oils contain metabolic products of linoleic acid such as γ-linolenic acid and are found in evening primrose oil, but these are not important dietary constituents.

The second most common dietary n-6 PUFA is arachidonic acid, which is found in foods of animal origin, such as meat and eggs. Linoleic acid is the metabolic precursor of γ-linolenic acid, dihomo-γ-linolenic acid, and arachidonic acid. Membrane phospholipids of human cells contain significant proportions of both linoleic and arachidonic acids

and often contain some dihomo-γ-linolenic acid. Linoleic acid is an important constituent of ceramides, especially those found in the skin, and essential fatty acid deficiency results in breakdown of skin integrity and inability to prevent transdermal water loss. However, only a fairly low intake of linoleic acid is required to prevent essential fatty acid deficiency (1% of energy), and most diets provide intakes greatly in excess of this.

Linoleic acid lowers blood cholesterol and LDL cholesterol concentrations, particularly when it replaces the common saturated fatty acids. It has an effect in hepatic cholesterol metabolism by inducing the gene encoding cholesterol 7α-hydroxylase, which is the rate-limiting enzyme in the synthesis of bile acids from cholesterol. This upregulation increases the production of bile acids that are exported from the liver to the gallbladder, thereby lowering hepatic cholesterol and LDL. Linoleic acid was found to increase insulin sensitivity and activate NF-κB, but is not associated with increasing CRP, IL-6, or soluble TNF receptor and may thus have only a limited effect on inflammation in humans.

Arachidonic acid has a structural role in the brain. Studies of infants receiving formulas that combine arachidonic acid with the long-chain n-3 PUFA docosahexaenoic acid have found improvements in cognitive development. Free arachidonic acid has roles in cell signaling and can directly promote inflammation by acting via the NF-κB pathway. A major role of cell membrane arachidonic acid is as a substrate for the synthesis of eicosanoids, which include series 2 prostaglandins, thromboxanes, and leukotrienes. These are formed by metabolism of arachidonic acid by cyclooxygenase or lipoxygenase pathways. The resulting metabolites have many roles in platelet aggregation and blood clotting, inflammation and pain, regulation of the immune response and bone turnover, smooth muscle contraction, tumor cell proliferation, renal function, and cancer progression. Eicosanoid mediators are formed in a cell-specific manner and often have opposing effects to one another, thereby acting to ensure a controlled biological response [54]. It is well-known that n-6 and n-3 fatty acids share metabolic pathways and can potentially compete with each other, causing n-6 to interfere with potential cardiovascular benefits of the n-3. Studies have found that the combination of both types of fatty acids is associated with the lowest levels of inflammation and lowest risk for metabolic diseases [60].

41.2.8.4 Effects of n-3 PUFAs

The essential n-3 PUFA α-linolenic acid is synthesized in plants. Flaxseeds and flaxseed oil, walnuts, and chia seeds are rich sources of α-linolenic acid. Soybean oil and rapeseed oil contain about 7–10% α-linolenic acid. There is a metabolic pathway by which α-linolenic acid can be converted to eicosapentaenoic acid (EPA) and then on to docosapentaenoic acid (DPA) and docosahexaenoic acid (DHA). However, the conversion of α-linolenic acid to DHA is poor. There is direct competition for metabolism of n-6 and n-3 PUFAs as this pathway shares the same enzymes as the metabolism of linoleic acid. A typical dietary ratio of linoleic to α-linolenic acid in Western diets is 7–20. This may be one reason why metabolism of α-linoleic acid to EPA is poor in humans and that to DHA is extremely limited.

EPA, DPA, and DHA are found in seafood, especially in fatty fish, and in fish oil supplements. Unless a person is regularly consuming fatty fish or taking a fish oil supplement daily, α-linolenic acid will be the most common n-3 PUFA in the diet. Cell membranes contain very little α-linolenic acid, but most contain modest amounts of EPA and greater amounts of DPA and DHA. Membranes of the brain (gray matter) and eye (rod outer segments) contain high amounts of DHA. The structure of n-3 PUFAs, especially DHA, has a strong influence on the physical properties of membranes into which they are incorporated and on membrane protein function. As the result of effects on membrane-generated intracellular signals, EPA and DHA can modulate transcription factor activation and thereby expression of genes. The transcription factors affected by EPA and DHA include NF-κB, Ki-67, SREBPs, and PPAR-α and PPAR-γ. These effects are central to their role in controlling inflammation, fatty acid and triacylglycerol metabolism, and adipocyte differentiation.

The replacement of cell membrane arachidonic acid by EPA and DHA influences the pattern of lipid mediators produced. There is decreased production of eicosanoids from arachidonic acid and increased production of eicosanoids from EPA, especially of the selective proresolving mediators (SPM), which play an anti-inflammatory role and also influence the immune system. Therefore, EPA and DHA can influence inflammation, immune function, blood clotting, vasoconstriction, and bone turnover, along with several other processes. An adequate supply of DHA is essential for optimal neural, behavioral, and visual development of the infant. EPA and DHA have important roles in brain function throughout the life course.

These n-3 PUFAs are effective at lowering blood triglyceride concentrations. DHA can influence the concentrations of cholesterol-carrying lipoproteins and can cause a small increase in both LDL and HDL cholesterol. EPA and DHA also increase LDL particle size, rendering LDL less atherogenic. They also exert an effect on blood pressure, aldosterone secretion, generation of nitric oxide by the endothelium, vascular reactivity, and cardiac hemodynamics. EPA and DHA also reduce inflammation.

Evidence from prospective and case-control studies indicate that consumption of EPA and DHA reduces the risk of CVD outcomes. Three key mechanisms have been suggested to contribute to the therapeutic effect of EPA + DHA: first, altered cardiac electrophysiology, seen as lower heart rate, fewer arrhythmia, and increased heart rate; second, an antithrombotic action resulting from the altered pattern of production of eicosanoid mediators that control platelet aggregation; and lastly, due to the anti-inflammatory effect of EPA and DHA, which serve to stabilize atherosclerotic plaques, preventing their rupture. EPA and DHA may directly influence cancer cells and the tumor environment by inhibiting or slowing tumor initiation, invasion, and cell proliferation and by promoting tumor cell apoptosis [54].

Most human studies of the functional effects of EPA and DHA have used supplemental forms with differing ratios and dosages, where the fatty acids have been provided without any dietary change and without removal of other fatty acids from the diet [54]. While this has undoubtedly contributed to confusion among medical professionals, the current scientific literature provides a strong evidence that n-3 fatty acids reduce the risk of metabolic diseases, including cardiovascular risks and brain health [61]. This has encouraged national and international guidelines to collectively recommend that healthy adults consume at least 250 mg per day of long-chain omega-3 fatty acids to maintain cardiovascular health, with many organizations recommending higher amounts for those at greater risk of CVD and other inflammatory conditions [62, 63].

41.2.8.5 Role of Trans Fats

Industrially produced trans fats resulting from the hydrogenation of vegetable oils are generally found in snack foods and baked goods, such as cakes, muffins, and pies. These are identified as partially or fully hydrogenated vegetable oils on the label. A 2% increase in trans fat consumption is associated with a 23% increase in the incidence of cardiovascular disease. The presence of a trans double bond causes the physical properties of the fatty acid to be more like a saturated fatty acid than an unsaturated one. Therefore, incorporation of trans fatty acids into cell membranes causes the membranes to become less fluid, which then influences membrane protein function and interactions, in turn affecting cell-signaling processes. The trans fats adversely affect LDL particle number and inflammation markers such as CRP and IL-6. Because of these biological effects, trans fatty acids as a class appear likely to confer greater health risk than other fatty acid classes. The current dietary guidelines recommend that trans fats should be limited to less than 1% of energy or as low as possible [54, 64].

The functional medicine use of fatty acids, especially essential fatty acids, in nutrition intervention is an important therapeutic tool. Understanding the pathophysiology involved in inflammation and metabolic dysfunction allows the nutrition professional to manage patients in a vigilant and systematic manner.

41.2.9 Adequate Water Intake

Hydration is integral to health, and water trails only air among the most important substances in maintaining hemodynamics and functional reserve. The human body survives for only a few days without meeting essential water requirements but could sustain itself for several weeks without ingesting macronutrients or micronutrients. Water is involved in critical anatomical and physiological functions, such as in providing mass and structure to the cells, functioning as the medium and reagent for metabolic reactions. Intercellular water binds to proteins, carbohydrates, and nucleic acids to maintain their proper function, lubricates adjoining tissues, transports substrate and metabolic waste, and is the primary means for dissipating excess body heat. When a person is dehydrated, the structure of critical cellular biomolecules is adversely affected, reducing their function. All systems are influenced by dehydration, resulting in reduced energy production, neurotoxicity, alteration in the function of concentration of substances within cells, pH changes, and altered enzyme function. Muscle cramping, muscle soreness, constipation, fatigue, and sensitivity to toxic substances all increase during states of dehydration, while mental clarity is reduced. In these cases, water becomes the limiting nutrient for support of functional physiology [65].

In a functional medicine assessment, the adequacy of water to maintain functional organ reserve should be a first-stage priority. Body composition measurements using bioimpedance analysis can provide information about both intra- and intercellular water status. Three simple indicators of hydration status include thirst, body weight, and urine osmolality. Thirst typically lags behind an acute change in hydration, developing after humans incur a 1% to 2% acute reduction in body mass. It is observed that endurance and cognitive performance decline at slightly less than 2% acute loss of body mass. The signal to initiate drinking behavior does not appear to be synchronized to prevent deterioration of function, and therefore thirst is commonly viewed as a less-than-ideal method of tracking hydration. Therefore, thirst should be used in combination with acute change in body weight and urine color to develop fluid intake strategies. Body weight and acute change in body weight following exercise and/or heat exposure are a relatively accurate and reliable measures of hydration status. Specific gravity or urine osmolality is also a predictor of hydration status, and elevations in osmolality or specific gravity of a urine sample suggest the onset of dehydration. For specific gravity, a value of greater than 1.020 (equivalent to an osmolality of approximately 900 mOsm/kg) categorizes an individual as dehydrated, and a value of 1.035 is considered frank dehydration.

Hydration has shown to impact various aspects of human health. Poor hydration status may be associated with compromised oral health, such as dental caries and erosion of dental enamel. Adequate fluid consumption has a positive effect on intestinal and hormonal health. Consumption of water has shown to increase stool weight and volume along with decreasing bowel transit time in some individuals. It has also been associated inversely with certain types of cancers. This is because water consumption results in accelerated transit of potential carcinogens through the intestinal tract and decreased time for exposure and dilution of carcinogens in the water phase (phase 2 detoxification – sulfation and glucuronidation) of the stool. It may also be because of greater intestinal excretion of hormones such as estrogen that are associated with cancer, because weak evidence of a relationship was seen between bowel motility and breast cancer. Enhanced hydration also leads to a reduced sympathovagal ratio, decreases the sympathetic nervous system drive to retain fluids, and increases the parasympathetic activation to excrete fluids, all of which could, in a state of dehydration, facilitate responses leading to hypertension. In individuals

who are susceptible to nephrolithiasis, increased water ingestion reduces the risk of subsequent kidney stones, specifically calcium nephrolithiasis with stones composed primarily of calcium oxalate. The mechanism is thought to be a result of the dilution in concentration of materials that would precipitate stones on saturation. Continuous ingestion of water stimulates urine production and contributes to the dilution and excretion [66].

The WHO has declared that "all people, whatever their stage of development and their social and economic conditions, have the right to have access to an adequate supply of safe drinking water." Although presence of a public water distribution network is often an indicator of a suitable water supply, it should not be expected that the piped water quality is always adequate for human consumption [67]. Like the fish we eat – which are now significant sources of toxins such as mercury, cocaine, and antidepressants – our water can contain everything from pesticides to substances we add to water as a function of general public use (chlorine, fluoride, lead, and iron leaking from lead pipes, softening agents), to residues from farming practices, to bacterial or parasitic agents resulting from contamination or overuse. People are also exposed to disinfected drinking, shower, or bathing water containing at least 600 identified disinfectant by-products [68].

Citizens of a small town in Colombia had a significant prevalence of autoimmune thyroiditis, which was traced back to the contamination of drinking water with phenolic chemicals. Those chemicals adversely influenced the immune system, resulting in production of anti-thyroid antibodies. When the water supply was purified, the prevalence of autoimmune thyroiditis was significantly reduced in the community [69, 70].

In April 2014, the city of Flint, Michigan, switched to the Flint River as a temporary drinking water source – without implementing corrosion control – discontinuing the purchase of treated water from the Detroit Water and Sewer Department (DWSD). Ten months later, water samples collected from a Flint residence revealed progressively rising water lead levels – 104, 397, and 707 μg/L – coinciding with increasing water discoloration. An intensive follow-up monitoring event at this home investigated patterns of lead release by flow rate. All water samples contained lead above 15 μg/L, and several exceeded hazardous waste levels (>5000 μg/L). After analysis of blood lead data revealed spiking lead in the blood of Flint children in September 2015, a state of emergency was declared, and public health interventions (distribution of filters and bottled water) likely averted an even worse exposure event due to rising water lead levels. This incidence will have long-term health consequences in infants as well as in adults, including developmental delays, learning difficulties, mood disorders, miscarriages, joint pains, hypertension, and cognitive decline in adults [71].

The Safe Drinking Water Act (SDWA) is the federal law that protects public drinking water supplies throughout the nation. Under the SDWA, the Environmental Protection Agency (EPA) sets standards for drinking water quality and, with its partners, implements various technical and financial programs to ensure drinking water safety. Even with the law in place, more action needs to be taken with regard to the water quality. The EPA in January of 2017 initiated a peer review of draft scientific modeling approaches to inform the agency's evaluation of potential health-based benchmarks for lead in drinking water [72].

Pure water on this planet has become a diminished resource. All of these problems have significant health implications, ranging from neurological damage to respiratory problems to gastrointestinal ailments. Access to safe water for drinking, bathing, and normal household use is a very important part of a healthy life – one of which we are most aware when it no longer exists.

One of the smarter options is to recommend patients filter their own water and carry it with them in a stainless steel bottle. There are many filtering options. A few options would be to use simple carbon filters or a reverse-osmosis filter system, which puts the water through a multistep process to remove the toxins. There is an initial installation cost, but it is cheaper over the long run. Filtering bathing and washing water is also recommended. A practitioner may recommend a whole-house water filter with an additional drinking water filter as the best option.

Hydration Tips

- On a sedentary day, try to drink around 2 liters of water.
- Start by drinking a glass of fresh water when you get up in the morning.
- If you are not used to drinking water regularly, try initially replacing just one of your other drinks a day with fresh water, increasing your consumption as the weeks go by.
- Drink a glass of water before and during each meal.
- Hot water with fresh mint, lemon balm, or a piece of fruit in it – like lime, lemon, and orange – often helps those who want a hot drink.
- Carry a bottle filled with water with you whenever you leave the house.
- During exercise, drink at 10- to 15-minute intervals, or think of it as a full glass every 30 minutes. Drink slowly and drink early, as it's physically easier to do this when you are still feeling fresh.
- Keep a check on your urine. As a general guide to hydration, it should be plentiful, pale in color, and odorless.

41.2.10 Inclusion of Prebiotic and Probiotic Foods

Nutrition plays a key role in the modulation of gut microbiota composition, and, in turn, the gut microbiota plays a critical role within the body. The gut microbiota is mainly

involved in the development and growth of immunity; the promotion of barrier integrity; the prevention of antigens and pathogens from entering the mucosal tissues; the regulation of several fundamental metabolic pathways such as synthesizing vitamin K; the promotion of angiogenesis and enteric nerve function; and reductive reactions such as methanogenesis, acetogenesis, nitrate reduction, and sulfate reduction, to name a few.

Dysbiosis, on the other hand (quantitative and/or qualitative alterations of gut microbiota), impairs homeostasis in the immune system as well as metabolic pathways, leading to the development of several gut microbiota-related diseases. These include functional gastrointestinal diseases, inflammatory bowel disease, gastrointestinal malignancies, allergic diseases, intestinal infectious diseases, liver diseases, obesity and metabolic syndrome, diabetes mellitus, autism, and others.

The four major microbial phyla that represent over 90% of the bacterial component of the gut microbiota are *Firmicutes*, *Bacteroides*, *Proteobacteria*, and *Actinobacteria*. The majority of "good" bacteria harboring the human gut microbiota are represented by *Firmicutes* and *Bacteroides*. *Firmicutes* are subgrouped in *Clostridium*, whereas *Bacteroides* phyla are subgrouped with a great number of *Prevotella* and *Porphyromonas*. The human gut microbiota also includes viruses, especially phages, Eukarya as fungi, *Blastocystis*, Amoebozoa, and Archaea. Lactic acid bacteria (LAB) and bifidobacteria (*Actinobacteria*) are two important types of gut bacteria, which are present from birth or acquired from digested food. *Lactobacillus* and *Leuconostoc* spp. are the main lactic acid bacteria found in the human intestine. *Bifidobacterium* spp. are the predominant bacteria found among the first colonizers of newborns and persist at a low level in adults. Infants fed with breast milk had higher levels of *Bifidobacteria* spp., while infants fed with formula had higher levels of *Bacteroides* spp., *Clostridium coccoides*, and *Lactobacillus* spp. [73].

Diet has been known to have a strong influence on the composition of intestinal microbiota, and to confirm this hypothesis, researchers sequenced oral microbiota from skeleton teeth of people who lived over the various eras. The most significant changes in human gut microbiota occurred during two socio-dietary breakthroughs over the human history: the first one around 10,000 years ago, during the passage from the hunter-gatherer Paleolithic era to the farming Neolithic era, with a diet rich in carbohydrates, and the second one at the beginning of the industrialized period approximately two centuries ago, characterized by a processed flour and sugar diet. Studies show that there are differences between the intestinal microbiota of subjects fed with a standard American diet and that of subjects with a diet rich in fibers. Literature shows an increased prevalence of *Bacteroides* and *Actinobacteria* is positively associated with animal protein and a high-fat diet (more prevalent in Western countries), but is negatively associated with fiber intake, whereas *Firmicutes* and *Proteobacteria* show the opposite association. In contrast, the *Prevotella*-prevailing enterotype is associated with high consumption of carbohydrates and simple sugars, indicating a correlation with a carbohydrate-based diet more typical of agrarian societies and vegetarians [74].

41.2.10.1 Probiotics

Probiotics are live microorganisms that, when administered in adequate amounts, confer a health benefit on the host [75]. There exists a long history of human consumption of probiotics (particularly lactic acid bacteria and bifidobacteria) and prebiotics, either as natural components of food or as fermented foods.

The colonic microbiota is able to metabolize complex carbohydrates and oligosaccharides into short-chain fatty acids (SCFAs) such as butyrate, acetate, and propionate. These metabolites play a role in regulating intestinal pH. A small variation of acid concentrations may exert important consequences. A one-unit decrease in pH from 6.5 to 5.5 has been shown to have a profound selective effect on the colonic microbial population, with a prevalent decrease of *Bacteroides* spp. and a growth of butyrate-producing gram-positive bacteria. The decrease of pH caused by high concentration of SCFAs prevents the growth of potentially pathogenic bacteria, such as *E. coli* and other members of the *Enterobacteriaceae* family.

The most common sources of probiotics are yogurt, buttermilk, cheese, and kefir. Traditionally, yogurt has only one or two bacteria, whereas kefir tends to have several probiotic bacteria. Other foods produced by bacterial fermentation are Japanese miso, natto, tempeh, sauerkraut, sourdough, kimchi, kombucha, olives, and pickled vegetables.

41.2.10.2 Prebiotics

Different types of dietary fibers, complex carbohydrates (digestible and nondigestible) and oligosaccharides, act as prebiotics and exert a different influence on the composition of the gut microbiota and, consequently, on its fermentative metabolism. Prebiotics are nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon that can improve the host health. Prebiotics cannot be digested by pathogenic bacteria. They stimulate the growth of probiotic bacteria and allow them to grow predominantly. Prebiotics are usually polysaccharides or oligosaccharides. They are naturally found in such fruits and vegetables as asparagus, bananas, dandelion greens, eggplant, endives, garlic, honey, Jerusalem artichokes, jicama, leeks, legumes, onions, radishes, tomatoes, and whole grains. The commonly known prebiotics are inulin, fructo-oligosaccharides (FOS), galacto-oligosaccharides (GOS), soya-oligosaccharides, xylooligosaccharides, pyrodextrins, isomalto-oligosaccharides, and lactulose [76].

The Western diet is considered to cause intestinal dysbiosis and trigger local inflammation, leading to an increase of intestinal permeability. Studies show that a high-fat diet induces the proliferation of certain gram-negative bacteria which can ultimately result in increased intestinal lipopolysaccharide (LPS) and increased gut permeability. Increased

gut permeability is associated with a decrease in *Bifidobacteria* spp., bacteria that are known to reduce LPS levels and also improve gut barrier function. Interestingly, prebiotic treatment with nondigestible carbohydrates increases bifidobacteria and reduces intestinal permeability, LPS concentrations, and metabolic endotoxemia [74].

The healthful effects of probiotics and prebiotics factor in their potential impact on the balance of the body's microflora and directly or indirectly in their enhancement of the function of the gut and systemic immune system. Tailoring the diet to include probiotic foods that the patient enjoys can have a significant positive impact in improving the patient's nutritional intake [77].

41.2.10.3 Translating Expertise into Intervention

Diet has an enormous impact on many aspects of our health, even beyond providing energy and essential nutrients. The circulating substrates derived from food have both direct and indirect actions to activate receptors and signaling pathways, in addition to providing fuel and essential micronutrients. Ultimately one can consider food as a cocktail of "hormones." A hormone is a regulatory compound produced in one organ that is transported in blood to either inhibit or stimulate specific cells in another part of the body. They exert their effects on target tissues by acting on cellular receptors to alter activity through intracellular signaling cascades or via nuclear receptors to regulate gene transcription. Although food is not produced in the body, its components travel through the blood, and nutrient substrates can act as signaling molecules by activating cell-surface or nuclear receptors [78]. If the body does not receive appropriate materials or if there is inappropriate signaling due to nutritional deficiencies – for example, B12 and homocysteine or excessive amounts of omega-6 foods – metabolic processes suffer and health decline.

As nutritional practitioners, we hold a valuable position in helping patients through one of the most critical modifying lifestyle factors, and that is food and nutrition. Planning and implementation are two components of nutrition intervention. The practitioner has to prioritize nutritional diagnosis, based on the severity of the problem, safety, patient/client need, the likelihood that the nutrition intervention will impact the problem, and the patient's perception of importance. The nutrition intervention is directed whenever possible at the etiology or the cause of the problem identified. If it is not possible to direct the nutrition intervention, the nutrition intervention is aimed at reducing the impact of the signs and symptoms of the problem. For example, if the etiology is related to food allergies or sensitivities, nutrition intervention is based on the elimination of trigger or offending foods. If excessive energy intake is caused by depression and initiation of a psychiatric prescription (changing or withholding prescription drugs is out of RDNs' scope of practice), the nutrition intervention is aimed at reducing the impact of the signs and symptoms of the problem – for example, weight gain or high blood glucose due to increased energy intake.

During the planning phase of intervention, the nutrition practitioner uses evidence-based guidelines along with institutional policies and procedures to reach medical nutrition therapy goals, desired behavior changes, and/or expected outcomes. The nutrition prescription identifies the specific nutritional interventional strategies and establishes the patient-focused goals to be accomplished. The goals should be measurable, achievable, and time-defined. The functional medicine nutrition professional must make sure that they are jointly set with the patient, keeping in mind not just the clinical indicators and biomarkers but also the socioeconomic, cultural, spiritual, and emotional aspects of healing.

Implementation of nutrition intervention should also be accompanied by data collection initiated during nutrition assessment, and practitioners should revise the intervention based on the patient's response. In most cases, the initial nutrition intervention consists of nutrition education, where the nutritional practitioner imparts knowledge and shares skills to help the patient manage and modify food choices and eating behaviors. Nutritional counseling, a supportive process, organically follows, either during the first visit or during follow-ups. This is a collaborative relationship to set priorities, evaluate goals, and fine-tune a nutrition plan to foster self-care and treat or manage an existing condition and promote health.

It is important to note that initiating multiple changes during one single visit may overwhelm indiviudals seeking help. Some patients are able to make many changes at a time, but most patients with long-term chronic issues need time. They might need to make just a few changes at a time. The key to successful nutrition intervention in the nutrition care process is helping patients understand the rationale behind prescribing an individualized food plan; keeping health goals and objectives at the forefront; and fostering self-efficacy by sharing recipes, menu-planning, and providing resources that will enable them to translate the nutrition consultation into practical application and behavioral change. This helps with compliance, builds trust, and fosters a healthy practitioner-patient relationship.

Recipe: Carrot Beet Probiotic Beverage (Carrot-Beet Kanji)

- *Ingredients*:
  - Water – 8 cups
  - Carrots (orange or purple) – 2 medium, peeled and julienned
  - Beet – 1, peeled and julienned
  - Green chilies – to taste, slit on one side (1 small, optional)
  - Powdered mustard seeds – 1 1/2 tbsp
  - Salt – 1 1/2 tsp (or to taste)
  - Red chili powder (optional) – 1 tsp

- *Method*
  1. In a clean pitcher or bottle with a lid, preferably glass or ceramic, add all of the ingredients and mix well. Do not use plastic bottles or pitchers.
  2. Cover and keep the pitcher in the sun for 3–4 days, stirring at least once daily with a clean spoon.
  3. Once fermented, taste the kanji. When it's ready, it has a tangy and fermented taste. Taste it daily just to understand the change in flavor, its food chemistry in action! Store the kanji in the refrigerator.
  4. Serve chilled. Mix before serving. Carrots, beets, and green chilies can be eaten.

  In North India, deep purple-colored carrot is fermented along with crushed mustard seed, hot chili powder, and salt for a few days to get a popular drink called kanji, which is considered to have high nutritional value and cooling and soothing properties. According to the *Indian Journal of Microbiology*, lactic acid bacteria (LAB) play an important role in the fermentation of vegetables, improving nutritive value, palatability, acceptability, microbial quality, and shelf life.

41.2.10.4 Dietary Supplements

The majority of adults in the United States take one or more dietary supplements either every day or occasionally (*ODS. NIH*). According to the Academy of Nutrition and Dietetics position paper on nutrition supplementation, "dietetics practitioners should position themselves as the first source of information on nutrient supplementation." In order to accomplish this, the registered dietitian/clinical nutritionist must keep up to date on the issues associated with regulation, safety, and efficacy, along with identifying supplements available in the market.

According to the *Food and Drug Administration* (FDA), a dietary supplement is a product intended for ingestion that contains a "dietary ingredient" intended to add further nutritional value to (supplement) the diet. A "dietary ingredient" may be one, or any combination, of the following substances:

- A vitamin
- A mineral
- An herb or other botanical
- An amino acid
- A dietary substance for use by people to supplement the diet by increasing the total dietary intake
- A concentrate, metabolite, constituent, or extract

Dietary supplements may be found in such forms as tablets, capsules, softgels, gelcaps, liquids, or powders. Some dietary supplements can help ensure that you get an adequate dietary intake of essential nutrients; others may help you reduce your risk of disease.

Dietary supplements are complex products. The FDA has established good manufacturing practices (GMPs) for dietary supplements to help ensure their identity, purity, strength, and composition. These GMPs are designed to prevent the inclusion of the wrong ingredient, the addition of too much or too little of an ingredient, the possibility of contamination, and the improper packaging and labeling of a product. The FDA periodically inspects facilities that manufacture dietary supplements.

In addition, several independent organizations such as US Pharmacopeia and NSF International offer quality testing for dietary supplement manufacturers and allow products that pass these tests to display their seals of approval. These seals of approval provide assurance that the product was properly manufactured, contains the ingredients listed on the label, and does not contain harmful levels of contaminants. These seals of approval do not guarantee that a product is safe or effective. NSF International also offers an NSF Certified for Sport Program so that athletes can be sure that their dietary supplements do not contain banned substances.

Several companies provide unsolicited post-market surveillance of dietary supplements to ensure quality and integrity in the supplement industry. Consumer Labs and the nonprofit Center for Science in the Public Interest are two such prominent entities.

Under the Dietary Supplement Health and Education Act of 1994 (DSHEA), supplement manufacturers are solely responsible for ensuring that their products are safe. There is no approval of claims, no product registration, and no formula standards. The FDA does pre-market review of new dietary ingredients (NDI). The term "new dietary ingredient" means a dietary ingredient that was not marketed in the United States in a dietary supplement before October 15, 1994. There is no authoritative list of dietary ingredients that were marketed in dietary supplements before October 15, 1994. Even if the NDI is reviewed by the FDA, there is no guarantee of safety. If a dietary supplement causes harm, it is up to the FDA to prove the supplement is unsafe and remove it from the market. Under the current legislation, it is a daunting task for the government to regulate the dietary supplement industry.

Very few supplements have been banned by the FDA in recent times. *Ephedra sinica*, aristolochic acid, and dimethylamylamine (DMAA) are on the list of banned supplements. Herbal products may pose a significant risk in some cases as they have multiple chemical constituents that have not been adequately characterized. *Hypericum perforatum*, also called St. John's wort, is one of the most problematic herbs as far as pharmacokinetics and safety go, along with *Schisandra chinensis* and black pepper. It is important that a nutritional professional recommending herbal products therapeutically seek additional herbal training.

41.2.10.5 Rationale for Recommending Supplements

Before recommending supplements, the functional medicine/nutrition practitioner must determine the clinical indicators for the use. Some of the factors that can help in the decision making are:

- *Filling nutritional gaps*: Does the patient have nutritional deficiencies evident from dietary analysis, signs and symptoms, or laboratory evaluations?
- *Increased nutritional needs*: Does the patient have an increased need for nutrients as a result of inborn errors of metabolism, absorption or transport defects, abnormal enzyme production, or excessive renal losses? The patient may have elevated needs of additional nutrients or enzymes secondary to acute or chronic illness, such as burns, traumatic brain injury, hypochlorhydria, small intestinal bacterial overgrowth, IBD, and pancreatic enzyme deficiency.
- *Maintenance*: Does the patient need supplements to maintain balance of nutrients? For instance, patients who are on calcium supplements for bone health often require magnesium to maintain an appropriate calcium-to-magnesium ratio.
- *Drug-nutrient interactions*: Is the patient on prescription drugs such as statins, antacids, or corticosteroids? If so, they might benefit from supplementation of CoQ10, B12, and calcium, respectively.
- *Genetic factors*: Does the patient have single-nucleotide polymorphisms and therefore increased needs of certain nutrients? For example, MTHFR hyperhomocysteinemia might require adequate folate and B12 intervention.
- The recommended daily allowances (RDAs) and adequate intakes establish nutrient intake levels for healthy individuals and may not address the specific needs of every individual. Individuals who are very active or participate in sports, or who have chronic inflammatory conditions, may benefit from dietary supplementation. There might be a need for supplementation even in women of childbearing age, pregnant women, and older adults to meet optimal nutrient needs.

41.2.10.6 Roles and Responsibilities

It is important to use an evidence-based approach when recommending supplements and screen for drug-nutrient interactions and over-supplementation to ensure safety.

It is the responsibility of the nutrition practitioner to make sure any products dispensed from the office are high-quality products and that the manufacturers comply with Good Manufacturing Practices to ensure safety and efficacy. Look for quality ingredients such as chelated minerals that can be more easily absorbed than mineral salts; active B vitamins, especially for patients with single nucleotide polymorphisms, for example, pyridoxal 5-phosphate instead of pyridoxine hydrochloride; and D-alpha tocopherol with mixed tocopherols versus the synthetic counterpart DL-alpha tocopherol. Just as the functional medicine nutrition practitioner encourages patients to choose clean eating and minimally processed foods, the practitioner should also recommend dietary supplements with minimal processing and excipients: binders, flavorings, colorings, high-fructose corn syrup, and so on. For patients with food allergies or sensitivities, ensuring allergenic-free supplements is critical.

Some of the responsibilities of the practitioner initiating the use of dietary supplements are as follows: to assess nutritional status of the patient to determine the likelihood of inadequate or excessive intake of minerals and vitamins; to evaluate for the potential benefit or harm of nutrient supplementation; to evaluate safety with regard to dosage and potential drug-nutrient interaction; to educate patients about the potential benefits and rationale behind using dietary supplements; to be informed of the research on the supplements suggested; and to be aware of the regulatory, legal, and ethical issues of recommending and selling supplements.

Whenever possible, it is advisable to validate the need for supplementation with laboratory testing and therefore collaboration of care. Referrals, and building a community of healthcare providers, become important in a functional medicine practice. Specific nutrient levels can be obtained through standard labs and specialty functional medicine testing such as organic acid tests, stool analysis, fatty acid profiles, hormone metabolites, and nutrigenomic testing.

The functional nutrition practitioner should be aware of potential adverse effects of dietary supplements and should monitor patients appropriately. While the use of dietary supplements usually has an excellent safety profile, side effects can occur, and high doses of certain nutrients such as B3, B6, B12, zinc, and vitamin D can have serious toxic effects. Sensitive individuals may have allergic reactions not only from the excipients, additives, colorings, and flavorings added but also from food-based ingredients and products containing herbs. Patients with advanced renal or hepatic insufficiency may develop toxicity from some nutrients. In such patients, supplements may be contraindicated, and they should be used only under the direction of practitioners who are proficient in management of serious cases.

The functional nutrition practitioner must update his/her knowledge on dietary supplements on a regular basis.

41.2.11 Lifestyle

Lifestyle is way of living. It is a set of habits and attitudes – physical, mental, social, and spiritual – that together constitute a mode of living for an individual or group.

At the base of the functional medicine matrix are modifiable personalized lifestyle factors such as sleep and relaxation, exercise and movement, nutrition and hydration, stress and resilience, and, last but not least, relationships and networks. Earlier in this chapter, we reviewed the nutrition and hydration aspects. This section will be an overview of the other lifestyle factors.

41.2.11.1 Sleep

Circadian rhythms are endogenous rhythms with a periodicity of approximately 24 hours, plus or minus 4 hours. These rhythms are dependent on an internal clock located in the suprachiasmatic nucleus (SCN) of the anterior hypothalamus. Each of the paired suprachiasmatic nuclei is composed of a group of about 10,000 interconnected neurons that give rise to circadian rhythms through specific neuronal gene expression patterns and by the rate at which they fire action potentials. In addition to the SCN, peripheral clocks have been identified in numerous tissues such as the liver, kidney, heart, skin, and retina, and these are capable of acting in an autonomous manner. The SCN subsequently synchronizes peripheral clocks with each other and thus aligns the entire circadian system to the external light-dark cycle.

The circadian system in human beings is a complex entity that starts in the eye and terminates in the pineal gland, which produces melatonin and is essential for functioning of the clock. In humans, melatonin is secreted during the dark phase of the light-dark cycle. Daytime melatonin levels are very low. Light is considered to be the most potent circadian synchronizer for humans, although non-photic time cues – such as meal times, physical activity, and social interaction – also play a part in synchronization of the circadian system.

Even low-intensity light, as emitted by recent technologies such as LEDs, computer screens or televisions, mobile phones, and tablets, is capable of acting on the clock, thus leading to a phase delay and a slowing of melatonin secretion. In addition to being exposed to light from a range of LED consoles throughout the day, many individuals use such devices at night. This results in circadian phase delay and is associated with a lack of sleep and is thought to underlie clock desynchronization disorders. This amounts to a type of chronic jet lag, also referred to as social jet lag – that is, a misalignment between the clock and social time – and can jeopardize health. Desynchronization manifests through atypical clinical symptoms, such as persistent fatigue, sleep disorders leading to chronic insomnia, poor appetite, and mood disorders that can cause depression, though some desynchronized people do not experience any of these clinical signs.

Chronic sleep deprivation results in drowsiness, decreased levels of attention and alertness that underlie a doubling in the risk of traffic accidents, cardiovascular risk (elevated blood pressure and lipids), GERD, dysregulation in glucose metabolism, insulin resistance (diabetes and obesity), macular degeneration, and cognitive and mental health disorders.

Educating and creating awareness in patients about the importance of sleep and encouraging them to have good sleep hygiene may help bring metabolic and physical changes and improve health and well-being along wih preventing societal harm [79, 80].

Strategies for Restful Sleep

- Avoid exposure to light up to 30 min prior to going to sleep.
- Opt for a morning shift that starts before 7 a.m.
- Keep the same sleep timing most days.
- Avoid stimulants such as alcoholic, caffeinated, or sugary beverages.
- Complete aerobic exercise 3 hours before bedtime.
- Avoid reading stimulating materials at night.
- Avoid arguments and difficult conversations before bedtime.
- Avoid large meals before bedtime.
- Take hot Epsom salt aromatherapy baths.
- Sleep in a dark room.
- Use HEPA or air purifiers/filters to clean air in your bedroom.
- Use humidifiers if needed.
- Avoid shift work or night work when pregnant.

41.2.11.2 Exercise and Movement

Exercise and movement may alter and therapeutically impact mental (improve memory, increase hippocampal size, and increase BDNF), emotional (increase mood, decrease depression, mood, and anxiety), and spiritual aspects (experience sense of purpose; enhance social network, peer support, and sense of community; nature-based exercises aka "dose of nature") in an individual – the very core of the functional medicine matrix [81–83].

Exercise and movement also have a therapeutic impact on each of the clinical imbalances in the function medicine matrix.

- **Assimilation:**
  - Exercise initiated early in life increases gut bacteria species which promotes psychological and metabolic health.
  - Exercise improves the *Bacteroidetes-Firmicutes* ratio and stimulates proliferation of bacteria which can modulate mucosal immunity and improve barrier function.
  - Exercise may also stimulate bacteria capable of producing substances such as SCFAs that protect against gastrointestinal disorders and colon cancer along with providing psychological health benefits [84].

- **Structural integrity:**
  - Increases muscle mass
  - Helps in the reduction of body fat
  - Increases peak oxygen intake
  - Decreases blood viscosity and fibrinogen

- **Communication:**
  - Increases insulin sensitivity, AMPK, adiponectin, NO, semen quality, and vagal tone [85, 86]
  - Reduces HbA1c, adrenergic activity, and estradiol [85, 87]

- **Transport:**
  - Increases maximal oxygen consumption, heart rate variability, flow-mediated dilatation, angiogenesis, endothelial function, HDL, and aerobic threshold
  - Decreases resting heart rate, blood pressure, LDL, and triglycerides [88]

- **Biotransformation and elimination:**
  - Improves bowel function
  - Increases skeletal muscle glucose uptake

- **Energy:**
  - Increases mitochondrial biogenesis and ATP production
  - Decreases fatigue

- **Defense and repair:**
  - Improved immune system
  - Decreased inflammation
  - Increase natural killer cell activity

The intensity and duration of exercise also determine energy consumption. Exercise performed for the same duration at different intensities results in more energy consumption during the higher-intensity segments. Exercise intensity also affects the secretion of hormones associated with energy substrate oxidation. Studies report that carbohydrates are the main energy substrate in high-intensity exercise, compared with lipids being utilized more in low-to-moderate intensity exercise. In recent times, high-intensity interval training (HIIT) has gained attention [89].

Many individuals may feel daunted by the thought of changing their lives and starting new, more active routine. A functional medicine practitioner/nutritionist can help provide motivation and support during this transition by helping patients to remember a few key tips:

1. Emphasize fun: Focus on what the patient enjoys and loves to do rather than exercise being a punishment.
2. Attach activity to habits: Taking a walk after dinner is a time-honored way to get moving. Any routine behavior can have a small activity bonus built in.
3. Involve others: Chances are that the patient's friends, family, and co-workers want to be more active too. It then becomes a community and peer-shared experience. Swap sitting at a coffee shop for walks; swap dinners for bowling or after-dinner walks.
4. Be inventive: Challenge your patient with more active living. Suggest ideas such as an extra lap around the grocery store perimeter, standing while watching television, getting off a bus earlier, using a standing desk at work, and stretching one part of the body when your patient texts someone.
5. Be forgiving: If the patient had one sedentary day, suggest them to not overwork the next day or punish themselves.
6. Track progress: Consider suggesting a pedometer app/device and having fun with it.

It is very important for functional medicine practitioners to walk the talk. Modeling healthy habits not only provides the functional medicine practitioner the deep knowledge of what is required of the patient but also increases the likelihood that you will counsel patients successfully – may it be providing recipes, healthy eating, exercising, or creating a work-life balance. Improving one's own health practices increases efficacy at lifestyle counseling. Practicing one's own preventative and healthy behaviors increases patient adherence to recommendations.

41.2.11.3 Stress and Resilience

Walter Cannon, professor and chairman of the Department of Physiology at Harvard Medical School, wrote extensively about stress, and his work during World War I helped to establish the groundwork for understanding the physiology of mind-body interactions [90]. Later, Hans Seyle reintroduced the term and he is now considered the "father of stress." Per Seyle, "stress is the nonspecific response of the body to any demand, and a stressor is any agent that produces stress at any time." Stressors can be loosely classified as direct physical systemic threats, e.g., starvation, cold, pain, hemorrhage, or "progressive threats," e.g., psychosocial threats such as defeat, separation, helplessness, and social isolation.

Allostasis is the ability to achieve homeostasis when a stress is applied to the system. Homeostasis is achieved via acute and chronic changes through the neuroendocrine axis (primarily the hypothalamic-pituitary-adrenal, or HPA, axis), the immune system, the autonomic nervous system,

and the cardiovascular system. The HPA axis responds to input by involving the immune, cardiovascular, and metabolic systems. Acute stress induces changes that are generally thought to be adaptive and essential, whereas chronic stress is thought to induce a higher physiological price by creating an allostatic load, defined as a long-term effect of physiologic response to stress.

While acute stress heightens cognition, these same responses when activated chronically are highly deleterious. It may injure hippocampal cells via cortisol release in response to CRF and ACTH. Such injury could lead to dysfunction and atrophy of critically important memory and emotional brain structure [91].

Chronic or cumulative stress, representative of lifetime exposure to adversity, is also thought to exert its influence through a "chain of risk," wherein early adverse life events increase the risk for later exposures. The cumulative stress, in turn, impacts physical, behavioral, and mental outcomes such as hypertension, pain, physical disability, psychiatric disorders, drug and alcohol abuse, and other chronic illness. Such chronic stress may impact the autonomic nervous system (ANS) and can be noninvasively measured by methods such as heart rate variability (HRV). Lower indices of HRV and altered ANS function may contribute to cardiac mortality, decrease vagal tone, and increase cardiac workload and endothelial dysfunction [92].

Simply asking a patient "What are the main stressors in your life?" can be very useful. Together the functional medicine practitioner and patient can generate a list of all the stressors, so that they can be tracked and addressed.

Like nutrition and exercise, there is a role for personalization in one's approach to stress, which can be encompassed in the diversity of modalities from which an individual can choose to modify their behavior to cope with it. This may include such mind-body practices as relaxation response developed by Herbert Benson, mindfulness-based stress reduction (MBSR) from Jon Kabat-Zinn, vipassana meditation [93], yoga, Kirtan Kriya, squared breathing, and diaphragmatic breathing.

Studies in the area of mind-body medicine are now becoming more molecular-focused. For instance, Balasubramanian et al. compared salivary expression of 22 differentially expressed proteins in subjects after 20 minutes of yogic breathing and those who chose to read a text of their choice. The subjects who practiced the 20-minute yogic breathing technique had increased salivary secretion which regulates digestive, nervous, immune, and respiratory systems. The researchers also elucidated that yogic breathing could potentially stimulate salivary expression of the nerve growth factor, a trophic factor involved in the development, maintenance, and survival of the peripheral nervous system and cholinergic neurons of the CNS that are significantly reduced in Alzheimer's disease patients [94].

Certain individuals may be epigenetically and genetically more inclined to respond to stress. Children subjected to abuse have decreased hippocampal expression of glucocorticoid receptor and heightened stress responses. Early stressed offspring must learn to adapt to environmental challenges and maintain stability through change, a characteristic referred to as "resilience." In addition to epigenetic effects, a number of genetic variants have been identified to cause altered response to stress and mood disorders. For example, polymorphisms in catechol-O-methyltransferase enzyme have been implicated in mental illness with the presence of certain SNPs resulting in susceptibility to posttraumatic stress disorder.

In summary, a functional medicine practitioner/nutritionist needs to not only understand the nutrition intervention aspect but also have insight into psychosocial and genetic aspect of an individual in order to better help the patient. Functional medicine can be integral throughout a patient's life, from prevention to preclinical symptoms to disease manifestation and progression [95].

Relaxation Response

Herbert Benson, MD, elucidated the physiological underpinnings of the trophotropic center – a combination of the parasympathetic nervous system, somatic muscle relaxation, and cortical beta rhythm synchronization. First, he described what he called "the four states": awake, sleep, dream, and the fourth state. The difference between the first three states and the fourth state is that the first three happen spontaneously, while specific actions are required to enter into the fourth state or what Benson initially called "eliciting the relaxation response (RR)."

- Comfort: Sit easily in a chair or on the floor.
- Quiet: Be alone in a spot where you will not be disturbed, i.e., no texts, emails, cell phones, etc., while eliciting the relaxation response.
- Tool: Focus on a word, thought, breathing, sound, or short prayer.
- Attitude: When other thoughts enter your mind, refocus on your tool to the exclusion of everything else for 10–20 minutes twice a day.

What Is Squared Breathing?

Squared breathing is just four simple breath segments done to a count of four.

- Inhale 2 3 4
- Hold 2 3 4
- Exhale 2 3 4
- Hold 2 3 4

Focus on the breath and the count of four; repeat the same process until you reach a relaxed state.

41.2.12 Referrals

There might be cases in practice when nutritional therapies, use of supplements, and lifestyle modifications show no improvement or benefit or only slight improvements. For a functional medicine practitioner, it is imperative to get to the root cause of the problem. In such cases, look for toxicity and underlying infections such as molds and their toxins, silicone breast implants and other implants, parasites, viruses, or Lyme disease and its co-infections. In such cases, refer the patient to a practitioner proficient in those areas.

No single practitioner – and no single discipline – can cover all the viable therapeutic options. Interventions differ by training, specialty focus, licensure, and even by beliefs and ethnic heritage. Practitioners in any specialty can, to the degree allowed by their training and licensure, utilize a functional medicine approach, including integrating the matrix as a basic template for organizing and coupling knowledge and data. So it is important to seek out other providers who have also acquired some functional medicine training, building a team of practitioners in the community you work with, whether in-office or virtual. Treatment success can be affected by the cultural bias of the patient and the provider, so get to know your colleagues in other fields.

Educate yourself about what other disciplines have to offer. As a nutritional practitioner, you may want to build up a team that includes physicians, a chiropractor, a naturopathic or osteopathic physician, an acupuncture specialist, practitioners trained in traditional Chinese medicine, a yoga instructor, practitioners trained in Ayurveda, a personal trainer, a psychologist, a functional medicine psychiatrist, and so on. It is beyond the mission of this chapter to discuss the training, scope of practice, or therapeutics of the many different healthcare approaches available today, but many publications and websites do provide such information. Developing a network of capable, collaborative healthcare practitioners with whom you can co-manage challenging patients and to whom you can refer for therapies outside your own expertise will enrich the care your patients receive and will strengthen the clinician-patient relationship. Many patients do not tell one practitioner about care they are receiving from other practitioners. Keep those lines of communication open and alive. All referral relationships should be handled with the same professionalism and courtesy.

41.3 Monitoring and Evaluating Interventions

At every follow-up visit, the nutrition practitioner monitors the amount of progress made toward the patient's goals and expected outcomes and compared to the patient's previous status. The four categories of outcomes that the nutrition practitioner monitors and evaluates are food- and nutrition-related outcomes (intake of food and dietary supplements, knowledge and beliefs, food availability, physical activity, nutrition, and quality of life); biochemical data, medical tests, and procedure outcomes; anthropometric measurement; and nutrition-focused physical findings.

Follow-up visits give the patient and practitioner the time and space to monitor and evaluate for compliance of nutrition intervention and laboratory biomarkers; clarify patients' questions or concerns and provide support; identify positive and negative outcomes; change nutrition behaviors with foods and supplements; implement other new behaviors, including sleep, exercise, relaxation, relationships, and hydration; and reinforce motivation and a sense of well-being for the patient until the patient reaches his or her goal. The follow-ups can be spaced out for longer duration at regular intervals during the maintenance phase until the patient is discharged.

42.1 Introduction

We so often hear the saying by Hippocrates, "Let food be thy medicine and medicine be thy food," but do we really pause to consider the meaning and relevance of his words? "Food as medicine" is using the functional characteristics of foods that allow the body to heal and function optimally. Medicine as our food is the idea that how we eat can be used on a daily basis, as a lifestyle or preventive medicine-type approach that will keep us well or prevent disease. This chapter will summarize and examine therapeutic diets from an integrative and functional perspective. We will describe dietary approaches used therapeutically by practitioners, the evidence for their use, the application, and any caveats or cautions for their use.

42.2 Defining "Therapeutic Diets"

The term "therapeutic diets" is defined by the Academy of Nutrition and Dietetics as "a diet intervention ordered by a healthcare practitioner as part of the treatment for a disease or clinical condition manifesting an altered nutritional status, to eliminate, decrease, or increase certain substances in the diet [1]." We will use this working definition of therapeutic diets within the context of nutrition approaches for integrative and functional medical nutrition therapy (IFMNT).

42.3 Traditional/Historical Perspective on Therapeutic Diets

In early civilizations, particularly of India and China, ancient traditions included dietary approaches to healing. These were some of the earliest documented accounts of using food as medicine. India's ancient healing paradigm, Ayurveda, is one of the oldest medical systems in the world. Its name is derived from Sanskrit words "life science" or "life knowledge." Ayurveda takes the approach to health with the belief that all aspects of an individual's lives are interconnected (humans, health, and the universe) [2]. Ayurveda also uses individual constitutions or "doshas" that characterize an individual's tendencies to disease and specific remedies, especially dietary recommendations.

Similarly, and slightly more recently, traditional Chinese medicine (TCM) is an ancient medical system that also uses therapeutic diets as part of its foundation to health. TCM is similar to Ayurveda in viewing human health as connected to the larger environment and universe as a whole [3].

42.4 Conventional Approaches to Therapeutic Diets (and the Nutrition Care Process)

Conventional nutritional approaches to therapeutic diets have included several categories of diet modifications, including nutrient modifications (i.e., macronutrients, micronutrients, fiber), texture or consistency modifications (mechanical soft, puree, etc.), food allergies and intolerance modifications, and additional feedings (snacks and oral supplements). Each of these is recommended based on assessment of the patient and recommendation by the doctor, another healthcare provider, and/or a registered dietitian.

42.5 Integrative and Functional Approaches to Therapeutic Diets (and the Nutrition Care Process)

IFMNT is a specific approach to medical nutrition therapy (MNT) that expands on the assessment portion of the nutrition care process (NCP). The NCP involves assessment, diagnosis (nutritional diagnosis), intervention, monitoring, and evaluation. An expanded assessment requires specific tools (including time) as a means to investigate core nutritional imbalances in patients. The IFMNT practitioner has the benefit of additional time with the patient, often spending 60–90 minutes for an initial consultation and close (often frequent) monitoring of interventions.

42.6 IFMNT Assessment Tools

Prior to an initial appointment, a patient completes paperwork that includes prompts about their goals, lifestyle barriers and challenges, health history, family history, social history, nutrition and diet histories, environmental exposures history, physical activity, dental history, symptoms, dietary supplementation and medication histories, and other backgrounds. During the initial consultation (often 60–90 minutes), the IFMNT practitioner will ask about any questions identified from the patient's initial intake forms. Through the interview, the IFMNT practitioner collects the patient's story (see ▶ Chap. 38 for more on the patient's story) and fills in any gaps left in the paperwork.

During the initial appointment, the IFMNT practitioner assesses more than just the patient's nutritional status and metabolism; she also assesses their readiness to change, self-efficacy, and level of feasibility to make necessary changes. The IFMNT practitioner will be able to help troubleshoot any of the patient's challenges to ensure that if the patient would like to make changes, they will be able to access the support they need to make them. Sometimes this involves family, friends, and their community to serve as caregivers or support systems (▶ Box. 42.1).

42.7 Commonly Used IFMNT Therapeutic Diets

There are countless "diets" widely promoted on the Internet and social media that may or may not be based on evidence and many that are conventionally accepted and used: carbohydrate counting for diabetic patients (often matching carbohydrate intake to insulin dosage) [4]; a "cardiac diet," which includes lowering total and saturated fat intake [5], sodium levels, and egg yolks; calorie counting for weight loss; and a general Mediterranean diet for heart health. These are generally well accepted in the conventional medical world but in a broad sense lack the nuance of each individual patient. The IFMNT approach to therapeutic diets is based on the foundational concept of evaluating the patient's nutrition status and implementing an intervention that is personalized to that individual.

42.7.1 Elimination Diets

Elimination diets (also called "exclusion diets") [6] are both a diagnostic tool to identify food adverse food reactions and a broad term for a systematic dietary approach to mitigate symptoms of adverse food reactions or to alter disease progression. At the extreme end, celiac disease and food allergies are conditions that necessitate the avoidance of certain foods to protect the patient from life-threatening illness. Less severe, but also on the spectrum of adverse food reactions, are food sensitivities and intolerances, which also warrant the elimination of certain foods (e.g., lactose or fructose intolerance or non-celiac gluten sensitivity); these have a less severe but still detrimental impact on one's health and often quality of life. Another category of conditions that may warrant an elimination diet are autoimmune diseases like rheumatoid arthritis [7] or Crohn's disease [8].

Although there has been skepticism of sensitivities to foods like wheat and gluten outside of overt celiac disease, evidence is emerging that there can be measurable physical changes in immune activation and cellular damage in people with wheat sensitivity without celiac disease [9]. Alessio Fasano [10] has contributed significantly to the evidence around characterization of non-celiac gluten sensitivity.

A PubMed search for "elimination diet" shows that most recent publications were specifically related to therapeutic use for eosinophilic esophagitis (EoE) [11–31]. When searching for "exclusion diet," one may find that most publications refer to inflammatory bowel diseases [6, 32–38]. Terminology of elimination diets seems to vary by diagnosis or area of research. Other conditions studied for the therapeutic use of elimination diets include irritable bowel syndrome (IBS) [39, 40], autism spectrum disorder [41–43], migraine headache [44], and others.

The elimination diet is often used by individuals who suspect they have food intolerances. Food intolerances are adverse food reactions that are not overt food allergies (mediated by immunoglobulin E (IgE)). Food intolerances involve an adverse reaction to food due to a lack of adequate amounts of an enzyme to digest the food (e.g., lactose intolerance is a deficiency of the enzyme lactase) [45]. Food sensitivities are a non-IgE, immune-mediated reaction to a food when ingested. These are often less severe reactions like adverse digestive symptoms (stomach pain, bloating, nausea, breathing problems, eczema, brain fog, etc.). Non-celiac gluten sensitivity is a condition characterized by adverse symptoms (fatigue, digestive problems, brain fog, etc.) caused by ingestion of gluten without having classic characteristics of celiac disease [10]. Although the mechanism is not fully understood, some hypothesize that the adverse reaction may be due to histamine intolerance [46]. Further, evidence suggests that the pathophysiology of celiac disease is related to a response by the adaptive immune system, while non-celiac gluten sensitivity is a reaction by the innate immune system [47]. This phenomenon has been measured via fecal assays suggesting an immune reaction to gluten/dairy [48].

People with IBS often try to eliminate certain foods (e.g., gluten and dairy) in an attempt to alleviate symptoms [40]. A low FODMAP diet is another version of an elimination diet with compelling evidence that it contributes to amelioration of IBS symptoms [49].

42.7.1.1 Implementation of an Elimination Diet

Elimination diets are often followed for 4–12 weeks (the time period foods are withdrawn) with additional time to systematically reintroduce foods back into the diet. To begin, a person avoids one or several foods for the specified time period. During that time, the individual keeps a diary of their dietary intake and symptoms (see Fig 42.1) to ensure that suspected foods are completely removed and there aren't any hidden sources of the food(s) remaining in the diet. Symptoms are recorded, along with the time and food eaten, to note any patterns in food ingestion with elicited symptoms. At the end of the period of elimination, each of the eliminated foods is reintroduced ("challenged") back into the diet, one-by-one, to determine which (if any) foods elicit symptoms. If the person has an adverse response to the food, they are to eliminate it again, wait for the symptom(s) to subside, and try another new food to assess tolerance. After all foods are reintroduced or "challenged" back into the diet, then the person can wait another period of time before trying to reintroduce any remaining foods again.

42.7.1.2 Types of Elimination Diets

There are many dietary approaches that aren't necessarily referred to as "elimination diets" but may fall within the general umbrella of the term: foods are eliminated with the expectation that symptoms or signs of disease or illness may improve. Examples of elimination diets include (1) the Paleolithic or ancestral diet (Paleo diet) [50], (2) a low FODMAP diet (fermentable oligo-di-monosaccharides

Reviewed by _____ **Date/Time** _____

Table 42.1 Potential vulnerabilities

Eliminated food	Macronutrient vulnerabilities	Micronutrient and phytonutrient vulnerabilities
Gluten [54]	Fiber, carbohydrate	Iron, folate, calcium, selenium, magnesium, zinc, niacin, thiamin, riboflavin, vitamins A and D
Dairy	Protein, fat	Calcium, potassium, phosphorus, vitamin A, vitamin D, vitamin B12, riboflavin, niacin
Soy [55]	Fiber, protein	Calcium, B-vitamins, iron, zinc
Egg [56]	Protein, fat/cholesterol	Choline, retinol (vitamin A), vitamin E, thiamin (B1), riboflavin (B2), niacin (B3), pantothenic acid (B5), pyridoxine (B6), folate (B9)
Nuts [57]	Mono- and polyunsaturated fatty acids, protein, fiber	Vitamins E and K, folate, magnesium, copper, potassium, selenium, carotenoids, antioxidants, phytosterols
Grains [58]	Fiber, carbohydrate	Folate, thiamin, iron, niacin, riboflavin, vitamin B6, zinc, sodium
Paleo (Free of grains, dairy, legumes) [50]	Fiber, carbohydrate	Folate, thiamin, iron, niacin, riboflavin, vitamin B6, vitamin B12, zinc, sodium, calcium, potassium, phosphorus, vitamins A and D
Low FODMAP [51]	Fiber, fat	Iodine, selenium
Specific carbohydrate diet [32] (study in pediatric population)	Fiber (due to rationale for the diet)	Vitamin D, calcium [32] (limited data and study in pediatric population)

and polyols): eliminating all categories of highly fermentable carbohydrates and reintroducing them back into the diet one FODMAP category at a time) [51], and (3) the specific carbohydrate diet [32]. Other approaches involve individualized elimination diets based on food sensitivity testing (IgG blood testing) to determine which foods to eliminate [52]. Even a low-histamine diet and a ketogenic diet (high fat, low carbohydrate) could be considered elimination diets, and they will be covered later in this chapter. Although there have been clinical trials on the implementation of elimination diets [53], there is still a lot to be learned about elimination diets and their indication and safe implementation.

42.7.1.3 Cautions for Elimination Diets

A major concern for the implementation of an elimination diet is the risk for nutritional deficiencies or insufficiencies, especially if followed for a long period of time. Table 42.1 summarizes the potential macro- and micronutrients that may be insufficient in someone following an elimination diet.

42.7.2 Low-Histamine Diet

A low-histamine diet is one of several specialized food patterns to assist patients with food sensitivities, food intolerances, and/or food allergies. Focusing on this specific diet is

warranted, as this is a therapeutic diet that is seemingly more and more common. Many integrative and functional nutrition practitioners are noticing an increase in patients needing support for histamine intolerance.

Histamine belongs to a family of biogenic amines that are classified into monoamines and polyamines. Monoamines are derived from one ammonia molecule, NH3, where one of the hydrogen molecules is dropped and replaced with another chemical structure. Polyamines have more than one NH3 starter group. Five commonly known monoamines are histamine, serotonin, dopamine, norepinephrine, and epinephrine [59]. Another trace monoamine is tyramine, which can be yet another cause of biogenic amine-related food intolerance. To understand histamine, it is helpful to understand genetic and biochemical possibilities. Several boxed genetic notes are provided for more in-depth understanding.

> Genetics Note 1: the enzyme histidine decarboxylase (HDC) is made from the HDC gene. Its purpose is to convert the amino acid histidine into histamine. In some individuals, genetic variants may cause an increase or decrease in the enzyme function possibly resulting in too much or too little histamine. Active Vit B6 or P-5-P is a required cofactor of HDC [60]. Some fish are high in microbes that are capable of producing HDC that, when consumed by some individuals who do not clear histamine well, can contribute to histamine overload [61].

Histamine is most recognized for its role in symptoms associated with classic allergy in IgE-mediated immune system activation: hives, tissue swelling, nasal congestion, asthma, headaches, oral allergy symptoms, and gastrointestinal complaints. However, histamine has many beneficial roles in human function including neurotransmission, gastric acid secretion, inflammation and immune system support, and smooth muscle tone [60].

Those with histamine intolerance may be affected by a variety of sudden onset and seemingly unexplainable symptoms such as flushing, hives, rapid heartbeat, profuse sweating, nosebleeds, car sickness, migraines, itchiness, and more. For a comprehensive lists of symptoms of histamine overload, see references listed below, especially the books by Jarisch and Lynch.

42.8 Where to Find Histamine

Histamine intolerance may actually be an imbalance between histamine production and accumulation and the ability to degrade histamine. The body is capable of making histamine and storing it in specialized immune cells called mast cells. Mast cells are sentinel cells found primarily in mucosal tissue that help initiate an inflammatory response when a threat is detected. Releasing histamine is important for immune function, unless the mast cells are overactive. This is a phenomenon known as mast cell activation disorder (MCAD) [62]. Because mast cells live in the mucosal lining of the gut, if the gut lining is inflamed for any reason, mast cells may become activated and/or have the opportunity to migrate from the mucosa system-wide due to leaky mucosal tight junctions [63].

Histamine load may also come from food, especially food subject to spoiling or degradation as microbes degrade the amino acid histidine in food with the HDC enzyme and make histamine. Foods rich in protein are culprits, but so are foods and beverages allowed to ferment, such as wine, sauerkraut, and kombucha. Foods high in protein will be degraded by microbes after cooking, raising histamine content. While refrigeration will slow histamine production, only freezing will stop histamine content from increasing [64].

Allergies to food and the environment are the more obvious sources of histamine production. IgE-type allergy testing may be warranted to reduce load [64]. Elimination of antigens and/or treatment for allergic-type hyper-response may be needed.

The stress response may increase histamine production [65]. Assisting patients with stress management is key in regulating histamine load.

Estrogens (both naturally occurring and estrogen-mimicking "xenoestrogens") also contribute to the histamine load [66]. Assessing patients for estrogen dominance and genetic risk for estrogen dominance may be helpful. Lifestyle and dietary interventions to reduce estrogen involve avoiding exposure to plastics or heating food in plastics. Increasing cruciferous food intake is also supportive to decrease estrogen.

Emerging evidence suggests that specific species of gastrointestinal microbes produce histamine. Examples are *Lactobacillus casei*, *Lactobacillus delbrueckii*, and *Lactobacillus bulgaricus*. Testing for small intestine bacterial overgrowth may be a diagnostic tool in determining if dysbiosis may be an underlying contributor. Certain microbes are known to assist with histamine degradation such as spore-based probiotics, *Lactobacillus plantarum*, *Lactobacillus rhamnosus*, and *Bifidobacterium longum* [63].

> Genetics Note 2: the enzyme catechol-O-methyltransferase (COMT) made by the gene of same name is important for estrogen degradation. Individuals who are homozygous positive for variants may have estrogen dominance and benefit from estrogen clearing support. SAMe (methylation ability), magnesium, and vitamin C are cofactors for COMT [67].

Based on the above-described reasons that histamine may accumulate and individual sensitivity to histamine, it is best to describe histamine intolerance as "histamine overload." When the body is unable to handle the load, histamine can build up and eventually "spill over" the tolerable limit for the individual and create a histamine response.

42.9 How Can We Support Histamine Overload?

1. Decrease the dietary load. Limit very high histamine foods: red wine, champagne, aged cheeses, cured meat and fish, bone broth and fish stock, vinegar and fermented foods such as sauerkraut, and chocolate. A more comprehensive list of high and moderately high histamine foods is available in the references. Patients may benefit from suggested meals and meal plans based on lower histamine foods.
2. Avoid fish high in histamine unless very fresh or fresh and flash frozen.
3. Avoid or limit eating leftovers. Freeze leftovers for future reheating and consumption.
4. Assess genes that may influence the ability to degrade histamine. See boxed notes for DAO and HNMT genetics.
5. Support with probiotics (mentioned above) that are known to degrade histamine.
6. Identify possible allergens and eliminate and/or refer for treatment.
7. Assess for gut inflammation and/or SIBO and support as needed
8. Support with nutrients and/or supplements known to support degradation of histamine such as selenium, quercetin, vitamin C, stinging nettle, EGCG (primary catechin in green tea), and the DAO enzyme [68, 69].
9. Collaborate with other healthcare providers who may be able to offer support with prescription antihistamines. Be aware that many antihistamines decrease stomach acid secretion that may result in low vitamin B12. Consider assessing for B12 deficiency.
10. Assist with stress management techniques.

Genetics Note 3: the enzyme diamine oxidase (DAO) is produced by the cells that line the gastrointestinal tract. DAO is a key enzyme that degrades dietary histamine in the extracellular space (especially the gastrointestinal tract). Individuals with significant genetic variants might be impaired at making adequate DAO. Even without genetic variants, a damaged gut lining may impair DAO production. DAO is available as a supplement that is recommended for use as 15 minutes prior to consuming high histamine foods. Vitamin B6 is a cofactor for DAO [68, 69].

Genetics Note 4: the enzyme histamine N-methyltransferase (HNMT) degrades histamine inside the cell. It is primarily concentrated in the liver. Individuals with significant genetic variations may benefit from additional cofactor support to help speed up HNMT which is SAMe [68, 69].

Genetics Note 5: the enzyme monoamine oxidase B (MAOB) provides an important step in the histamine degradation pathway. HNMT degrades histamine to N-methylhistamine, which then is further degraded by MAOB so the body can finally get rid of the histamine. If MAOB is not working well due to lack of cofactor and/or presence of genetic variants through feedback inhibition, HNMT slows down making histamine buildup. The easy fix is a trial of the cofactor vitamin B2 (riboflavin) as about 400 mg taken 2–5 times a week [68, 69].

42.9.1 Low-Carbohydrate High-Fat Diet

"There has been a dramatic resurgence of interest in the ketogenic diet during the past several years," as stated in a 1997 review article by Swink et al. [70]. This original study emphasized the utility of the KD in treating children with epilepsy starting in the 1920s, which then fell out of favor in the 1970s due to the invention of antiepileptic medications. The 1997 paper mentioned the return of interest in the KD in severe cases of pediatric epilepsy when medications did not work. The same research team published a follow-up review in 2007, *The ketogenic diet: one decade later*, where they acknowledged that this diet, with evidence of use as far back as 500 B.C., was maintaining its momentum after 10 years [71]. This food trend continues to thrive as numerous research teams are diving into its many health applications [70–78].

This summary of the KD will be referred to from this point on as the low-carb high-fat or low-carb healthy fat (LCHF) food pattern. Many health professionals are making the transition to using the term LCHF due to the negative and often misunderstood confusion between nutritional ketosis and diabetic ketoacidosis.

42.10 How Do Diabetic Ketoacidosis and Nutritional Ketosis Differ?

Diabetic ketoacidosis is an acute life-threatening condition usually only seen in type 1 diabetes and rarely in type 2 diabetes [79]. In diabetic ketoacidosis, there is too little insulin to control a sharp rise in glucose and ketones, a result of an acute (usually within 2–4 hours) onset of a catabolic state [80]. Other biomarkers include a pH less than 7.0, a bicarbonate less than 10 mEq/L, and an anion gap >15 mEq/L. Blood ketones are measured as beta-hydroxybutyrate with serum levels >8 mmol/L [80] or 15–25 mmol/L [72]. Notice that researchers do not agree on a standard level for beta-hydroxybutyrate, but the combination of the above markers is what is significant. This combined "perfect storm" can result in a critical threat warranting immediate medical treatment.

Nutritional ketosis is a mild form of ketosis where blood glucose is relatively low, blood pH remains within normal reference ranges, and blood ketone values usually are between 0.5 and 5 mmol/L [74]. Medically therapeutic ketosis for treating epilepsy ranges from 2.0 to 7.0 [81].

Table 42.2 Macronutrient percentages

Macronutrients as percent of total kcals	Standard American Diet [82]	Paleo diet [83]	Mild LCHF diet [72, 73]	Moderate LCHF diet [72, 73]	Medically therapeutic LCHF (epilepsy and Alzheimer's disease [70, 73]
Carbohydrate	50	22–40	20	10–15	7–8
Protein	15	19–35	20	15–20	12–13
Fat	35	28–47	65	70	79–80

42.11 What Is LCHF?

A LCHF food pattern is high in (healthy) fat, adequate or moderate in protein, and low in carbohydrates. Healthy fats are considered, in the context, to be fats derived from whole food sources (grass-fed meat and poultry, avocados, olives, cold-pressed oils, butter, etc.) versus fats derived from chemical and heat processing (seed and soy-based oils). This pattern is able to assist the human body in making ketone bodies for energy. The formation of ketones for energy occurs with fasting, prolonged exercise, and very low carb intake. Comparing the macronutrient percentages of LCHF variations with the standard American intake may be helpful as listed in Table 42.2. The Paleo diet was included for additional reference as this food pattern, which emphasizes a whole food approach to food intake, is often used as a reference template for LCHF.

42.12 What Are the Benefits of LCHF?

Scientists are rapidly studying many possible benefits of a LCHF food pattern. Research covers a wide range of hypotheses from effects on exercise performance to metabolic derangement to chronic disease. Here is a summary of some of the current findings.

42.12.1 Carbohydrate Restriction in Cancer Therapy

First, note that not all cancers are related to diet, such as those associated with virus, environmental exposures, age, and genetic mutations [74]. However, when these types of cancer are diagnosed and treated, diet can be an important factor in outcomes.

Some common cancers have been linked to dietary influences. These cancers include breast, colon, some lung, prostate, and gallbladder/biliary cancers and endometrial adenocarcinoma. These cancers are linked to hyperinsulinemia based on data from people with diabetes mellitus (DM) [84–86]. A therapeutic diet could be one that promotes lower insulin and may be helpful in cancer prevention. Dr. Dawn Lemanne is recommending a moderate carbohydrate restriction of about 100 grams of net carbohydrates per day in breast cancer and in stage III colon cancer in those with BMI >25 [74, 75]. The breast cancer recommendations come from the large WHEL (Women's Healthy Eating and Lifestyle) and WINS (Women's Interventional Nutrition Study) trials [87, 88]. A LCHF food pattern may also increase lifespan of those with glioblastoma and metastatic glioblastoma [77, 78].

In addition to insulin, other biomarkers may be considered. An observational study of 269,391 participants in Korea over 2 years between 2002 and 2005 found that all-cause mortality, including cancer, was lower in those with higher blood lipids [89]. Certainly clinical trials are needed to verify this, but studies such as this support possible benefits to higher lipids which can occur in some people following LCHF.

The LCHF food pattern may support starving cancer cells of glucose. The energy demand of cancer cells dependent on glucose for energy is about twenty times greater than normal cells. This altered energy utilization and increased demand is known as the Warburg effect [76].

When should LCHF be avoided in cancer? Genetic mutations such as the BRAF V600E mutation result in dietary fat-fueled tumor growth [90]. Note that some cancers are learning to use other sources of fuel such as protein, amino acids, and fats instead of glucose [91–93].

Rationale for benefits of a LCHF dietary pattern

1. Alzheimer's disease: LCHF resulting in mild to metabolically therapeutic level of ketone production is recommended by The Bredesen Protocol to End Alzheimer's for three reasons: (1) to provide an alternative energy source to brain cells, (2) to decrease neural inflammation, and (3) to increase brain-derived neurotrophic factor [73].
2. Cardiometabolic disease: LCHF may support reversing chronic diseases such as type 2 DM, blood lipid dysregulation, hypertension, obesity and overweight, and chronic inflammation and decrease the need for insulin in type 1 DM [72, 94].
3. LCHF has been shown to enhance athletic performance, especially in endurance athletes [95].
4. LCHF may simplify food intake as many find this food pattern more satiating with a reduction in cravings for carbohydrates and the need to eat frequently [72, 94].

42.13 Who Should Avoid LCHF?

Many people are finding benefit from increasing healthy fats while lowering carbohydrates. As more adopt this food pattern and research data accumulates, we may find additional

reasons to avoid LCHF, but at this time the only recommended avoidance is for starting this food pattern during pregnancy [72, 94]. The most important consideration when adopting LCHF is a slow acclimation and progression to LCHF to assist the body to adapt to using fat for fuel over carbohydrates to avoid possible flu-like symptoms and muscle cramps [96].

42.14 Intermittent Fasting

Intermittent fasting (IF) is the conscious choice to abstain from food for health-promoting reasons such as spiritual, cleansing, or detoxing or as a method to ameliorate a disease. IF is also referred to as time-restricted feeding or periodic fasting. This section will refer to IF but could mean any of the three above titles. Intermittent fasting is not starvation. Starvation is a state of forcefully being deprived of food such as lack of availability (war or famine) or withholding food. Note: anorexia nervosa is considered a form of purposeful food refusal involving complex emotional, social, mental, and nutrition-related factors. Appropriately, this discussion does not include anorexia nervosa.

Fasting has no set duration. It is a cycle of consuming food followed by an abstinence period from food. The concept of IF represents cyclical and pre-planned periods of fasting followed by appropriate food intake. This could be simply avoiding food intake between meals, i.e., avoiding snacking between a standard breakfast and lunch. Other examples of fasting cycles are overnight, alternate-day, or extended-day fasts. The modified, shorter versions of fasting are showing promise with many health benefits and are more appealing to the general population over extended fasts. IF can be eucaloric or hypocaloric and still result in positive outcomes. The variability in fasting regimens allows the healthcare professional to individualize the needs of patients. Many patients benefit from individualized guidance on how to implement a fasting protocol based on health goals and reason(s) for fasting. Understanding the basics of fasting will provide guidance for patient support.

42.15 Benefits of Intermittent Fasting

A 2017 review by Patterson et al. [97] found that IF supports weight loss, improves metabolic health markers, and may influence other aspects of health, such as improved sleep circadian rhythm and microbiome biology. Some of the metabolic health markers include lipids, such as lower total cholesterol, lower LDL cholesterol, improved HDL cholesterol, lower triglycerides, and improved blood glucose and insulin. A more recent review found that most evidence related to IF and weight loss and improved lipid profiles are observational and suggested the need for more clinical studies to confirm these initial findings [98].

Regarding weight loss, IF is supportive as a manageable method for caloric restriction, promoting adipose thermogenesis, and altering the gut microbiome to increase metabolism via influences on adipose tissue [99–101]. Stockman et al., in a 2018 review, summarized findings in animal models showing that IF may reduce oxidative stress, improve cognition, and slow down the aging process [102]. This same review found that while the human clinical trials are small (many with fewer than 300 participants), they are showing evidence of sustainable weight loss and improved insulin sensitivity.

IF between meals and overnight is a newer dietary therapy for digestive problems such as inflammatory bowel disease (IBD), irritable bowel syndrome (IBS), and small intestine bacterial overgrowth (SIBO). The author (TL) uses IF for 12 hours overnight and 4–5 hours between meals for bowel rest with good clinical and anecdotal success for these gastrointestinal (GI) conditions. This concept is based on the work of Mark Pimentel, MD, the director of the GI Motility Program and Laboratory at Cedars-Sinai. He has authored many papers, and his book, *A New IBS Solution*, describes the migrating motor complex (MMC) function in the gastrointestinal tract [103]. The MMC is a wavelike pulse that has been shown to sweep microbes and food debris out of the small intestine helping to prevent SIBO. He describes the MMC as pulsing naturally about every 90 minutes when food is not present. He has found that when the MMC runs 10–12 times every 24 hours, IBS/SIBO treatment is optimized. This can only occur during intermittent fasting states instead of the conventional ideal of eating three meals and two to three snacks each day. Additionally, bowel rest has traditionally been used for IBD conditions for the past 40 years as a method to decrease inflammation. IF is a method to provide rest intermittently with nutritious food intake [104, 105].

Prominent clinicians are using varying methods of IF to support treatment of some chronic diseases. One example is Dr. Jason Fung, MD, Canadian nephrologist and head of the Intensive Dietary Management program to support weight loss and type 2 diabetes reversal. He teaches both low-carbohydrate diets and IF to patients. Dr. Fung has written two books on his methods noted in the references. He is collecting data in his clinic and shares many clinical and anecdotal stories about his success using his protocols to reverse diabetes, a disease that conventional wisdom has touted as being progressive, insidious, and irreversible [94, 106]. Because Dr. Fung's IF methods are individualized to each patient, such as 12-hour overnight fasting, between-meal fasting, and/or alternate-day or extended-day fasting, refer to his books for further examples and application. He shares clinical assessments to ensure safe implementation of IF.

Dale Bredesen, MD, neurologist and founder of MPI Cognition, studies Alzheimer's and other neurodegenerative diseases. A key dietary aspect of his protocol is IF. Dr. Bredesen recommends a 12-hour overnight fast on a daily basis, but those with increased genetic risk are instructed to extend their fast more. Those with the ApoE 3/4 genetics for Alzheimer's risk use a minimum 14-hour overnight fast, and those with the ApoE 4/4 genetic variants for Alzheimer's risk are instructed to use a minimum overnight fast of 16 hours. The goal is to produce a state of mild nutritional ketosis to help fuel the brain, optimize brain mitochondrial function, and reduce neural inflammation [73].

Also noteworthy is the research by Valter Longo, PhD, Professor in Gerontology and Professor in Biological Science, University of Southern California. His clinical animal trials have yielded the following findings [107, 108]:

- IF is chemo protective because it protects normal cells from treatment side effects. When starved, normal cells slow division, which is protective during cancer treatment. However, when cancer cells are starved, they continue dividing because their growth switch is broken in the "on" position making them more vulnerable to treatment.
- IF sensitizes tumor cells to chemotherapy treatment.
- IF slows tumor growth even without chemotherapy.

In 2010, a group of ten volunteer patients requested that Dr. Longo use them in a human trial with a model used in his rodent trials. At the time, he refused, citing many concerns that included unlikely IRB approval. The group of patients said they would attempt his animal model fasting techniques on their own, and he was invited to take notes. The results of this volunteer study were published in 2012 with the following findings [109, 110]:

- Fasting was well tolerated with some mild lightheadedness and weakness (temporary).
- Fasting reduced fatigue.
- Fasting reduced overall weakness.
- Fasting resulted in fewer gastrointestinal side effects.
- No adverse effects on tumor volume or serum tumor markers were identified.
- The proposed mechanism is that fasting enhances leptin sensitivity and lowers insulin (a growth hormone).

Note: this study included ten volunteers with various malignancies. They fasted 48–140 hours prior to chemotherapy and for 5–56 hours following.

42.16 Concerns and Special Considerations for Intermittent Fasting

Concerns and considerations for IF vary depending on the model. These are summarized below based on Dr. Jason Fung's book and on the clinical experience and application of IF by the author (TL) [106]. A literature review did not reveal any specific scientific studies on possible harm with IF, although basic understanding of physiology, psychology, and biochemistry provides background to address concerns and considerations.

- Making drastic, significant changes: Many patients get enthusiastic about fasting, which can lead to discouragement and failure. Proper assessment for readiness and appropriate stage is important. Starting small, like fasting overnight for 12 hours and/or helping patients restructure meals to feel satiated (often with higher healthy fat and higher fiber options), will help with a between-meal fast.
- Electrolyte imbalances: Some patients may experience symptoms such as dizziness, headaches, and muscle cramps. Patients should be carefully monitored and provided with electrolyte replacement if warranted, along with plenty of water during any fast [106]. Be aware for extended fast, usually beyond 3 days, risk of refeeding syndrome is possible [111].
- Coach patients about managing feelings of hunger. Hunger tends to come in waves so strategies to assist through these sporadic periods are important. Some strategies include drinking a glass of water or a cup of green tea, taking a walk, or engaging in an activity that requires concentration; staying busy during the fasting period can be helpful.
- Many overeat when breaking a fast, especially longer fasts. Patients need to be guided in breaking a fast, such as planning a small snack to start with or pretend he/she never fasted and eat a normal meal.
- Advise patients that they should not make an announcement about their fast. Many people will think fasting is extreme and may not be supportive. Suggest that patients only share this with a few supportive people.
- Heartburn can be a problem when breaking a fast. This can be avoided by consuming smaller meals after fasting.
- Some patients may need to take medication during a fast. Dr. Fung suggests that while fasting patients can eat a few pieces of lettuce before swallowing medications [106].
- Patients on blood sugar-lowering medication need to carefully monitor blood glucose levels and seek assistance on altering medication doses during fasting, if needed.
- Patients with diagnosed eating disorders should not fast. Each situation needs to be assessed. For example, a mother of teenage girls may want to avoid fasting due to risk of influencing possible disordered eating in her children.

42.17 Different Methods of Intermittent Fasting

The studies of IF have been difficult to review due to varying models. Table 42.3 below summarizes the most commonly used fasting models. Some fasts encourage water-only fasting with electrolytes, as needed. Other models, especially when combined with a low-carb high-fat protocol, allow for consumption of fat such as MCT oil or cream and/or bone broth during the fast. Beverages such as coffee or tea with added cinnamon and/or added fat are acceptable according to some providers [106]. Another type of fast called the 5:2 fast suggests continuing normal dietary intake for 5 days out of the week; the other 2 days are fasting days that allow for intake of 0–600 kcals from protein, fat, and non-starchy vegetables. A primary goal of many fasting models is a compressed eating window (CEW). Because eating food (some foods more than others) creates an inflammatory response, a CEW is often recommended as a method to decrease inflammation [104, 105]. A CEW may also support gastrointestinal conditions mentioned above like IBD, IBS, and SIBO.

Table 42.3 Types of intermittent fasting

Type of intermittent fasting	Description
Time-restricted fasting	Compressed eating window such as 12:12 (fasting for 12 hours followed by food intake occurring during the next 12 hours). Other examples are 14:10, 16:8, 18:6, and 20:4
Time-restricted fasting for cancer prevention and treatment (breast, colon, and glioblastoma) [112]	13-hour overnight fast: not eating from 6 p.m. until 7 p.m. the following day
Time-restricted fasting for Alzheimer's prevention and/or reversal [73]	3/12–16: (3-hour fast between dinner and bedtime with an overnight fast of 12–16 hours depending on ApoE 4 genetics)
5:2 fast	Eat normal intake for 5 days during the week. For two consecutive or nonconsecutive days, eat 0–600 kcals of protein, fat, and non-starchy vegetables
Alternate-day fasting [106]	For alternating days during the week, fast for 20–24 hours such as Monday, Wednesday, and Friday. For example, eat dinner on Sunday night at 7 p.m. and avoid eating again until 5 p.m. on Monday[a]
Extended fasting [106]	Fasting for 2–14 days. Note: fasting beyond 3 days may increase risk of refeeding syndrome
Extended fasting as an adjunct to cancer treatment [112]	Fasting 24–48 hours prior to chemotherapy and for as long as possible after as applied by Dr. Dawn Lemmane based on research by Dr. Valter Longo

[a]Coffee or tea with added fat such as MCT oil or cream and/or bone broth is considered acceptable or as a strict water-only fast. Electrolytes are recommended during alternate-day and extended-day fasts [106]

42

42.18 Summary and Conclusion

Therapeutic diets have been used for thousands of years for the purpose of promoting health and healing. The modern IFMNT approach involves applying the nutrition care process in order to personalize the therapeutic use of nutrition, food, and targeted supplements. The IFMNT practitioner should be aware of the nutritional vulnerabilities (potential nutrient deficiencies) of each individual diet and ensure that any dietary intervention provides adequate amounts of macronutrients, micronutrients, and phytonutrients, which can be achieved by foods and/or supplements.

43.1 Trends in Dietary Supplement Use

Complementary and integrative healthcare includes a selection of modalities, products, and dietary approaches that usually begin outside the biomedical or modern healthcare system. This may include chiropractic, naturopathic medicine, functional medicine, massage therapy, acupuncture and traditional Oriental medicine, nutritional medicine, and mind-body therapies [1, 2]. When evaluating the use of integrative healthcare in the population, published reports consistently place the frequency from 32% to 62% [3, 4]. In an analysis of the 2012 National Health Interview Survey, it was determined that 59 million Americans had at least 1 payment dedicated to complementary health with $30.2 billion in total out-of-pocket expenditures, which included $14.7 billion for visits to practitioners and $12.8 billion for purchases of natural products [5]. The total out-of-pocket expenditures for purchases of natural supplements increased significantly as family income increased and the total spent ($12.8 billion) represented approximately 24% of out-of-pocket expenditures ($54.1 billion) for prescription drugs.

From a sample of 89,000 Americans, it was determined that nonvitamin, nonmineral dietary supplements remained the most prevalent complementary health approach in use when examining trends from 2002, 2007, and 2012 [3]. Investigators determined that participants reported taking at least one of the following supplements within the prior 30 days: fish oil, glucosamine or chondroitin, probiotics or prebiotics, melatonin, Coenzyme Q–10 (CoQ10), *Echinacea*, cranberry (pills or capsules), garlic supplements, ginseng, *Ginkgo biloba*, green tea pills (not brewed tea), or EGCG pills [4], "combination" herb pills, MSM (methylsulfonylmethane), milk thistle (*Silybum*), Saw palmetto, and Valerian [3, 6]. Supplement use was also found to be associated with female gender, older age, more education, any physical activity, and being of normal weight or slightly underweight [4]. The top-selling herbal supplements in 2016 included Ashwagandha (*Withania somnifera*), cranberry, and turmeric (*Curcuma longa*) [7], which are summarized in Table 43.1. Ashwagandha sales were found to increase approximately 55% from 2015 to 2016, and sales of turmeric alone topped $47 million. In individual populations, supplement use was found to be common in cardiac patients [8], cancer patients [9], hospitalized patients [10, 11], the military [12], those with sickle cell disease [13], and among athletes [14, 15]. Although supplement use continues to be widespread, there remains considerable confusion about how best to navigate the marketplace, wade through the myriad of products and their formulations, and arrive at the most appropriate product choice for an individual's healthcare needs [16–18].

Table 43.1 Change in sales of top selling herbal supplements in 2016

Ingredient	Latin binomial	Total sales	Change from 2015
Ashwagandha	*Withania somnifera*	$8,732,489	55%
Cranberry	*Vaccinium macrocarpon*	$7,513,172	36%
Turmeric	*Curcuma longa*	$47,654,008	32%
Horsetail	*Equisetum* spp.	$5,334,706	16%
Dandelion	*Taraxacum officinale*	$2,520,049	15%
Mushrooms	Order *Agaricales*	$4,527,372	14%
Cherry fruit	*Prunus* spp.	$3,507,680	13%
Kava	*Piper methysticum*	$3,232,327	10%
Ginger	*Zingiber officinale*	$2,454,767	9%

43.2 A Growing Marketplace

Analysts have been assessing the ebb and flow of the dietary supplements mentioned above as well as the broader nutraceutical marketplace for decades. According to PricewaterhouseCoopers Global (Global PwC), nutraceutical sales were estimated at $142 billion in 2011 and were expected to grow to $180 billion into 2017 [19]. BCC Research projected that the market would grow to $199 billion in 2016 while adding growth of functional beverages and functional foods upward of $71.5 and $64.6 billion, respectively [20]. According to a recent report by Zion Market Research [21], the global, nonvitamin, nonmineral dietary supplement market was valued at $133 billion in 2016, increasing to well over $220 billion (US) by 2022. These analyses suggest dietary supplements are a very large and expanding market. The use of the Internet for patient-directed purchasing and expanding markets in Eastern Europe, India, and China [22] will ensure steady growth in all of these sectors for decades to come.

43.3 Nomenclature and Formulations

One of the first legally acceptable definitions of dietary supplements was put forth in the federal Dietary Supplement Health and Education Act (DSHEA) of 1994. The historical underpinnings of DSHEA are rooted in the Food Supplement Amendment or the Proxmire Amendment, also known as "the Vitamin Bill," S.2801, introduced in the 93rd Congress between 1973 and 1974 [23]. The Proxmire Amendment was proposed to set forth the potency of ingredients of vitamin and mineral products that are not inherently dangerous. When introduced in 1973, its language included, "shall not limit the potency, number, combination, amount, or variety of any synthetic or natural vitamin, mineral, or other nutritional substance, or ingredient of any food for special dietary uses if the amount recommended to be consumed does not ordinarily render it injurious to health." Two decades later, DSHEA amended the

Federal Food, Drug, and Cosmetic Act [23–25] and defined a dietary supplement as:

» ...a product other than tobacco, intended to supplement the diet, that contains a vitamin, mineral, herb or botanical, dietary substance, or a concentrate, metabolite, constituent, extract, or combination of the above ingredients; that is intended for ingestion, is not represented as food or as a sole item of a meal or diet, and is labeled as a dietary supplement; that includes an article approved as a new drug, certified as an antibiotic, or licensed as a biologic and that was, prior to such approval, certification or licensure, marketed as a dietary supplement or food, unless the conditions of use and dosages are found to be unlawful; and excludes such articles which were not so marketed prior to approval unless found to be lawful. Deems a dietary supplement to be a food.

This definition lays the groundwork for the regulatory aspects of DSHEA, which will be discussed below, but it does little to provide practical education to healthcare providers, practitioners, and patients. For example, the common term "dietary supplement" may refer to a large range of ingredients including vitamins, minerals, botanical and/or herbal products (concentrates, metabolites, constituents, and extracts), fish oils, amino acids, glucosamine, creatine, and essential fatty acids [6]. These products can be found sold and marketed as single ingredients or in a multitude of combinations [26], as well as added as ingredients to medical foods [27], functional foods [28], and/or beverages. In contrast to dietary supplements, the Food and Drug Administration (FDA) distinguishes prepared tube feedings as medical food in the use and dietary management of a specific disease or health-related condition that causes distinctive nutritional requirements different from healthy people and "formulated to be consumed or administered *enterally* under the supervision of a physician [28]." However, "functional" foods and beverages do not have a formal FDA designation and are commonly defined based on ingredients, formulations, and label or health claims.

In addition to taking into account the broad definition of dietary supplements put forth under DSHEA, when selecting or advising patients on the most appropriate choice for them, it is critical to understand the common forms by which dietary supplements are delivered and find their way into foods, beverages, and the multitude of products in the marketplace [25, 29]. An overview of some of the most common forms that product ingredients are available is provided in ▶ Box 43.1. From bulk herbs (which can be purchased by the pound) to essential oils (by the ounce) to common lozenges, tablets, and topicals (creams, gels, salves, poultices, clay, and lotion), most individual products limit themselves to one "form," such as in a Calendula cream, a cranberry (fruit) or turmeric (root /rhizome) extract [25, 30–34]. Other manufacturers may combine numerous forms into complex combination products with 15 to 25 or more individual components, not including binders, fillers, and additives. These combinations may include vitamins; minerals; glandulars; fatty acids; probiotics; bulk botanicals parts (fruit, leaf, or root); botanicals in the form of dried, crystallized solid extracts; and essential oils [4, 30, 35–37].

Box 43.1 Common Forms and Delivery of Dietary Supplements

- *Bulk herbs* – Minimally processed herbal material (sort, cut, and dry)
- *Capsules* – Encapsulating a defined amount of liquid or powder into a gelatin capsule
- *Essential oil* – Distilled aromatic oils, applied orally, via inhalation, or topically within a fixed oil
- *Extracts* – Process of concentrating an herb with a specific solvent
- *Extract, decoction* – Raw herbal material (stems, roots, leaves) boiled in water to concentrate
- *Extract, fluid* – Herbal mixtures (alcohol, glycerine, vinegar, water) concentrated via evaporation
- *Extract, solid* – Fluid extracts concentrated via evaporation to form a solid (soft or crystalline)
- *Extract, tea* – Steeping fine herbal material in water to concentrate water-soluble material
- *Extract, tincture* – Soaking herb in alcohol and water to concentrate alcohol-soluble components
- *Glandulars* – Animal gland extracts (thyroid, adrenal)
- *Homeopathics* – Ultradilution of a variety of materials (animal, vegetable, or minerals)
- *Lozenges* – Candied, gummy, tableted, sublingual
- *Spa therapy* – Baths, colonics, steam, wraps, sauna
- *Suppositories* – Material combined and delivered in a vehicle (glycerine)
- *Tablets/pill* – Compressing a defined amount of active material under force
- *Topicals* – Balm, creams, gels, slaves, poultice, clay, and lotion

In addition to the delivery form and/or route, it is critical to consider that different forms may be easier to absorb or deliver a higher dose as compared to another. For example, although not set in stone, a good rule of thumb to follow is that as the form of (a botanical) product becomes more concentrated, the strength and dose may increase. So the bulk herb may be less potent when compared to its solid extract, i.e., potency of bulk herb < tea < decoction < tincture < fluid extract < solid extract [38]. In addition, scientific advances in the formulation of plant extracts have led to changes in how healthcare practitioners approach drug delivery. These new systems, which include nanoparticles, nanocapsules, liposomes, phytosomes, nanoemulsions, and microspheres, are transforming product solubility, bioavailability, and stability, which ultimately will lead to enhanced biological activity and novel clinical applications [39]. Therefore, the forms, dosage, and standardization information should be clearly presented on all dietary supplement bottles and delivery devices to help guide the consumer, patient, and healthcare team. Caution should be exercised as the same product formulated differently may impart a variety of biological effects. For example, consider green tea and its L-theanine (γ-glutamylethylamide) extract, which is now widely used as a mild anxiolytic as opposed to a low-dose caffeine stimulant [40].

43.4 Dietary Supplement Labels

The Department of Health and Human Services' Office of Inspector General (OIG) outlined several key aspects of dietary supplement labels that are required to ensure that consumers make the best possible choices to increase safety and lower risk when selecting products [41]. In the report "Adverse Event Reporting for Dietary Supplements, an Inadequate Safety Valve," the OIG presents a template composed of two main elements: [1] label content (ingredients, intended use, safety information, directions for use, and product information) and [2] label presentation (standardized format, distinct product features, readability, balance, and constructive use of space). Ingredients should be listed fully and clearly and reflect the accurate amount per serving and per bottle as much as possible. Intended use would distinguish "support to health" from health claims, which require scientific validation. Information on safety should include potential interactions or contraindications, such as whether it is safe in pregnancy. Directions for use may include suggested dosage, if known. Product information would identify the manufacturer, lot, and possibly gross and net amounts of the ingredients listed. The label presentation template provides details on consistency, similar types of information in a similar order, design, and format, made easy to understand by a wide range of consumers and provides information in a balanced manner (benefits, risks, claims, and facts) while using product packaging to provide additional sources of information beyond the nutrition facts panel.

43.5 Nutrition Facts Panel Selection and Dose

In addition to being able to identify the list of key components on dietary supplement labels, a more pressing issue is selecting and distinguishing a product based on the individual ingredient(s), their forms or parts used, as well as additional additives such as dyes, binders, and fillers. In Table 43.2, examples of some of the most common forms of vitamin, mineral, and botanical ingredients are highlighted. Vitamin A can be found as acetate, beta carotene, mixed carotenoids, palmitate [42], and vitamin B12, in either the cyanocobalamin or methylcobalamin form [43]. Calcium carbonate is said to be cheaper and harder to absorb than citrate, but a clinical determination must be made when choosing citrate over malate or pantothenate [44]. When choosing iron for a patient with gastrointestinal upset [45], would the best choice be ferric (citrate, sulfate) or ferrous (aspartate, fumarate, sulfate, gluconate) conjugates, and are these best delivered in liquid, tablet, or fortified in food [46]?

To many, interpreting botanicals within dietary supplements is even more overwhelming when compared to vitamin and mineral ingredients [6, 36, 47]. Once the botanical therapeutic is chosen based on the health indication, the genus and species should be verified, and then a determination must be made to validate that the dietary supplement contains the correct part and therapeutic strength of the extract [36, 37, 48]. For example, with *Camellia sinensis* or green tea, identifying that material as a leaf extract is very straightforward, since tea is derived from or is the leaf product. Next is the therapeutic determination of a dose and delivery provided by a wide range (10–50%) of total polyphenols or the individual green tea polyphenols, such as catechin, epicatechin gallate, epigallocatechin, gallic acid, and/or epicatechin [49]. Both the ranges (%)

Table 43.2 Common forms of dietary supplement ingredients

Vitamin/mineral ingredient	**Common forms**
Vitamin A	Acetate, beta carotene, mixed carotenoids, palmitate
Vitamin B12	Methylcobalamin, cyanocobalamin
Calcium	Carbonate, citrate, dibasic calcium phosphate, malate, pantothenate
Vitamin D	Cholecalciferol-D3, ergocalciferol-D2
Vitamin E	Tocopherols – alpha, beta, delta and/or gamma
Folate	Folic acid, L-5-MTHF- Metafolin®
Iron	Ferric (citrate, sulfate), ferrous (aspartate, fumarate, sulfate, gluconate)
Magnesium	Glycinate, malate, oxide, stearate, sulfate
Selenium	Sodium selenite, selenomethionine
Zinc	Citrate, gluconate, oxide, sulfate
Botanical ingredient	**Form, part, and standardization**
Camellia sinensis	Green tea: leaf extract – 30–50%, polyphenols, EGCG, picatechin, epicatechin gallate, epigallocatechin, catechin, gallic acid
Echinacea purpurea	Herbal: stem, leaf, and/or flower extract, 3–4% phenolics
Curcuma longa	Turmeric: rhizome or root extract. 70–95% curcuminoids
Allium sativum	Garlic: bulb and/or oil extract. % Alliin, allicin, diallyl sulfide, or ajoene
Ginkgo biloba	Ginkgo: leaf extract (1:4–50:1). 6–24% heterosides, terpene lactones
Hypericum perforatum	Hypericum: aerial/herb. 0.3% hypericins
Polygonum cuspidatum	Resveratrol: root extract. 5–50% trans resveratrol
Rhodiola rosea	*Rhodiola*: root extract. 0–30% rosavins (rosarin, rosavin, rosin)
Serenoa repens	Saw palmetto: fruit extract. 45% fatty acids
Tanacetum parthenium	Feverfew: aerial, leaf extract. 0.4% to 0.7% parthenolide

and content of polyphenols may vary widely. With *Allium sativum*, or garlic, the consumer must distinguish between the garlic bulb and oil, if it was extracted, and what percentage of common sulfur-containing compounds (alliin, allicin, diallyl sulfide, or ajoene) is represented in the product [50]. For all botanical ingredients, high-quality products should clearly distinguish the part (aerial, bulb, fruit, leaf, herb, rhizome, or root), as well as if there is a particular marker compound to which the botanical ingredient has been standardized. Most should be clearly defined, such as *Boswellia serrata* gum extract (standardized to alpha and beta boswellic acids), *Curcuma longa* rhizome extract (standardized to total curcuminoids), *Crataegus oxyacantha* leaf and flower extract (standardized to total flavonoids), *Coleus forskohlii* root extract (standardized to forskolin), and *Tanacetum parthenium* feverfew leaf extract (standardized parthenolide). It is also important to consider that marker compounds [51] may be different from the active compounds, if they are known, and the product should be dosed accordingly.

Also as part of the manufacturing process, additives are commonly used to preserve, bind, absorb moisture, add color, smooth or distribute flavor, and provide a coating and moisture barrier. See Table 43.3. When selecting a product, the educated consumer should question whether additives are necessary, cause harm, or should be avoided if sensitive or intolerant [52]. For example, gelatin, gellan gum, and microcrystalline cellulose are naturally derived additives, whereas butylated hydroxytoluene or BHT [53], polyethylene glycol, polyvinyl alcohol, and FD&C colorants are not [54]. Consider if the effectiveness and quality of the dietary supplement are altered when individual additives are removed or remain in the product. Additionally, as the dietary supplement market continues to expand, manufacturers are constantly adding new products and formulations. This requires that healthcare providers and patients continually educate themselves and be aware of the benefits and risks of the individual ingredients as well as therapeutic goal of the combined product.

Table 43.3 Common additives found in dietary supplements

Common additives	Function	Avoid or consider
Butylated hydroxytoluene (BHT)	Preservative – prevents oil oxidation	Avoid
Corn Starch, modified	Binder/filler – absorbs moisture	Avoid
FD&C Blue 1, Yellow 6, Red 40	Colorant	Avoid
Gelatin	Collagen containing gelatin capsule	Consider
Gellan gum	Stabilizer-bacterial fermentation	Consider
Lactose	Milk sugars – thickener, filler	Consider; avoid if intolerant
Magnesium stearate	Excipient, binder	Avoid
Maltodextrin	Thickener, filler – prevents crystallization	Consider
Microcrystalline cellulose	Bulking agent and filler	Consider
Parabens	Preservative and anti-microbial agent	Avoid
Polyethylene glycol	Flavor distribution (GRAS)	Avoid
Polyvinyl alcohol	Coating agent-moisture barrier	Avoid
Silicon dioxide	Anti-caking agent	Avoid >2% by product weight
Talc	Absorbs moisture, debulking agent	Avoid

43.6 The Role of Government Regulations

Since DSHEA, government agency oversight of dietary supplements and their regulation is complex and still evolving. The Congress of the United States granted authority to the FDA and FTC to provide oversight of manufacturing and health claims on food labels as well as false advertising [29, 55, 56]. The FDA regulates foods, drugs, and cosmetics in interstate commerce, and new drugs are not allowed to be introduced into interstate commerce until they are proven safe and effective for their intended use. Foods have different regulatory requirements and commonly bypass safety and efficacy trials. Currently dietary supplements and botanical new drugs in the United States are entitled to a waiver when conducting preclinical and pharmacology/toxicology studies. As with new pharmaceutical drugs in development, genotoxicity testing is required. Due to the lack of metabolic safety data, the FDA and NIH are considering mandating that genotoxicity testing be carried out on botanicals and herbal supplements in initial clinical trials under an IND application as an added layer of regulation and mechanistic testing.

As products become more and more concentrated (pineapple vs bromelain or green tea vs L-theanine) and their biological activity enhanced through specialty delivery mechanisms, the historical divide between drugs and foods and drugs become blurred. DSHEA allows manufacturers to distribute dietary supplements without having to prove safety and efficacy, so long as the manufacturers use good production practices and make no specific claims linking the supplements to treating a specific disease state [55–57]. State laws also play a small role in the regulation use and distribution of supplements through scope of practice, professional licensure, and malpractice coverage of prescribing healthcare providers. Regarding licensure, each state has enacted unique medical licensing that prohibits the unlicensed practice of medicine and thereby criminalizes activity by unlicensed providers who offer healthcare services to patients. Similarly,

scope of practice defines how these nutritional interventions may be applied. Discussions of liability have arisen when providers prescribe biologically active dietary supplements, which have drug-like activity (with potential side effects) but are regulated as food. The definitions of liability are no different in integrative medicine practice as compared general medicine; however, its application for use as a tool to provide legal protection and fill the regulatory gap produced by DSHEA raises novel questions that require consideration.

The Food and Drug Administration's Center for Food Safety and Applied Nutrition Adverse Event Reporting System, or CAERS [29], is one of the only mechanisms in which surveillance is carried out and reports on safety are generated. According to Schmitz, the CAERS reports were relatively small in number, had incomplete validation, and had inconsistencies within and are currently inadequate. He concluded that the concept and application of *Nutravigilance* or "the science and activities relating to the detection, assessment, understanding, and prevention of adverse effects related to the use of a food, dietary supplement, or medical food" require the entire industry to be proactive, systematic, and risk-based and must apply a scientific approach to all product safety. Only then can the public have full confidence that the products they choose are safe.

43.7 Supplement Selection and Education

In addition to suggestions from family and friends, patients who use dietary supplements are largely dependent on advice from online websites and manufacturer's label claims, both of which tend to diminish useful information on potential prescription-supplement interaction, which can be observed in the clinic [17, 58]. As outlined in ▶ Box 43.2, ask patients open-ended questions without judgment: Why are you taking this? Who suggested you take it? How did you arrive at the product, dose, and form? Do you have clear expectations of health outcomes to be evaluated, and do you understand interactions or potential side effects? It is critical that patients discuss their intended or current use with their entire healthcare team and practitioners must be proactive in querying patients. By asking straightforward commonsense questions within the patient intake or via discussion, providers can engage patients, gain their trust, and learn about their home health habits and the degree to which they may be self-prescribing appropriate or inappropriate dietary supplements.

In investigating the attitudes and beliefs providers and patients have toward supplements, Tarn and colleagues [59] discovered that there were several topics that were identified as important to all parties. Summarized in ▶ Box 43.3, all supplements should be discussed and the potential for supplement-supplement or supplement-drug interactions outlined, and providers need to advise and provide an evidenced-based opinion about the supplements their patients take. Patients have numerous concerns about dose ranges, what is therapeutically optimal, and what, if any, risk is there in overdosing. Physicians and the healthcare team ought to provide additional options or alternatives to prescription medications and discuss the accuracy of information acquired from outside sources. Lastly, there is an increasing interest for consumers to understand more details about such supplement characteristics as their composition, if they should be natural or synthetic, and their purity and quality.

Box 43.2 Questions to Ask When Taking Dietary Supplements

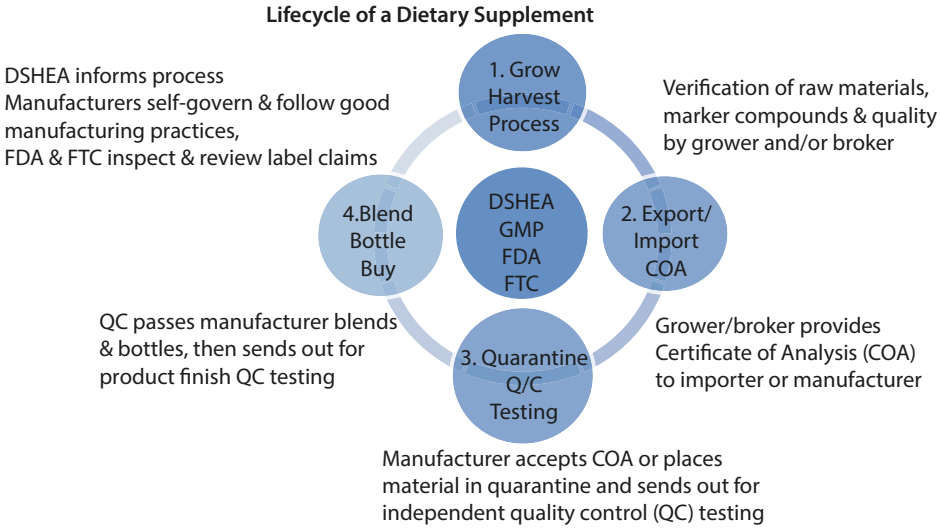
1. Why am I taking this?
2. Who suggested I take this?
3. What are the health or medical indications for use?
4. What dose and duration are appropriate?
5. What is the optimal form to take?
6. What other ingredients contribute or detract from effectiveness?
7. Are there any safety concerns or interactions?
8. Are laboratory tests required?
9. Do I have clear expectations of outcomes and need to reevaluate?
10. Do I understand signs of any potential side effects?

Box 43.3 Common Supplement-Related Topics Important to Providers and Patients

- All supplements taken by a patient should be mentioned during medical visits
- Supplement-drug interactions and potential effects or adverse events should be discussed
- Importance of providers advising or providing an opinion about supplements
- Potential benefits and risks of overdosing on supplements should be discussed
- Patients believed that doctors should talk about alternatives to prescription medications
- Providers discuss accuracy of information (friends, iInternet, television, other providers)
- Supplement characteristics, composition, purity, quality, natural or synthetic

43.8 Quality Control and Safety

One of the most concerning aspects of dietary supplements is fully understanding quality control and being able to guarantee product safety [32, 60–62]. There is an urgency to acquire reputable information assuring both that the individual is selecting the best product for their health interest and that manufacturers provide premium product formulated with the highest quality, safety, and stability. As an overview of this process, consider the life cycle of a dietary supplement or an individual ingredient as it goes into making single or combination products (◘ Fig. 43.1). In this example, we will use *Ananas comosus*, the common pineapple. During every step of the process, the source product and extracted material (bromelain, the enzymatically active pineapple



Lifecycle of a Dietary Supplement
DSHEA informs process
Manufacturers self-govern & follow good manufacturing practices,
FDA & FTC inspect & review label claims
1. Grow Harvest Process
Verification of raw materials, marker compounds & quality by grower and/or broker
4.Blend Bottle Buy
DSHEA GMP FDA FTC
2. Export/ Import COA
QC passes manufacturer blends & bottles, then sends out for product finish QC testing
3. Quarantine Q/C Testing
Grower/broker provides Certificate of Analysis (COA) to importer or manufacturer
Manufacturer accepts COA or places material in quarantine and sends out for independent quality control (QC) testing

Fig. 43.1 Life cycle of a dietary supplement

extract) require verification [63, 64]. Beginning with step #1, the pineapple is grown and harvested and bromelain processed. Pineapple is verified through organoleptic techniques (inspection via sense organs such as sight, taste, odor color, texture) to determine maturity and ripeness. To obtain bromelain, the primary raw material, mature stems are then processed via maceration, centrifugation, extraction, and drying. The marker compounds (bromelain) are verified via high-performance liquid chromatography (HPLC) and Fourier-transform infrared spectroscopy (FTIR) after which product activity or potency (strength of enzymatic activity) is assessed. In step #2, this information, as well as basic quality control testing (for heavy metals and microbial profile), is summarized in a certificate of analysis (COA) by grower and/or broker, and the product is available for import to the manufacturer. Upon acquiring the raw material, step #3, the dietary supplement manufacturer decides to accept the COA and may begin product formulation, or the material is placed into quarantine and independent quality control (QC) testing begun. This is one of the key differentiators of what determines the quality of finished products on the shelf. Since many of the raw materials, such as bromelain, are supplied by the same companies, it is the verification and validation of the COA and by testing each lot that makes the difference. Once the product passes this secondary QC testing, the manufacturer can, in step #4, blend, formulate, bottle, and send out the finished product for one final round of authentication testing. Those companies that pay for testing of each lot of every ingredient that they use are generally very willing to share this information. Lastly, this life cycle of a dietary supplement, albeit complex, is similar for almost all ingredients described under DSHEA. The manufacturers largely self-govern and are required to follow good manufacturing practices. The FDA can inspect facilities and hold manufacturers accountable for documenting and maintaining strict oversight of the life cycle, whereas the Federal Trade Commission reviews label claims and issues surrounding advertising.

One of the best series in understanding the complex process of dietary manufacturing and quality control was published in "Integrative Medicine: A Clinician's Journal" from 2007 to 2009 [31, 65–68]. In this brief series, the issues of quality control and quality assurance are clarified. "Simply put, quality control is conducting *testing* and performing the procedures to ensure that established quality specifications for raw material and finished products are met. Whereas quality assurance is the *strict regulation* of all of the *processes* used to create the final product." It is very important to consider that a manufacturer may have a robust quality assurance program while actually conducting very little quality controls testing. A dietary supplement manufacturer can have established raw material, and finished product specifications as part of a GMP certification process have assurance processes in place, but some or all its products may not meet standards of acceptable quality control. Such products can be low or high potency, contaminated, and adulterated (contain unwanted ingredients such as pharmaceutical drugs) and have poor stability and lose potency over the duration of their shelf life. Consider that the FDA cGMPs do not mandate that manufacturers establish high-quality specifications; they just must meet specifications, which may unfortunately turn out to be low quality.

43.9 Engaging Manufacturers

One of the best ways to ensure that dietary supplements are of highest quality is to ask the salesperson to differentiate between products or directly ask the manufacturer to answer your questions. As practitioners, patients, or providers who use dietary supplements, the goal is to ensure that products exceed all regulatory requirements and are clinically effective and safe for use. It is difficult to improve health and succeed without reputable, high-quality materials and services. Therefore, we want to work with outstand-

ing dietary supplement manufacturers and their products that meet and exceed national standards set forth by DSHEA, FDA and USP, and GMP and published in the Federal Register. It is good to recognize suppliers who provide legitimate proof through documentation that their products consistently meet label claims, are authentic, and lack contamination or adulteration and assure raw material and finished product authenticity and stability. When trying to ensure that the supplements you are taking are safe, here are ten questions to consider asking dietary supplement manufacturers (► Box 43.4). This list is a summary from Dr. Liva's quality control and quality assurance series, which provides a more comprehensive and detailed list in the Supplier Certification Questionnaire, which he created and is accessible online [65, 67, 68].

Box 43.4 Ensuring Supplement Quality via Manufacturer-Directed Questions

1. Does your quality control department have the authority to approve and reject procedures, specifications, test methods and results, raw ingredients and components, finished ingredients, packaging materials, and labels?
2. Do you have a cGMP system? Which do you follow: Ffood cGMPs or FDA cGMPs for dietary supplements?
3. Have you been independently certified for cGMP compliance via USP, NSF, and/or NPA?
4. Do you use an in-house lab or contract lab? How are they audited?
5. When conducting testing of raw materials, are they checked for microbiology profile (bacteria, yeast, and mold), identity (authenticate material or botanical genus and species), potency (if potency claim exists), heavy metals (lead, mercury, cadmium, arsenic), chemical solvent residue, aflatoxins, and herbicide and pesticide residue?
6. Do you accept a certificate of analysis (COA) in lieu of independent testing of raw materials?
7. Are your finished products tested for label claim potency prior to release for sale?
8. Do you put expiration dates or a use-by date on your products?
9. Do you conduct label claim stability testing, verifying product through its expiration date?

Reputable manufacturers should be able to provide written examples of #2, #3, #5, #8, #9, and #10 (► Box 43.4) above by providing the testing information for two or three lots of a random product you select from their catalog. The manufacturers may need assurance that this is for patient safety and educational purposes only and, if reputable, should respond quickly. It has been the experience of the author that if companies readily conduct these tests, PDFs can be emailed within 2–24 hours. If companies choose to exclude product details that may reveal intellectual property on a research or patent basis, then select another basic product from their catalog, such as a multivitamin, B complex, or a 1–5 botanical combination, to determine the degree to which the manufacturer is adhering to or exceeding quality control testing standards.

43.10 Clinical Relevance and Controversies

The health outcomes and clinical benefits attributed to dietary supplements remain highly controversial and debated topics. It is important to note that the field is regulated (see ► Box 43.5). In terms of the general benefit to society and individual populations, there are numerous studies which suggest that dietary supplements may improve overall health and specific aspects of quality of life. A report by the US Centers for Disease Control and Prevention suggests that three in ten people experience selected nutritional deficiencies [69]. Blumberg et al. reviewed nutrient intake data in more than 10,000 adults recorded in the National Health and Nutrition Examination Surveys and determined that, as compared to food alone, the added use of dietary supplements significantly increased an average of 15 out of 18 nutrients assessed and reduced nutrient inadequacy rates [69]. Elia and colleagues examined the cost-effectiveness of using nutritional supplements (energy-/protein-enriched functional foods, vitamins, and/or minerals) in community and home care environments [70]. Their group conducted a systematic review of high-quality publications and found that both short-term and long-term use produced significant cost savings. In addition to cost benefits, the authors noted clinically relevant benefits such as improved quality of life, lower infections, and postoperative complications.

Box 43.5 Government, Regulatory, and Association Resources

- *National Institutes of Health Office of Dietary Supplements:* ► https://ods.od.nih.gov/HealthInformation/makingdecisions.sec.aspx NIH ODS provides a variety of information for consumers, researchers, and professionals including dietary supplements fact sheets, consumer safety updates, and a dictionary of terms used throughout healthcare and supplement industry

- *The US Food and Drug Administration*: ► https://www.fda.gov/Food/DietarySupplements/ Information for consumers and industry on dietary supplement products, ingredients, recalls, and adverse event reporting
- *The Herbal Medicine Institute and the American Botanical Council*: ► http://abc.herbalgram.org/site/PageServer Council provides reliable information on botanicals and natural products and advocates for consumers and industry.
- *Consumer Healthcare Products Association (CHPA)*: ► https://www.chpa.org/ CHPA advocates for consumers and industry and provides educational tools to ensure safe use of dietary supplements and OTC medicines
- *Dietary Supplement Label Database*: ► http://dsld.nlm.nih.gov/dsld/ Searchable database of ingredients, products, and ~2500 manufacturers

There is also growing clinical evidence for the use of select categories of supplements in well-defined clinical populations. For example, the effect of dietary prebiotics on gut microflora and metabolism in human subjects was reviewed by Kellow and Reid [71, 72]. In 26 trials with more than 830 subjects, prebiotics were found to significantly reduce postprandial glucose and insulin, whereas effectiveness against lipids, inflammatory markers, and immune function was inconsistent. Green tea and its polyphenols have been determined to have numerous beneficial health effects [49]. Tea and its extracts act as antioxidants, reduce oxidative stress, provide defense against inflammation in cardiovascular disease, and modulate key metabolic pathways such as NF-kB and cyclooxygenase. Mechanistic studies have implicated a role for green tea in inflammatory bowel disease, apoptosis, neurodegeneration, fatty liver disease, cognitive function, and metabolic weight loss.

Turmeric, or *Curcuma longa*, has a long history of therapeutic use as a natural botanical in the Indian healing system of Ayurveda. In modern times, turmeric and its concentrated extracts are being investigated for its ability to act as an anti-inflammatory agent and improve dermatologic diseases [73], radiation-induced dermatitis [74], and arthritis [75]. Due to a lack of comprehensive and definitive research on efficacy, some investigators are calling for the public to abstain from use curcumin until both the benefits and potential side effects are thoroughly documented [76]. In addition to turmeric, one of the most commonly used and top selling herbs (from Table 43.1) is *Withania somnifera*, or Ashwagandha, also known as Indian ginseng. The therapeutic use of Ashwagandha spans psychiatric disorders to fertility. Modern research is beginning to validate its plant extracts to support patients in obsessive-compulsive disorder [77], fertility [78], sexual function [79], and anxiety [80].

When reviewing the strength of the literature and drawing clinical conclusions on individual supplements or categories, consider the robustness of the research design. ▶ Box 43.6 lists some common peer-reviewed sources for information. Is the research conducted in cell culture systems, in acceptable preclinical or translational animal models, with human subjects as uncontrolled observation study, or in an experimental research design (the most rigorous) such as a prospective randomized controlled trial [81]? Before making final judgments on clinical application, also take into consideration if the dietary supplement product categories are generally considered safe and supportive to the clinical area of concern.

In addition to the numerous potentially beneficial dietary supplements listed above, there remain several controversial categories that should be avoided. The majority of complaints to both FTC and FDA come from the dietary supplement specialty areas of sexual enhancement [82–88], weight loss [89–93], and sports/fitness [94–98]. Complaints in these categories range from false advertising, overaggressive sales tactics, and unsubstantiated health claims to product adulteration, contamination with prescription medications, "filler" dietary supplements, unnecessary window dressing, or poor-quality and untested product. Healthcare practitioners can check for regular FDA online alerts on fraudulent, adulterated, or contaminated supplements at ▶ fda.gov. Examples of products which have received warnings include:

1. Sexual enhancement: Tyrannosaurus (contained Viagra), Rhino 69 (contained sildenafil), Triple Green Capsules (contained Viagra), Big Penis Male Sexual Stimulant (contained Viagra), Black Mamba (contained Viagra), Kingdom Honey for Him (contained Cialis), African Viagra (contained Viagra), Duramaxxx (contained Viagra), My Steel Woody (contained Viagra), and Own the Knight 1750 (contained tadalafil and dapoxetine).
2. Weight loss: Asia Slim (contained sibutramine, diazepam, and bisacodyl), Queen Slimming Soft Gel (contained fluoxetine and sibutramine), Physic Candy (contained sibutramine), Skinny Bee Diet (contained desmethylsibutramine), ABX Weight Loss (contained sibutramine), Ultimate Lean (contained sibutramine), Dream Body Extreme Gold (contained sibutramine, fluoxetine, and sildenafil), Ultimate Body Tox (contained sibutramine), and Fruta Planta Life or Garcinia Cambogia Premium (contained sibutramine).
3. Sports/fitness: the ▶ bodybuilding.com company alone conducted a nationwide recall of more than 50 supplements because of possible adulteration by prescription and nonprescription steroids marketed as "Superdrol," "Madol," "Tren," "Androstenedione," and/or "Turinabol." Other individual products to avoid include Msten Extreme Mass Builder, Penta Built, Cannibal Pro Cutting Stack, Mass Destruction, Mayhem and Wolverine Xtreme, or Beast Stack.

If the pitches and marketing, such as a 110% money back guarantee, or the product itself seems too good to be true, then it probably is [48, 59]. It is important to use common sense by avoiding these categories of dietary supplements altogether and focusing on lifestyle modification such as healthy diet, exercise, stress reduction, and maintaining proper sleep-work balance.

Clinically it is critical to address the patient's interest in these products and bring questions back to the entire healthcare team. An appropriate care plan may include laboratory testing that could rule in or out the need for taking specific nutrients, as well as aid in product dosage, duration of use, and need for retesting. It is now common to test for many vitamins and minerals, such as B6, B12, iron, zinc, magnesium, calcium, and specialty supplements that may be related to biologically active biomarkers (homocysteine, folate, CoQ-10, essential fatty acids), as well as for steroid hormone cascades (DHEA, pregnenolone, testosterone, and cortisol). Also, with increasing age and prescription drug use, the potential for interactions increases. Evaluating the potential mechanisms of action of supplements and their pathways of detoxification, such as inhibition or induction of Cytochrome P450 enzymes (CYP450), may be critical, especially for those on life-sustaining medications which act through similar pathways. For supplements to be the most clinically relevant and beneficial, they should be used with good clinical judgment in the context of the best available information.

43.11 Summary

For consumers and patients who commonly use integrative medicine modalities, the overall goal of adding dietary supplements into a treatment plan is to maintain health, prevent future health issues, lower the risk of requiring heroic interventions, and reduce reliance on prescription medication. The added goals of the treatment team are to help patients navigate the complex and fast-moving regulatory terrain of the supplement industry and to help choose the most appropriate products in the proper form at the right dosage. At the same time, product safety must be assured while limiting any potential side effects or drug interactions and validating that the treatment course will be effective or efficacious when possible. When selecting dietary supplements, consider that there are numerous issues relating to nomenclature. Understand the unique and varied forms, dosage, potential combinations, and additives. Always read supplement labels carefully, and clarify any questions on formulations or unfamiliar delivery systems such as phytosomes and nanoemulsions. The nutrition facts label should be clear and easy to read and provide information about ingredients, dosage, serving size, and any known contraindications. The healthcare team must openly discuss, in a non-threatening and non-judgmental manner, all health-related information on use of dietary supplements. If needed, both consumers and practitioners can actively engage and request clarifying and quality control testing information that covers the entire life cycle of the supplement from manufacturers within the nutraceutical marketplace. Product safety depends on numerous factors which include growing conditions, herbicides and pesticides used in cultivation, formulation, additives, importation, the manufacturing processes and the use of multistage testing procedures, as well as industry manufacturing and government regulation. Those manufacturers, who are reputable and of high quality, who utilize good manufacturing practices, and who perform independent quality control testing, should make testing results available (barring any intellectual property issues) for each lot that they manufacture. Many will provide this information directly to the healthcare practitioner, which is critical to truly ensure product quality. In order to avoid unwanted exposure to adulterated and potentially contaminated dietary supplements, avoid the "terrible three" categories which include sexual enhancement, weight loss, and sports and fitness. Also avoid products that advertise by way of 2:30 a.m. infomercials. Acquiring a more comprehensive understanding of the dietary supplement landscape will help to ensure safer use, improve the clinical experience for those participating in healthcare, and maximize opportunities for health benefits.

Learning Objectives

By the end of this chapter, the reader will be able to:

- Describe the role of monitoring and evaluation from a functional medicine perspective in providing high-quality care to clients
- Explain how nutrition professionals use nutrition care indicators to monitor and evaluate the progress of clients
- Apply monitoring and evaluation principles including professional goal setting in a case example

44.1 Monitoring and Evaluation as a Step in the Nutrition Care Process

44.1.1 Definitions of Monitoring and Evaluation

Monitoring and evaluation is considered the fourth and final step of the four-step Nutrition Care Process (NCP) approach (Fig. 44.1). This stage of the NCP is unique in that it often spans multiple visits. At the initial visit, monitoring and

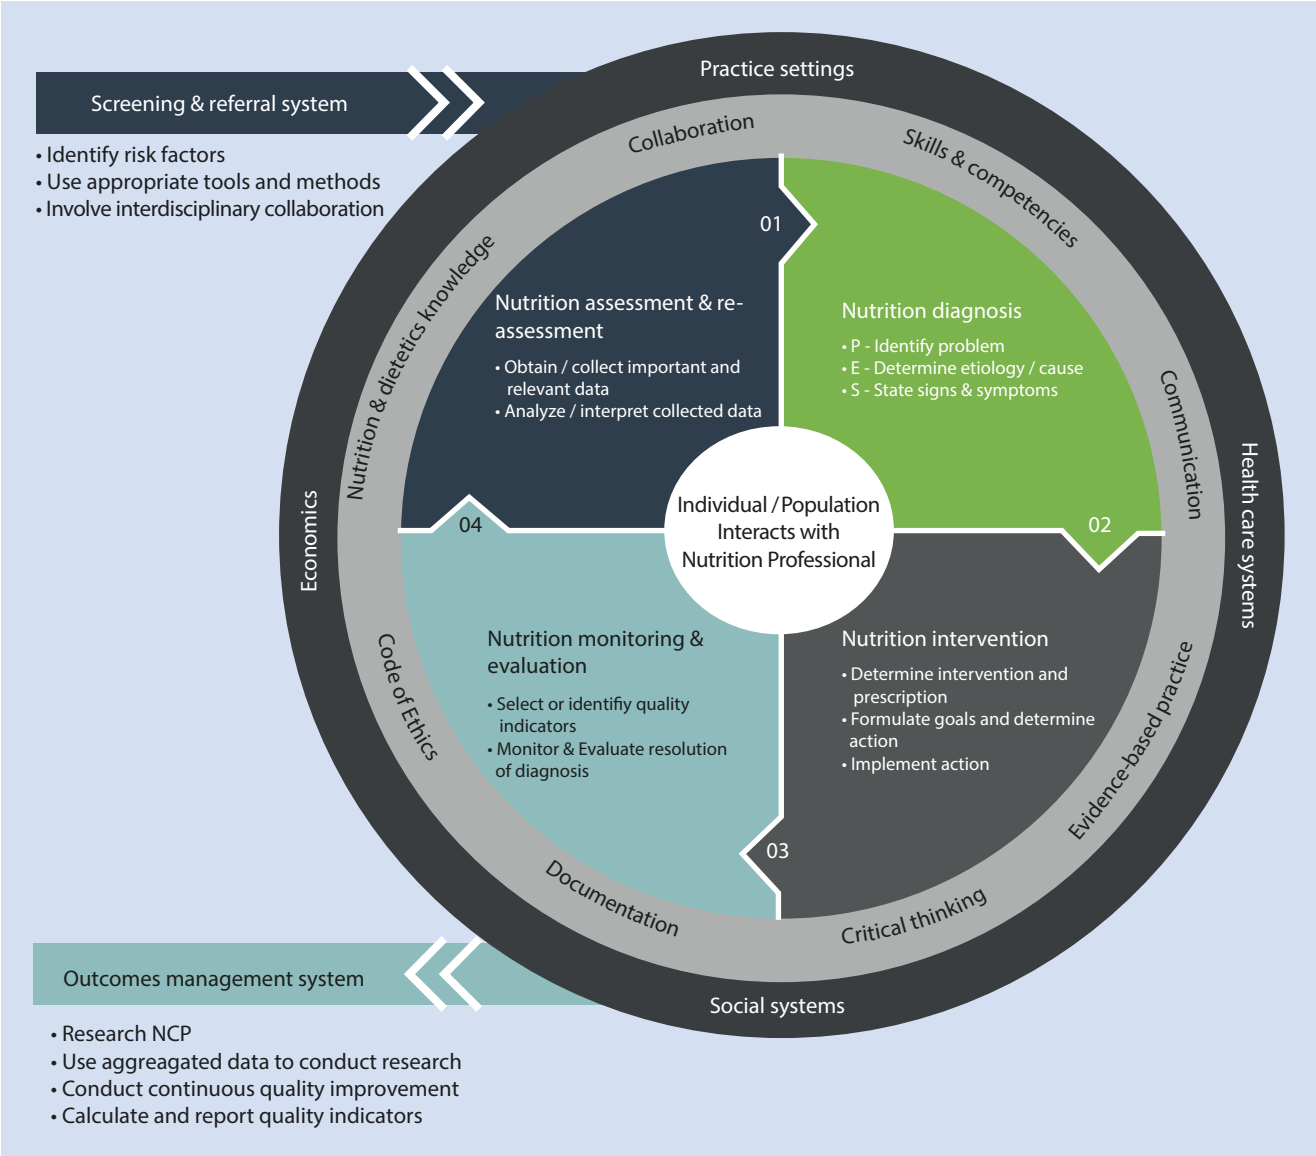

Fig. 44.1 The Nutrition Care Process (NCP) and Model. (Reprinted from Swan et al. [11]. With permission from Elsevier)

evaluation activities often include working with the client to assess whether the intervention delivered that day has had an impact on client outcomes, as well as setting a plan for follow-up care. The plan for follow-up may include decisions about when the client will return to the clinic (outpatient setting) or be seen again by the clinician (inpatient setting). In addition, the clinician often will develop (or "stage") a plan for interventions that will occur at subsequent follow-up visits and discuss that plan with the client.

At the follow-up visit, the clinician continues to engage in monitoring and evaluation activities. The clinician reassesses data points from the initial visit and gathers new information to determine whether the intervention was successful. If it was not, the clinician explores the reasons why.

Nutrition monitoring is defined as a "preplanned review and measurement" of key health and nutrition-related data points that can provide information about the nutritional status of the client [1]. Collection of monitoring data can begin at the initial visit. For interventions that are largely focused on educating the patient about a new diet that needs to be adopted, the clinician can assess the client's understanding of key aspects of the diet and its application throughout the session. Many counseling interventions are aimed at promoting self-efficacy of the client and/or increasing motivation to make changes. The clinician also can assess the client's self-efficacy or motivation for making a behavior change during the initial visit. In both these examples, by reassessing key variables during the initial session, the clinician not only gains immediate feedback about the effectiveness of the intervention (nutrition monitoring) but also increases the likelihood that the client will be successful in implementing the desired behavioral changes in the interim period until follow-up time. In all cases, the clinician also will assess key data points at the follow-up visit to determine if the patient continues to understand key concepts about the new therapeutic diet, continues to have self-efficacy and motivation for change, has implemented new health behaviors, and has experienced any potential impact of these changes on health and nutritional status.

After collection of this key data at the initial and follow-up visits, the clinician engages in nutrition evaluation, which includes a "systematic comparison" of this collected data to baseline (pre-intervention) data or desired outcomes of the intervention [1]. As with nutrition monitoring, it is possible to begin nutrition evaluation at the first visit to evaluate the immediate impact and effectiveness of education and counseling interventions with the client. However, since the ultimate goal is to impact client knowledge, motivation, self-efficacy, and behavior change in the long-term, nutrition evaluation conducted at follow-up visits is the highest priority feedback. Data collected at follow-up visits help the clinician to optimally evaluate the effectiveness of the intervention on the client's nutritional status and an opportunity to reflect on whether a different approach would be more effective for the client's subsequent interventions.

44.1.2 Purpose of Monitoring and Evaluation

While clinicians have always been interested in providing high-impact, effective interventions that result in improved health of their patients, the current healthcare environment is highly focused on demonstrating the cost-effectiveness of prevention and treatment efforts for chronic disease [2]. By engaging in monitoring and evaluation activities, the clinician is committing to ensuring that the client is receiving the most effective care possible. The clinician and client both receive feedback about progress at key points (initial visit, follow-up visit) and can respond to that feedback by revisiting interventions or engaging in different interventions that may be more effective. In addition, when used in combination with NCP-driven terminology and a focus on nutrition-specific outcomes, clinicians can contribute to an internationally unified approach to provision of nutrition care and measurement of outcomes of care. This type of data can be analyzed and published to document optimal types of interventions for a variety of clinical conditions as well as document the value of nutrition care with the chronic disease patient.

An integrative and functional nutrition (IFN) approach can be compatible with the standardized approach recommended by the NCP. There is substantial overlap between the data gathered during assessment, monitoring, and evaluation in both approaches. When approaches are not completely aligned, the NCP terminology is general enough to be adapted to functional assessment parameters, including digestion, metabolism, inflammation, oxidative stress, lifestyle influences, and the nutrition-focused physical exam. In 2011, the Academy of Nutrition and Dietetics published the Standards of Practice and Standards of Professional Performance for Registered Dietitians in Integrative and Functional Medicine [3]. This document provides specific guidance on how to merge the two approaches, including the use of the Integrative and Functional Medical Nutrition Therapy (IFMNT) Radial (◘ Fig. 44.2).

44.1.3 Relationship to Other NCP Steps

Monitoring and evaluation is the fourth and final step of the NCP. However, in practical application, outcomes-based clinical care means that monitoring and evaluation is considered at every stage of the NCP. During assessment, potential key outcome variables are identified and measured to serve as a baseline value from which to mark improvement (see ▶ Chap. 40). For the nutrition diagnosis, the defining characteristics section of the nutrition diagnosis terminology reference sheets of the Electronic Nutrition Care Process Terminology (eNCPT) specifically lists the assessment data points that are most indicative of the nutrition problem. As such, these data points not only are included in the signs/symptoms portion of the PES (problem-etiology-signs and symptoms) statement to provide direction for the monitoring statement but also serve as optimal data points for moni-

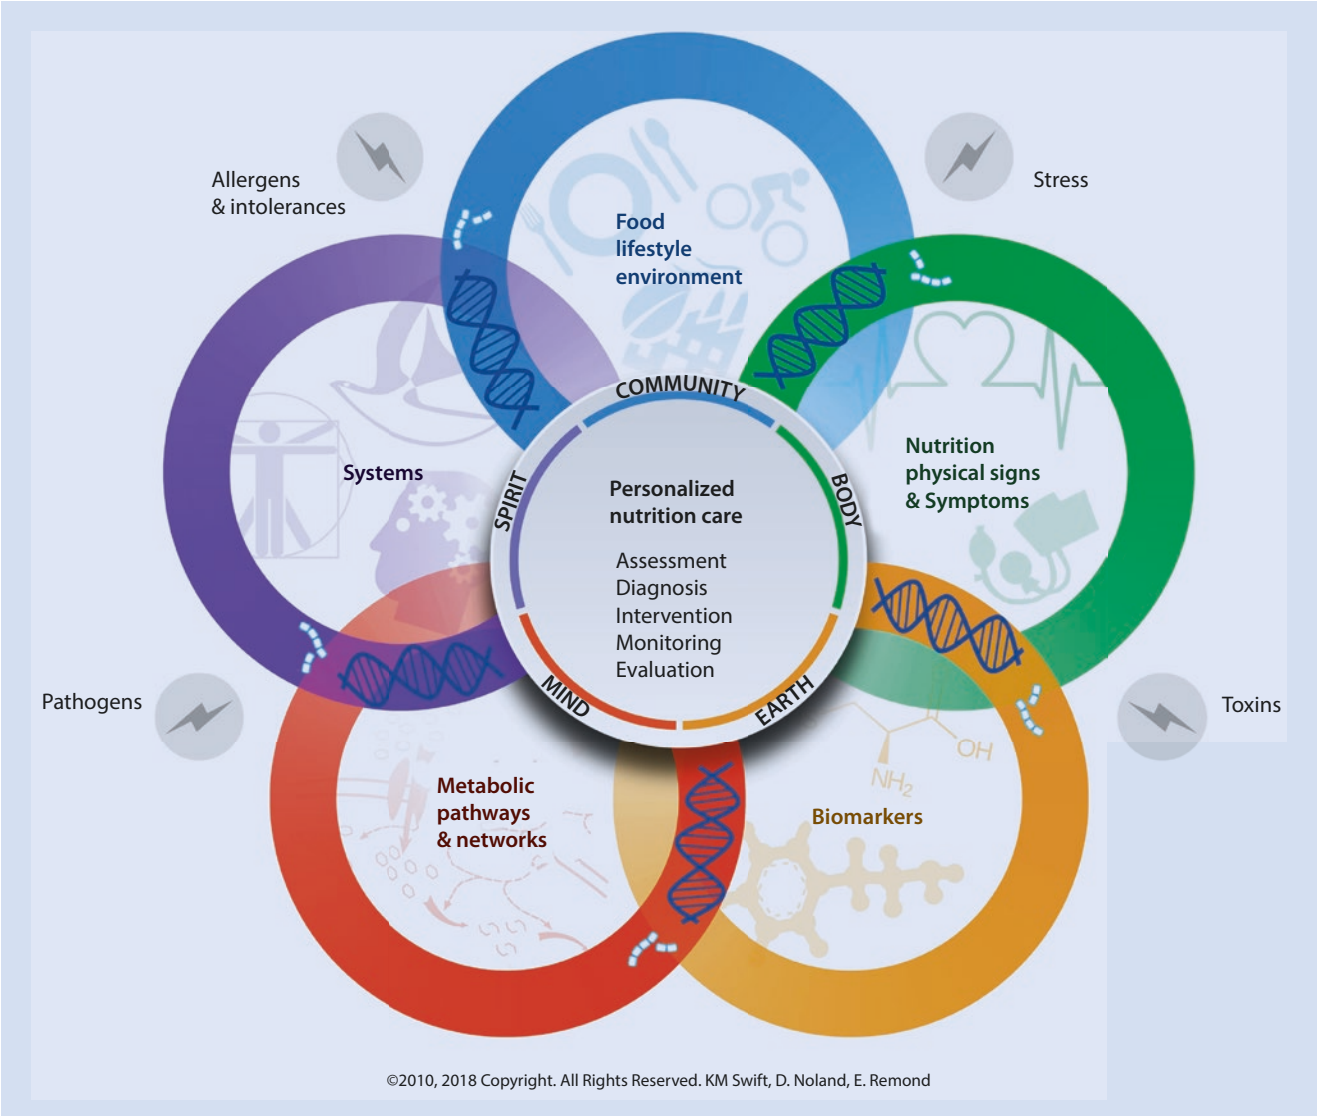

Fig. 44.2 The Radial: Integrative and Functional Medical Nutrition Therapy. (Courtesy of Kathie Madonna Swift, Diana Noland, Elizabeth Redmond)

toring the resolution of the nutrition problem. The intervention is specifically designed to address the problem stated in the PES statement, as well as result in improvement in the outcomes listed in the signs/symptoms portion. During the monitoring and evaluation stage, the clinician will reassess these outcome variables (monitoring) and evaluate them against predetermined standards to determine whether the client's health is improving (evaluation).

44.1.4 Process of Monitoring and Evaluating Outcomes

As described earlier, monitoring and evaluation activities can begin even at the initial visit. The clinician may reassess key variables such as nutrition knowledge, ability to implement a dietary change (skills), or motivation, self-efficacy, and/or readiness for behavior change. In addition, the clinician and patient collectively discuss a plan for following up, such as when the next visit will occur, when the patient is likely to see results of their behavior changes, when they will need a change of approach, and how long they may need to follow a specific therapeutic diet. Clinicians need to be aware that a patient may not ever return or return on a different time frame than recommended. Clearly communicating about the follow-up plan will help the patient receive maximum benefit and limit the potential harms from an intervention by helping them understand time limits on interventions such as temporary dietary changes or therapeutic supplement use.

At subsequent visits, the clinician often will start the appointment by asking specific and detailed questions that assess the patient's:

- Understanding of the specific intervention delivered at the previous visit
- Success with behavior changes discussed at the previous visit

- Ability to fully implement the intervention
- Barriers to fully implementing the intervention
- Experience of positive and negative outcomes from the intervention

The clinician uses this data to determine whether the nutrition intervention delivered at the previous visit has resulted in behavior change and improvement in nutritional and health status. If the reassessment reveals that the nutrition problem named in the PES statement still exists and is still a priority, the clinician will continue to focus that visit on exploration of the nature, cause, and significance of that problem. As described above, this could include a more in-depth investigation of IFN indicators that may be contributing to the patient's lack of improvement and additional interventions aimed at addressing IFN contributions to the nutrition problem.

The clinician may identify health and behavioral problems during reassessment that are outside of the clinician's expertise or scope of practice. The clinician needs to be vigilant and attentive to situations when a patient would benefit from a referral to other care providers for integrative medical treatment. If the nutrition problem identified at the previous visit (PES statement) has resolved or become a lower priority, the clinician may spend time during the appointment completing a full reassessment of the patient. The clinician determines if new data are necessary to identify the nature, cause, and significance of other potential high-priority nutrition problems.

44.1.5 Critical Thinking Aspects of Monitoring and Evaluation

Critical thinking skills are needed to successfully use monitoring and evaluation concepts, including an understanding of the interconnected nature of body systems and influences on health. As described previously, the clinician considers outcomes-based care at all stages of the Nutrition Care Process to increase the likelihood of the patient experiencing an improvement in nutritional and health status from the intervention. This begins with the selection of optimal outcomes at the outset and assessing those variables during initial data-gathering activities.

A related decision point is choosing the appropriate reference or standard by which to evaluate the collected data. For example, nutrition clinicians often use the Dietary Reference Intakes (e.g., RDA) to evaluate the adequacy of intake, despite the fact that this reference standard was not intended to be used to describe the needs of individuals with ongoing disease processes or those with unique nutritional needs [4]. Using body mass index (BMI) to evaluate the weight status and adiposity of adults is one of the most controversial areas in the practice of anthropometric assessment. Alternative approaches to evade misuse of available reference standards include comparing the client with a previous/baseline value to assess change or comparing the client to an individualized recommendation stated in the nutrition prescription (see ▶ Chap. 42). If clinicians use standards or criteria such as the Dietary Reference Intakes, prescriptive diets (e.g., Mediterranean diet, elimination diets, or low-FODMAP diets), or reference data (e.g., BMI classifications, laboratory values), they need to be thoroughly versed in the limitations of those standards and the populations in which they have been validated. If using functional laboratory data, it is important to ensure the lab is CLIA (Clinical Laboratory Improvement Amendments) certified.

The clinician uses critical thinking skills to piece together the puzzle of why the patient may not have experienced as much improvement as expected. A monitoring and evaluation appointment lends itself to a deeper discovery of the interconnected relationships of functional core areas when trying to solve a complex health challenge. The clinician thoroughly explains in the chart any shortfalls from the expected outcomes and the factors that have affected progress. This explanation provides documentation that is helpful to both the clinician (for understanding the patient's needs over time) and other healthcare professionals who participate in the patient's care.

While nutrition clinicians often have long-term working relationships with patients with chronic diseases, there are circumstances when the patient may be discharged from care. The most obvious example is the patient who has had complete resolution of significant nutrition problems. With chronic disease patients, this situation typically occurs after a prolonged phase of "weaning off" of visits with the healthcare provider during which time the clinician and client have successfully navigated behavior change principles such as lapse and relapse prevention. Other patients with chronic diseases may occasionally go through periods of time when they would prefer to take a "vacation" from self-care. While this may be alarming for the nutrition clinician, it is important to express empathy with the client's feelings, acknowledge the goal to support the client through any situation, and indicate an ongoing interest in providing nutrition care whenever the patient is interested in returning to care. The nutrition care provider documents this situation, communicates it to other key providers in the patient's medical home, and provides the patient with a referral to any other care providers that may be helpful during this time (e.g., mental health specialist).

44.2 Monitoring and Evaluation Data

44.2.1 Nutrition Care Outcomes and Indicators

Nutrition care outcomes are measurable data points that may change with implementation of the nutrition intervention or provision of care by the nutrition professional. *Nutrition care indicators* are a subset of nutrition care outcomes that are considered the most responsive and most sensitive data

points for demonstrating improvement in or resolution of a nutrition diagnosis [5].

The Nutrition Assessment and Monitoring and Evaluation Terminology lists provide examples of nutrition care outcomes and indicators in the established domains of assessment data [6]:

- Food/nutrition-related history
- Biochemical data, medical tests, and procedures
- Anthropometric measurements
- Nutrition-focused physical findings

Even though the terminology is largely shared between assessment and monitoring/evaluation steps in the NCP, there are two distinct differences. First, not all data points that are included in assessment are considered to be nutrition care outcomes or indicators. Often these are data points that may provide feedback to the care provider about the nature and severity of the disease process, not necessarily a specific nutrition problem. Examples include such lab and test values as resting metabolic rate and toxicology reports or such physical exam data as body temperature or heart rate. Second, client history data (i.e., demographics and social history) are unlikely to be impacted by nutrition interventions and therefore are not optimal nutrition outcomes or indicators [7].

Nutrition care outcomes and indicators are distinctly different from other types of data discussed below (disease outcomes, healthcare outcomes, patient outcomes). Nutrition care outcomes and indicators are those data points that the nutrition practitioner can directly impact [7]. Nutrition care outcomes and indicators are important to select and use within the medical chart as they demonstrate the ability of nutrition clinicians and nutrition interventions to provide measurable and documentable benefits to patients and healthcare systems. Over time, this will lead to the ability to demonstrate the cost-effectiveness and efficacy of nutrition care in improving patient health and well-being, a desperately needed evidence base for the nutrition profession.

As nutrition care outcomes and indicators change (improve), the client is likely to experience improvements in other measurable healthcare outcomes such as:

- Health and disease status: changes in the severity, duration, and risk level of a disease process
- Cost outcomes: changes in the cost of providing care such as medications, medical interventions and tests, and length of stay
- Patient outcomes: changes in factors that impact the patient, such as quality of life and functional status [7]

Broadly trained medical providers such as naturopathic doctors, medical doctors, physician's assistants, and nurse practitioners may feel more comfortable tracking these healthcare outcomes. However, since they are likely to occur only after successful implementation of nutrition and physical activity changes over longer periods of time, we encourage all healthcare providers to track nutrition care outcomes and indicators when providing nutrition care.

44.2.2 Selection of Nutrition Care Outcomes and Indicators

Nutrition care outcomes and indicators can be gathered from the health record or referral letters, from patient interviews, and through direct measurements made by the clinician. Most clinicians face an overwhelming volume of data to sort through when completing an assessment and reassessment. Skilled clinicians become adept at identifying and focusing on the data points that are the highest priority for monitoring. Clinicians determine which information is the highest priority by considering the patient's medical diagnoses and their severity, the nutrition diagnoses that have been charted, the nutrition interventions delivered, and the desired outcomes of nutrition care (see [8] as an example). In addition, practical considerations, such as the patient's health insurance coverage, the practice setting, and time limits on appointments, may impact the selection of nutrition care outcomes and indicators. For example, in a hospital or integrative clinical setting, the clinician may have easier access to laboratory values and medical tests, making these readily available and potentially valid indicators of the outcomes of nutrition care. In an outpatient setting, where the client has the freedom to self-select food and beverage intake, food and nutrient intake data tend to be more important outcomes of care.

As clinicians monitor data, it is important to ensure the data are valid and evaluated against appropriate standards or criteria (see discussion above). As clinicians review data from the medical chart and interview the patient, they need to consider the possibility that the data are not valid. Patients may intentionally or unintentionally offer erroneous information. Medical errors can and do occur, including errors in test procedure results and laboratory data. Furthermore, as clinicians collect their own data and add it to the chart, they should always use techniques on which they are well-trained; make measurements using high-quality, calibrated equipment; and follow an established standardized measurement protocol. As the nutrition professional is likely to contribute unique, detailed data on the patient's food and nutrition intake to the chart, it is of utmost importance that this data be collected using as reliable and valid techniques as possible (see ► Chap. 9).

44.2.3 Monitoring and Evaluation of Integrative and Functional Nutrition Data

Listening to the patient's story is a foundation of an IFN assessment. When a patient returns for a follow-up visit, the process of monitoring and evaluation allows for a deepening of the relationship between provider and client and a more thorough examination of the patient's personal and medical history. As the clinician gains the patient's trust, the patient's story may unfold, and its inherent complexities may become

more apparent. This allows the clinician to identify the affected IFN core areas of health, draw connections between them, and continue to build a comprehensive treatment plan. An intake form that gathers details from each functional core area is very helpful.

Often a patient will have a chief complaint, such as hypertension, that needs to be addressed at the first visit. Using an IFN assessment tool such as *NIBLETS* (nutrition, inflammation, biochemical individuality, lifestyle, energy and metabolism, toxic load, and stress), the clinician may identify that the patient also has several inflammatory conditions (arthritis, elevated antinuclear antibody test), poor sleep, a high level of psychological stress, and exposure to environmental toxins that potentially increase blood pressure. While initial interventions may center around direct dietary interventions for hypertension, such as increasing fruit and vegetable consumption to increase potassium or decreasing ultra-processed foods to reduce sodium, subsequent visits will allow for greater education and discussion around the potential interconnected nature of inflammation, stress, sleep, and toxins on blood pressure. Because most health conditions have multifactorial causes, a clinician can skillfully use multiple visits to expand the treatment plan to assess a wide scope of influences in a stepwise fashion that is not overwhelming to the patient.

When using the Nutrition Care Process, IFN assessments may lead to nutrition diagnoses such as food- and nutrition-related knowledge deficit, undesirable food choices, predicted suboptimal intake, predicted excessive intake, and altered nutrition-related laboratory values. In most cases, the information that is provided in the etiology and signs and symptoms of the diagnosis or PES statement provides direction for the monitoring and evaluation phase.

44.3 Practical Application of Monitoring and Evaluation Principles

44.3.1 Developing and Charting the Monitoring and Evaluation Plan

Bastyr Center for Natural Health (BCNH) is one of Bastyr University's two nonprofit teaching clinics. Located in a Seattle neighborhood, BCNH is the largest natural health clinic in the Pacific Northwest, offering as many as 35,000 patient-visits a year [9]. The clinic serves as a training site for many of the university's health professions students, including Didactic Program in Dietetics students (students training to become registered dietitian nutritionists) as well as coordinated nutrition-counseling psychology students. University educators provide information and training about the NCP and our institutional charting standards through the use of case studies in clinical nutrition courses during the first year of the program. In the second year of the program, students attend two rotations at BCNH, applying the NCP to patients and charting those encounters through an electronic charting system that reflects NCP steps and terminology. The Nutrition Department at BCNH set up the monitoring and evaluation process to accomplish the following:

- Focus the nutrition clinician's appointment on outcome-based care
- Set up professional benchmarks that measure the level of success of nutrition care
- Communicate to the healthcare team and billing which medical diagnoses or problems the nutrition clinician is collaboratively treating
- Plan and deliver complex nutrition interventions over multiple visits
- Collaborate with patients in developing goals surrounding behavior change and follow-up treatment

44.3.2 Developing and Charting Professional Goals

For each intervention, the nutrition clinician writes at least one professional goal. The professional goal serves as an official record of the desired nutrition care outcome that results from the intervention delivered. Stating the desired nutrition care outcomes encourages the nutrition clinicians to develop realistic, achievable, high-impact goals that provide a measure of the success of nutrition care. In addition, student clinicians are encouraged to consider potential professional goals throughout all stages of the NCP, so they continually remain focused on the desired goal of the nutrition intervention (see ▶ Sect. 44.1.3).

At BCNH, nutrition clinicians include three required elements when charting professional goals:

1. The professional goal must state the primary health concern or medical diagnosis that is being collaboratively treated through nutrition care. This communicates to the healthcare team, clinic administration, and insurance companies the value nutrition care can add when managing patient illnesses and diseases.
2. The goal must include a comparative standard or reference value that follows the client through the NCP (see ▶ Sect. 44.1.5). This "criteria" value flows through the chart's assessment, diagnosis, nutrition prescription, and intervention sections to maintain cohesion in approach and thinking around managing the nutrition problem. This topic is covered in greater detail later in this chapter.
3. The goal should include *SMART goal* elements:
   - *S*pecific: The goal includes the comparative standard whenever possible. For saturated fat, "no more than 7 percent of calories" is more specific than "reduced saturated fat."
   - *M*easurable: The goal is written so that when the patient is reassessed, the nutrition clinician should be able to say "yes" or "no" about whether the client has achieved the goal.

- *A*ccountable: The goal states who is responsible for achieving it. Usually this is the client, but some goals, such as referrals (coordination of care), require the clinician to act.
- *R*eachable/realistic: The goal needs to be realistic for the client or nutrition clinician. Behavior change goals for patients often include interim steps toward achieving the optimal outcomes as well as an understanding that clinicians don't expect perfection in behavior change (e.g., "5 out of 7 days per week").
- *T*imely: The goal states a specific time frame for goal achievement, such as the end of today's visit, at the next visit, or some point in the future. Be practical; don't wait a year to see if your client has lost 30 pounds.

See ▶ Box 44.1 for examples of professional goals for a variety of settings, nutrition problems, and desired outcomes for interventions. See ▶ Box 44.2 for a self-check tool based on BCNH's quality control standards for charting professional goals.

Box 44.1
- To improve blood lipid levels, at 1 month follow-up, a 24-hour recall will show that the patient's reported consumption of saturated fat is <7% of kcal.
- To reduce cancer risk, food logs gathered at the 2-week follow-up will show the client has consumed at least three cups/day of vegetables on at least 5 of 7 days per week.
- To improve coordination of care for iron deficiency anemia, the RDN will notify patient's physician about food-drug interactions with iron supplement within 48 hours.
- To manage hypertension, at the end of today's visit, patient will express a willingness to modify diet toward DASH diet standards.

Box 44.2
Each professional goal within the chart:
- Forms a single sentence that is grammatically correct
- Includes a health outcome (when possible)
- Includes a comparative standard or criteria (when possible)
- Includes all five SMART form elements: specific, measurable, accountable, realistic, and timely
- Is a high-impact outcome that is (1) within the provider's scope of practice and (2) likely to result from the nutrition intervention
- Supports a logical flow with the related PES, nutrition prescription, intervention, and after-visit summary

44.3.3 Developing and Charting the Follow-Up Plan

As clinicians complete Step 2 of the NCP, the nutrition diagnosis (see ◘ Fig. 44.1), a key critical thinking activity is to prioritize the patient's nutrition diagnosis. At integrative clinics, nutrition clinicians typically select and intervene on only the top one or two nutrition diagnoses at each visit. However, the clinicians chart a list of additional nutrition problems, topics for education, and/or progressive steps in a complex nutrition intervention that should occur at subsequent visits in the "follow-up" section of the chart. When the patient returns and is reassessed during monitoring and evaluation activities, this follow-up plan may still be relevant, and its presence in the chart saves the clinician time. If the reassessment reveals new problems or indicates the need for reprioritization of problems, the follow-up plan would be adapted to reflect the most current assessment information.

44.3.4 Developing and Charting the After-Visit Summary Goals

The after-visit summary is a written document provided to clients at their visit that outlines specific instructions about how to implement the nutrition intervention to improve their health. For example, this document may include specific behavior changes, such as increasing consumption of particular therapeutic foods, engaging in additional self-education related to their health concerns or therapeutic diet, monitoring food patterns, journaling about concerns and feelings related to food and eating, and/or seeking out the help of other healthcare providers. Whenever possible, nutrition clinicians work with patients to write positive goals ("Do this") rather than negative goals ("Don't do this").

At BCNH, nutrition clinicians include three required elements when charting the after-visit summary:
- The goals focus on concrete, realistic, behaviors that the client has collaboratively developed with the clinician.
- The goals, if completed, directly lead to successful accomplishment of the nutrition clinician's professional goals.
- The goals are written in language that is accessible to the client – both in terms of general literacy, health literacy, and nutrition literacy.

See ▶ Box 44.3 for examples of after-visit summary goals for a variety of settings, nutrition problems, and desired outcomes for interventions. See ▶ Box 44.4 for a self-check tool based on BCNH's quality control standards for charting after-visit summary goals.

Box 44.3
Thank you for coming in today, [insert patient name]. Here are the goals we discussed for today's visit on 8/10/2017:
- Go shopping on Sundays and purchase at least 14 pieces of fruit.
- Wash and dry fruit when you get home, and put ten pieces in a bag to take to work, and place the remainder in a bowl on the kitchen counter.
- Your goal is to consume two pieces of fresh fruit per day either while at work and/or at home at least 5 days each week.
- Check off on a calendar the days you met this goal, and bring the calendar to the next appointment for feedback to the clinician.
- Note any barriers that prevented you from achieving this goal on the calendar.

Box 44.4
My after-visit summary:
- Is about concrete, realistic, behavioral changes the client will do, using positive language instead of "don't do this" goals
- Is in simple, nontechnical language and simple steps that improve patient compliance
- Includes important and effective behavior changes that will lead to achievement of the nutrition clinician's professional goal
- Supports a logical flow with the related PES, nutrition prescription, intervention, and professional goal

44.3.5 Alignment and Integration of the Nutrition Diagnosis, Intervention, Professional Goal, and After-Visit Summary in an Outpatient Clinic Example

Case Study 44.1 provides an example showing how a nutrition clinician uses outcomes-based care to align and integrate all stages of the NCP. During the assessment phase of the intervention, the clinician selects optimal criteria for evaluating the patient's data after considering the patient's situation, disease state, and the clinician's setting, resources, and skills. In this case, the clinician has selected the Dietary Approaches to Stop Hypertension (DASH) Food Plan and the DASH food and nutrient targets as an optimal disease-specific set of standards for assessing the patient's baseline food and nutrient intake [10]. The clinician assesses both food and nutrient intake using a 24-hour recall against DASH standards and then documents that suboptimal intake of both fruits and vegetables is leading to a suboptimal intake of potassium, a key therapeutic nutrient needed to regulate blood pressure. The clinician also charts the etiology of these suboptimal nutrition intake patterns, to support the PES statement charted and to place the first nutrition intervention in context.

Case Study 44.1

Situation: Patient would benefit from optimizing potassium intake to manage hypertension; goal is foods-based solution focusing on increasing intake of fruit and vegetables.

Excerpts from chart sections below show alignment and integration across all NCP steps and chart note sections.

In the diagnosis phase of the NCP, the clinician could opt to write a PES statement noting the discrepancy between actual food intake patterns and the prescribed 2000 kcal DASH diet food recommendations (nutrition prescription) using an "undesirable food choices" diagnosis (NB-1.7). This is an optimal approach in a setting where the clinician prefers food-based approaches and/or lacks access to dietary analysis software or the time to engage in this activity. In the example provided, the clinician has elected to approach this situation as a nutrient-based problem (inadequate mineral intake), works in a setting that has structural resources to measure potassium intake (dietary assessment software, time to complete analysis), and intends to monitor and evaluate this nutrition care indicator at follow-up points.

The two interventions that the nutrition clinician delivers build the patient's knowledge of the therapeutic diet, address known barriers to implementation, and increase the patient's self-efficacy and motivation for making the necessary dietary changes. Note that the nutrition clinician has delivered education and behavior change instruction around food choices, rather than nutrients, even though the clinician will be monitoring nutrient intake "behind the scenes." The intervention includes instruction in patient recordkeeping behaviors that will provide the nutrition clinician with helpful feedback about the interventions, including how often the patient has successfully followed through on grocery shopping, fruit intake, and vegetable intake goals, as well as barriers encountered when implementing the interventions.

For monitoring and evaluation, the clinician can intermittently assess patient understanding of key aspects of the nutrition interventions at the initial visit, such as:
- Does the patient understand why more fruits, vegetables, and potassium intake are therapeutic for treating hypertension?
- Has the patient resolved the discrepancy between saving money when grocery shopping and desiring a non-pharmaceutical resolution to their hypertension?
- Can the patient verbally state (with support of nutrition education handouts) the amount of fruits and vegetables that equal to one DASH serving?
- Can the patient verbally state the ultimate goals for fruit and vegetable intake and the interim goals set for this first intervention?
- How likely would the patient rate (on a scale of 1–10) the accomplishment of key behaviors listed on their after-visit summary sheet?

Upon the patient's return to the clinic in 3 weeks, the nutrition clinician will first review the patient's log to evaluate whether the patient has successfully completed grocery shopping to support the dietary change and discuss any barriers encountered. Without successful achievement of this goal, it is unlikely food and nutrient patterns have changed and time may need to be diverted to other types of data collection and interventions at that visit. If a quick review of grocery shopping and food intake behaviors shows relative success, the clinician could invest the time in collecting and analyzing a 24-hour recall to evaluate potassium intake and determine if the professional goal was achieved. Based on reviews of all this data, the nutrition clinician is in a good position to determine whether items on the follow-up list (other DASH food groups, physical activity) could be implemented at that visit or if the client needs to continue to work on fruit and vegetable intake. Additionally, at the follow-up visit, the clinician can address functional core areas that

may contribute to hypertension, including psychological health (stress level), lack of sleep, potential toxic exposures, inflammation, and oxidative stress, if not addressed during the first visit.

44.3.6 Alignment and Integration of the Nutrition Diagnosis, Intervention, Professional Goal, and After-Visit Summary in a Nutrition Support Example

Case Study 44.2 provides an example showing how a nutrition clinician uses outcomes-based care to align and integrate all stages of the NCP for a patient that is enterally fed. In the assessment phase of the NCP, the clinician gathers key data regarding the patient's significant weight loss over prior 5 years and the reasons that the patient's enteral prescription has failed to meet his needs (limited involvement of an RDN in care). Since there are few established quantitative criteria for intake of anti-inflammatory nutrients in patients experiencing gastrointestinal inflammatory disorders, the clinician qualitatively assesses the diet as lacking in key dietary components.

Case Study 44.2

Situation: Patient on nutrition support (enteral feeding) for the past 5 years would benefit from optimizing fatty acid and phytonutrient intake to manage risks of long-term enteral feeding and severe inflammatory state; initial goals include weight stabilization and improved intake of anti-inflammatory fatty acids and phytonutrients.

Excerpts from chart sections show alignment and integration across all NCP steps and chart note sections.

In the diagnosis phase of the NCP, the clinician identifies the highest concern as the patient's significant weight loss and likely malnutrition from 5 years of underfeeding. Secondary concerns include optimizing anti-inflammatory fatty acids and phytochemicals. The clinician writes three separate PES statements to describe the nature and etiology of these nutrition problems.

All of these concerns are addressed today in the two interventions conducted by the RDN. The RDN provides education to the patient and his wife for how to modify the formula to increase the calorie content and provide anti-inflammatory fatty acids and plant phytochemicals. After the visit, the RDN will communicate with the patient's doctor to request both short- and long-term changes in the nutritional composition of the patient's diet to better meet his nutritional needs.

For monitoring and evaluation, the clinician has already assessed the patient's understanding of how to prepare the new formula safely at today's visit and has instructed the patient in the use of a log to gather key outcome data for the next visit. Upon the patient's return to the clinic in 2 weeks, the nutrition clinician will first review the patient's log to evaluate whether the patient has prepared and consumed the new formula and then to review the impact of the intervention on patient quality of life and indicators of bowel health (bowel movement frequency). The clinician also will measure the patient's weight to determine if additional adjustments to calorie intake are warranted. Based on the review of all this data, discussions with the patient's doctor, and review of any prior laboratory tests, the nutrition clinician will be able to determine whether there should be any additional changes to the nutrition prescription at the follow-up visit.

44.4 Conclusion

Monitoring and evaluation is the fourth and final step of the Nutrition Care Process (NCP). However, in the current environment of outcomes-based care, nutrition clinicians are encouraged to think about the value of monitoring and evaluation across all stages of the NCP. This would include collection of critical baseline data during nutrition assessment, use of this data in the problem-etiology-signs and symptoms (PES) statement written as a nutrition diagnosis, and intervention activities directly intended to impact or address the nutrition problem and its key signs and symptoms. Utilization of an integrative and functional approach will allow for a deeper exploration of contributors of poor health using the NIBLETS mnemonic (nutrition, inflammation, biochemical individuality, lifestyle, energy and metabolism, toxic load, and stress). Monitoring and evaluation can occur during and immediately after the delivery of interventions designed to impact nutrition attitudes, beliefs, values, knowledge, and practical skills. At subsequent visits, the clinician can anticipate progress on food intake or physical activity patterns that may eventually lead to changes in anthropometry, body biochemistry or functioning, physical exam parameters, quality of life, disease process indicators, and medical costs. Well-developed systems for charting nutrition care can enhance the clinician's critical thinking skills in providing effective, outcomes-based nutrition care that enhances the quality of life for patients.

44.4.1 Assessment

Typical intake patterns do not match DASH goals for patient's estimated calorie needs. Fruit intake (2 servings/d) is suboptimal (50% of goal 4 servings/d). Vegetable intake (3 servings/d) is suboptimal (75% of goal 4 servings/d). Estimated intake of potassium is 2000 mg (42% of goal 4700 mg/d). Patient perceives eating more fruits and vegetables will be costly and time-consuming. Patient motivated to find non-pharmaceutical method to treat hypertension. IFN assessment reveals presence of elevated ANA, arthritis, poor sleep, occupational toxin exposure (carbon dioxide), and high levels of psychological stress.

44.4.2 Diagnosis/PES Statement

Inadequate mineral intake (Potassium, NI-5.10.1.5) related to perception that consumption of fruits and vegetables is expensive and time-consuming as evidenced by estimated intake of potassium of 2000 mg/d (42% of DASH goal 4700 mg/d).

44.4.3 Intervention

Nutrition prescription 2000 kcal DASH diet food plan

- **Interventions**

Nutrition Counseling – Strategies – Problem Solving (C-2.4): Opened a conversation about patient's concerns about the cost of therapeutic foods (vegetables and fruit) and desire for management of hypertension without medication. Supported client in generating a list of potential strategies to lower the cost of purchasing potassium-rich produce – patient offered shopping weekly specials at store, purchasing produce in season, and selecting frozen fruits and vegetables. After discussing pros and cons of various approaches and specific weekly amount of produce the patient would need to purchase and consume to meet intake goals, the patient decided that purchasing weekly specials and frozen produce would be the most cost-effective way to support achieving an intake approaching four servings per day of fruit and four servings per day of vegetables. Provided the patient with a list of high-potassium fruits and vegetables to guide choices in the grocery store. Patient agreed to shop once per week for produce.

Nutrition Education – Content – Priority Modifications (E-1.2): Reviewed the DASH Eating Plan handout with patient, focusing on fruit and vegetable groups, especially those with high naturally occurring nitrates (beets, carrots, arugula) to boost nitric oxide concentration for vasodilation. Reinforced previous intervention's content regarding the serving size for different types of fruits and vegetables and choices that were high in potassium. Collaboratively generated a goal for daily intake of three servings per day of both fruits and vegetables as an interim step toward the ultimate goal of four servings per day of each food group. Patient agreed to log the number of servings of fruit and vegetable consumed each day on a simple food log and make notes about any barriers encountered at follow-up in 3 weeks.

44.4.4 Professional Goals

To manage hypertension, a 24-hour recall at the 3-week follow-up visit will show that the patient is consuming 3600 mg potassium (77% of nutrition prescription) through foods.

44.4.5 Follow-Up Plan

3 weeks; potential topics: new food groups in DASH diet pattern, brainstorm substitutions for ultra processed foods to increase whole foods intake, physical activity of 150 minutes/week brisk walking, increasing anti-inflammatory compounds in the diet, managing environmental exposures including supporting organs of elimination, exploring the need for referrals for improving sleep and reducing stress.

44.4.6 After-Visit Summary

- Thank you for coming in today, [insert patient name]. Here are the goals we discussed for today's visit on 8/1/2017:
  - Go shopping on Sundays, and purchase enough fruit and vegetables to support your goal of three servings per day of fruit and three servings per day of vegetables with an emphasis on high nitrate options as discussed.
  - Fruit: 3 servings per day = 21 servings per weekly shopping trip. This could look like:
    - 21 pieces of medium-sized fruit
    - 2–3 pounds of frozen fruit
    - A mix of fresh and frozen fruit such as 10 pieces of fresh fruit and 1 pound frozen fruit
  - Vegetables: 3 servings per day = 21 servings per weekly shopping trip. This could look like:
    - 10 cups of chopped, mixed fresh vegetables
    - 2–3 pounds of frozen vegetables
    - A mix of fresh and frozen fruit such as 5 cups fresh vegetables and 1 pound frozen vegetables
  - Consult your list of high-potassium fruits and vegetables to aid in selecting high-potassium options whenever possible.
  - Check off on a calendar the Sundays that you met this shopping goal, and bring the calendar to your next appointment
  - Starting today, aim to consume a minimum of 3 servings of fruit and 3 servings of vegetables each day:
    - One serving fruit = 1 medium fruit, ½ cup frozen fruit
    - One serving vegetables = ½ cup raw, frozen, or cooked vegetables, 1 cup raw leafy vegetables
  - Try a breakfast fruit and vegetable smoothie, salads at lunch and dinner, and fruit for snacks to help you reach this goal.
  - Check off on your simple food log when you consume a serving of fruit or vegetables to track the number of days you achieve the target of three servings each of fruits and vegetables. Bring the log back with you to the next appointment.

- Return to clinic in 3 weeks for follow-up so we can review the plan and talk about other ways you can decrease blood pressure by increasing anti-inflammatory compounds in your diet, improving your sleep, reducing stress, and managing environmental exposures.

44.4.7 Assessment

Client Hx: A 56-year-old male with history of type 2 diabetes, iron-deficiency anemia, GERD and esophageal lesions requiring G-tube feeding, unintended weight loss/cachexia, COPD with asthma, chronic disease of teeth. *Food/nutrition:* Current prescribed intake is 8 × 8 oz cans Glucerna 1.5 enteral formula/day (1896 mL × 1.5 kcal/mL = 2844 kcal/d), which is 89% of estimated kcal needs. PUFA intake (*n*–3) is 3% of kcal (9.5 g). Enteral nutrition originally initiated during hospital visit; no referral to dietitian. Patient and wife seeking dietitian consult independently. RDN confirmed G-tube is greater than the 14 French diameter to allow for homemade tube feedings.

Medications include:

- Ferrous Sulfate Iron 325 mg (60 mg elemental iron) BID, monitored quarterly
- Omega-3 fish oil: 684 mg 1 cap QD
- Triamcinolone acetonide 0.5% topical cream
- Glipizide 5 mg BID before meals
- Pantoprazole SOD DR 40 mg 1 tab QD
- Metformin HCL 500 mg 1 tab BID before meals
- Tamsulosin HCL 0.4 mg 1 cap ½ hour following AM meal QD
- Proscar 5 mg 1 tab QD
- Enalapril maleate 2.5 mg QD

Anthropometric: height, 74.0 in./187.9 cm; current weight, 154 lb/70.0 kg (87% of IBW); previous weight 250 lb/113.6 kg 5 years ago (38% weight loss in 5 years). *Biochemical:* Hgb 15.2 g/dL (Low end WNL); HCT 43% (Low end WNL); HbA1C 6.8% (WNL for DM); FBS 92 mg/dL (WNL for DM); CRP 13.6 mg/L (H). *Nutrition-focused physical exam:* complaints of fatigue and dyspnea. Reports constipation (BM Q 3–5 days); improved BM frequency with two cups of coffee per day (BM Q 1–2 days)

44.4.8 Diagnosis/PES Statements

Unintended weight loss (NC-3.2) due to mismatch between enteral formula prescription and patient nutritional needs as evidenced by 38% weight loss over the past 5 years.

Intake of types of fats inconsistent with needs (NI-5.5.3, omega-3 fatty acids) due to long-term use of enteral formula with suboptimal fatty acid profile for inflammatory conditions as evidenced by inadequate omega-3 fatty acid intake compared to nutrition prescription.

Inadequate bioactive substance intake (NI-4.1) due to long-term use of enteral diet as evidenced by low estimated intake of plant phytonutrients and presence of inflammation (elevated CRP).

44.4.9 Intervention

Nutrition prescription:

- REE/kcals: 40–45 kcal/kg × 70 kg = 2800–3150 kcal/d
- Protein (g/kg): 2 g/kg = 140 g
- Fluids (ml/kg): 40 mL/kg = 3240 mL

Other: 6 × 325 ml Kate Farms (brand) 1.5 Whole Foods Peptide Formula (3000 kcals/144g/protein/38mg Fe). Recommended additional nutrients added to the formula via a blender to meet needs for calories, iron, essential fatty acids, antioxidants and anti-inflammatory nutrients: 2 opened capsules multistrain probiotic (10–50 billion CFU/capsule), 500 mg buffered vitamin C powder, 1 avocado, substitute fish oil with 2500 mg of an Omega 3-6-9 supplement. Additionally, provide 2 cups coffee/d via tube for bowel motility. Flush tube with water after each feeding. Twice a day, add 40 mg liquid ferrous bisglycinate to 240 mL water and flush into tube.

44.5 Interventions

Bioactive substance management – Other (essential fatty acids, ND-3.3.9): instructed patient on therapeutic additions to current enteral nutrition feeding plan. Patient will mix 5 × 325 mL containers of Kate Farms 1.5 formula with the ingredients listed in nutrition prescription and divide into two portions (breakfast and dinner), plus two cups of coffee per day for bowel function. Provided detailed instructions on how to make formula and answered patient questions. Patient and wife express willingness to prepare new formula and knowledge of how to safely prepare it. Patient and wife agreed to complete provided log to record preparation and consumption of new formula. Will also record any concerns or positive/negative outcomes including bowel movements. Follow-up visit in 2 weeks.

Coordination of nutrition care by a nutrition professional – Collaboration and Referral of Nutrition Care – Collaboration with other providers (RC-1.4): RDN to contact PCP to request diet prescription change to support restoration of nutritional status and stabilization of weight. RDN also will request labs from prior 2 years and request PCP obtain Spectracell Lab Micronutrient Analysis or Genova Nutreval to assist with evaluation of patient's nutritional status.

44.5.1 Professional Goals

To manage weight loss and inflammation, food logs collected at the 2-week follow-up will show consumption of formula preparation that meets the nutrition prescription on at least 6 of 7 days per week.

To coordinate care, the RDN will follow up with patient's PCP within 48 hours of visit to discuss recommendations for diet prescription change and request laboratory tests.

44.5.2 Follow-Up Plan

2 weeks; assess weight change and bowel habits, review logs with patient/wife to determine if new formula was well-tolerated, review labs (if obtained) with patient, discuss any change in enteral formula (if approved). Assess for GERD and blood glucose levels in response to diet changes. Consider switching iron to a bisglycinate iron, which is more absorbable.

44.5.3 After-Visit Summary

- Thank you for coming in today, [insert patient name]. Here are the goals we discussed for today's visit on 8/1/2017:
  - Follow food safety procedures for formula preparation and storage:
    - Wash hands with soap and water prior to preparing foods.
    - Thoroughly clean blender in hot soapy water after each use.
    - Prepare formula in a clean workspace using clean utensils and a clean can opener.
    - Wash the lids of all cans to remove dust and debris.
    - Thoroughly clean avocado with a scrub brush under running water.
    - Refrigerate all prepared formula that is not immediately consumed.
    - Discard any unused formula within 48 hours.
  - Using your blender, mix 5 × 325 mL containers of Kate Farms 1.5 enteral formula with the following additional ingredients:
    - 1 small avocado
    - 500 mg buffered vitamin C powder
    - 2500 mg Omega 3-6-9 (liquid or squeezed from a capsule)
    - Contents of two opened capsules probiotic 10–50 billion per CFU/capsule (discard capsule)
  - Divide mixed formula into 4–5 portions; consume the modified enteral formula for evenly spaced meals and a snacks (for example ~500 mL at 8 am, 11 am, 2 pm, 5 pm and 8 pm).
  - Have two cups of coffee per day to help with bowel function
  - 30 minutes before breakfast and again before bed, add 40 mg liquid ferrous bisglycinate to 90 mL water and infuse into tube, then flush with 90 mL water
  - Add at least 1.5 liters of additional fluid to the tube in divided doses each day as a flush before and after feedings (90 mL each) or when feeling thirsty.
  - Please use the log to record your observations:
    - Record your preparation and consumption of the new formula.
    - Record any problems or concerns with preparing or consuming new formula.
    - Record positive/negative outcomes.
    - Record bowel movements.
  - Schedule and attend a follow-up visit in 2 weeks.

Definitions

Ayurveda - Science and wisdom of life
Samhitas - Textbooks of Ayurveda
Agni - Digestive fire
Prakruti - Type of body constitution
Vikruti - Doshic imbalance
Dosha - Energy that circulates in the body around bodily tissues
Dhatu - Body tissues
Mala - Metabolic wastes (urine, sweat, feces)
Srotas - Elaborate network of channels carrying nutrients in the body and wastes out of the body
Vata - Wind energy
Pitta - Heat energy
Kapha - Building energy
Dinacharya - Daily routine and practices
Ritucharya - Seasonal routines and practices
Brahmacharya - Self-control
Panchakarma - Five Ayurvedic detoxifying treatments
Ama - Toxic substances
Rasayana - Rejuvenating herbs
Samprapti - Pathogenesis of the disease
Roga - Disease
Rasa - Taste

45.1 Origin and History of Ayurveda

Ayurveda is defined as the science of life. The name comes from Sanskrit, where ayur means life and veda means science or knowledge. Dating back about 5000 years, it is one of the world's oldest and most complete medical systems, originating from India. It was derived from the Vedas [1], texts composed of mantras that embody the very laws and energies of the universe, which are not merely inanimate forces but powered by consciousness itself. There are four Vedas: Rig, Yajur, Sama, and Atharva. Although all Vedas contain references to Ayurvedic concepts, the Atharva Veda contains the most. Therefore Ayurveda is considered an Upaveda, or a branch, of Atharva Veda [2, 3].

About 1500 B.C., Acharya Charaka, representing the Atreya School of physicians, compiled the medical material scattered in the Vedas into the Charaka Samhita. This first main textbook outlines the fundamental principles of Ayurvedic medicine, including treatment modalities, diet, and herbs for diseases. Sushruta Samhita, representing the Dhanvantari School of surgeons, was later compiled by Acharya Sushruta, regarded as the father of surgery. It contains description of surgical instruments and procedures, including plastic surgery. It also contains description of vital points, or Marmas, equivalent to acupuncture meridians in Chinese medicine. In about the sixth century, Vagbhata compiled Ashtanga Hridaya, which mentions Buddhist deities, teachers, and Tibetan medicine. These three ancient books, written in Sanskrit, are known as the *Great Trilogy or Brihat Trayi*. They have gained respect in the last 2000 years and are considered the main and oldest texts on Ayurvedic medicine [4, 5].

It is clear that Ayurveda is not some folk medicine that was thrown together, but a systematic medical practice that has served to restore health and wellness at the physical and mental level. Yoga, already popular in the West, originated with Ayurveda as part of the greater wisdom of Vedic science. Yoga as a therapy for treating disease, whether physical or mental, is part of Ayurveda, and it is traditionally used according to Ayurvedic diagnosis and recommendations [2].

In the olden days, Ayurveda was learned in the Gurukul tradition of education, which involved a long period of intense study under accomplished masters. The student stayed with the teacher in the Gurukul residential school for years to study and learn. Ayurvedic medicine was originally an oral tradition, taught and passed directly from teacher to apprentice. The modern system of Ayurvedic education evolved in the early 1950s, requiring the Ayurvedic physician to complete at least a 5-year postgraduate degree program [6].

It should be remembered that Ayurveda is not just the science of health. Healthful living, prevention of disease, and personal and social hygiene all come under its wings and not merely the cure of diseases. The fundamentals on which the Ayurvedic system is based are essentially true for all times and do not change from age to age. These are based on human factors and intrinsic causes. Being a natural and holistic life science, it can fit to any region, person, occupation, day, and age. In the West, Ayurveda is recognized as a complementary and alternative health system by the National Institutes of Health, and it is blossoming in various educational institutions [3, 7].

45.2 Advancement of Ayurveda in the USA

Interest in Ayurveda in the USA began in the early 1970s because of Maharishi Mahesh Yogi's Organization of Transcendental Meditation. Interest continued to grow as Indian physicians came to the USA in the 1980s and spread the awareness about Ayurveda. In the late 1980s, Dr. Deepak Chopra wrote *Perfect Health*, a book that helped open the door to India's ancient science for many in the West. Among those were Dr. David Frawley, of the American Institute of Vedic Studies, and Dr. Robert Svoboda, who studied and completed India's BAMS program. In 1995, two of Dr. Frawley's students founded the first two schools of Ayurveda in the USA [8].

45.3 Ayurvedic Education in India, the USA, and Beyond

Ayurvedic medicine is a well-established educational system. There are around 247 BAMS colleges in India imparting Ayurvedic knowledge and wisdom and preparing Ayurvedic doctors for the future [9]. Students still study from tradi-

tional books and *Samhitas* [10]. In the 1970s and 1980s, *Ayurveda* started spreading in the West, as many Indians started migrating to the USA and Europe. Today numerous colleges and institutes offer *Ayurveda* courses in the USA, Europe, South America, and Australia. In the USA, there are two main professional associations catering to Ayurvedic professionals and those interested in *Ayurveda*. The *National Ayurvedic Medicine Association* (*NAMA,* ► ayurvedanama.org) is a professional organization representing Ayurvedic professionals in the USA. The *Association of Ayurvedic Professionals of North America* (*AAPNA,* ► aapna.org), founded in 2007, is another professional organization in the USA whose focus is to create a community of Ayurvedic professionals with the common goal of growing the presence of Ayurveda in integrative healthcare. Both organizations have lists on their websites of colleges/institutes for anyone wishing to pursue Ayurvedic education in the USA. The *Council for Ayurvedic Counseling (CAC)* is an independent group of trained, highly experienced, academically qualified and professional Ayurvedic clinicians and teachers who are deeply committed to the field of Ayurvedic education in the USA (► cayurvedac.org). Several experts in the field of Ayurvedic education and licensure indicated in interviews that there is precise work going on to establish licensure in Ayurveda (MD Jayarajan, Ayurvedic approach in chronic disease management, personal communication, 21 Mar 2017; A Raut, Ayurvedic approach in chronic disease management, personal communication, 24 Mar 2017; V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017). In Europe, Ayurveda is growing at a fast pace and being recognized as a detailed traditional college of holistic medical system. The nonprofit *Rosenberg European Academy of Ayurveda* (*REAA,* ► ayurveda-academy.org) was founded by Kerstin and Mark Rosenberg in 1993 [11]. In South America, Ayurveda has been growing rapidly in the last 20 years, and courses are being offered in major medical schools in Argentina. *Fundación de Salud Ayurveda Prema, Argentina,* has been working to advance Ayurveda throughout Latin America. The organization is collaborating with Indian universities and has been accredited as a collaborating center for teaching and research in the field of Ayurveda in Argentina [12]. Based on the data from India, Europe, South America, and the USA, it is evident that Ayurveda is growing and becoming a prominent part of today's medical science. Integrative and functional medical nutrition therapies have a great potential to incorporate Ayurveda in practice.

45.4 Introduction to Ayurvedic Approach of Treatment

Ayurveda uses an individualized approach. It is based on the principle that everybody has a unique constitution or body type or humor, commonly referred to as dosha. The three main body types are Vata, Pitta, and Kapha, each defined by the composition of its dominant elements and their respective qualities, or gunas. There are 20 such qualities, described as pairs of opposites: heavy-light, dull-sharp, cold-hot, wet-dry, smooth-rough, dense-liquid, soft-hard, firm-mobile, gross-subtle, and sticky-clear. Every individual has a unique constitution in which one or two of the doshas can be dominant. In rare cases, all three doshas can be equally balanced; this is called Sama Prakruti. An examination of the individual based on their prakruti and subsequent imbalance, or vikruti, will shed light on the treatment modality for each individual.

45.5 Descriptions of the Doshas

Vata (air and space): It is responsible for any movement in the body and cooling energy. A Vata-dominant person will have a small frame and small eyes; a tall, thin, or lanky appearance; prominent bones and cracking joints; and wavy, rough, thick hair, to name a few. They are usually quick in movements, walking fast and talking fast, and constantly changing their ways and interests. They are enthusiastic and creative. Their digestion is usually irregular with bouts of hunger and not feeling hungry at times. They are prone to constipation, bloating, and joint pains. Their response to stress is usually anxiety, nervousness, or fear. Their memory is short-lived, and although they grasp things quickly, they also forget easily. They have very disturbed sleep and wake up easily.

Pitta (water and fire): It is responsible for heating energy, metabolism, and vision. A Pitta-dominant person will have a moderate frame, angular face, colored eyes, thinning or early graying hair, sharp and penetrating eyes, and pink nails. Their personality is one of passion and intensity, given the fire element. They are driven to do many things that they are passionate about and are very focused in their efforts. They are competitive, aggressive, controlling, very organized, and intelligent, and they assimilate knowledge very well. They have leadership qualities, but when stressed they tend to get irritable and angry. They have a strong appetite and can digest anything when in balance. Nightly sleep is moderate, about 7–8 hours, restful but not deep.

Kapha (earth and water): It is responsible for stability, binding, water balance, lubrication, healing properties, and cooling energy. A Kapha-dominant person usually has a large frame; solid muscles; fat; short bones; a flatter nose; large, beautiful eyes; a gentle look; dark-brown thick hair; a soft, oily clear complexion; a round face; and perfect teeth. They are very slow in movement and learning, but retention is excellent due to strong memory. Some other characteristics: being grounded, inertia, great stamina, a loving nature, compassion, and affection. They are miserly in spending money and hoard things because they can't let go. If imbalanced, they can become possessive, jealous, and depressed. Metabolism is very slow, so they tend to be overweight. They can skip meals, have cravings for sweet taste, find it hard to lose weight, and don't drink much water. Sleep is usually very deep, 9–10 hours, and they have difficulty waking up in the

morning. When stressed, they become quiet and withdrawn (▶ Box 45.1).

Ayurveda teaches that what exists in the macrocosm is also present in the microcosm. We see this correlation in the natural world around us. In the earth's ecosystem, Vata is expressed in the motion of the wind and in water currents. Pitta is present as sunshine and fire. Kapha brings us the solid structure of the earth, rocks, and water (V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017). Therefore, understanding nature and our relationship with it will help guide us intuitively in providing the right diet and lifestyle for healing and wellness.

Box 45.1
Ayurvedic approach to health, or Swastha: Definition of health:

» *sama dosha sama agnischa sama dhatu mala kriyaaha | Prasanna atma indriya manaha swastha iti abhidheeyate || Sushruta Samhita 15:38* [13]

One who is established in the self, who has balanced doshas, balanced agni (digestive fire), properly formed dhatus (tissues), proper elimination of malas (wastes), well-functioning bodily processes, and whose mind, soul and senses are full of bliss, is called a healthy person [23]

45.5.1 Three Supporting Pillars of Health (Trayopasthambas)

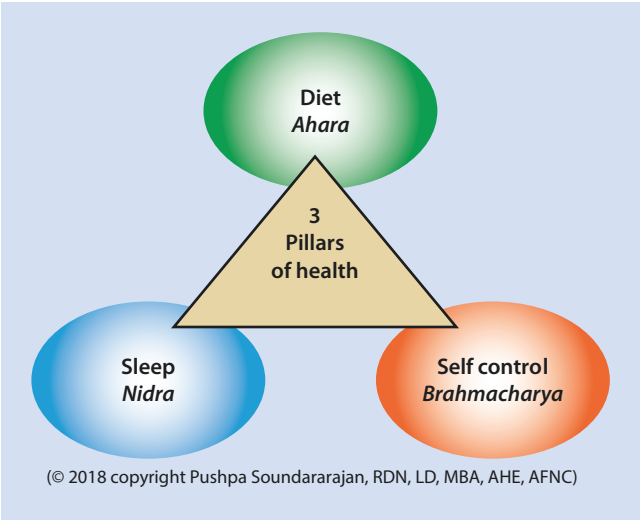
There are three pillars for an individual's utmost health and well-being, as per Ayurveda:

1. Ahara *(diet)*: This encompasses anything which we ingest to nourish our body and mind, which includes food, water, breath, emotions, and information through sense organs [14].
2. Nidra *(sleep):* Includes proper sleep habits, including duration and timing of sleep.
3. Brahmacharya *(self-control):* A self-controlled life, including sexual activity, is essential to attain physical, mental, and spiritual balance [4, 15].
   Overindulgence in any of the above pillars could potentially lead to disease (◘ Fig. 45.1).

45.6 Overview of Ayurvedic Nutrition and Principles

Ahara, or food, is essential for Prana, or life force. Ahara Rasa, the essence of the food we eat, provides the building blocks to create new tissues or the seven dhatus in the body. A great deal of emphasis is placed on nutrition, digestion, and metabolism, which correlate with the sense of taste and digestive fire or Agni.

Modern nutrition classifies food into food groups like fruits and vegetables, dairy, meats and beans, starches, and fats and oils. Ayurveda, however, classifies foods based on their Rasa (six tastes: sweet, sour, salty, bitter, pungent, and astringent), their Virya (potency, heating or cooling), and their Vipaka (post-digestive effect, sweet or pungent). Food recommendations in Ayurveda are based on body types and the tastes that are most suitable for pacifying their respective doshas or imbalances.



◘ **Fig. 45.1** Pillars of Health. (Based on data from Refs. [15, 16])

45.6.1 The Six Tastes

Nature has packaged all possible food sources into six tastes. Before the discovery of proteins, carbohydrates, fats, minerals, vitamins, and trace elements, Ayurveda taught that we need all six tastes present to make a balanced meal. The six tastes are sweet, sour, salty, pungent, bitter, and astringent [17]. Each taste is a combination of two dominant elements, and each has a different effect on the doshas. Diet is recommended based on the type of doshic imbalance, incorporating the appropriate taste to be included in each meal. ◘ Figure 45.2 lists some examples of foods from the six tastes and their impact on the doshas denoted by a "+"for aggravating the dosha or a "–" for a pacifying effect on the dosha. V, P, and K stand for Vata, Pitta and Kapha respectively.

45.6.2 Basic Ayurvedic Principles

A. *Agni,* the digestive fire, is a major principle in Ayurveda. Digestive fire is needed to digest anything we bring into our body. If the Agni is high, even a suboptimal intake can be fully digested, absorbed, and assimilated in the body to create energy. However, if the Agni is low, then even the best-quality foods do not provide the right nutritive value as the food is neither properly digested nor properly assimilated. The strength of appetite reflects the underlying state of our digestive fire (V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017). When Agni is weakened or disturbed, food is not properly digested. The undigested, unabsorbed food particles start to build up in the GI tract

SIX Tastes of Ayurvedic Nutrition

Rasa *Dosha +/-*	*Virya (elements)*	*Vipaka*	Food sources
Sweet ***Madura*** V - P - K+	**Cooling** (Earth + Water)	Sweet	Most grains like wheat, rice, barley, corn, and most bread. • Most legumes, such as beans, lentils, and peas. • Milk and sweet milk products, such as cream, butter, and ghee. • Sweet fruits like dates, figs, grapes, pears, and man-goes. • Certain cooked vegetables, potatoes, sweet potatoes, carrots, and beets. • All cooking oils including ghee, olive oil, coconut oil, sesame oil, and butter. • Almonds, walnuts, pistachios, sunflower seeds, and nut milks. • Sugar in any form except honey
Sour ***Amala*** V - P + K+	**Heating** (Earth + Fire)	Sour	Sour fruits like lemon, lime, and sour oranges. • Sour milk products like yogurt, cheese, sour cream, and whey. Fermented substances like wine, vinegar, soy sauce, and sour cabbage.
Salty ***Lavana*** V - P + K+	**Heating** (Water + Fire)	Sweet	Any kind of salt. • Foods to which a large amount of salt is added. • Most sea vegetables and animals. Pungent is a Kapha-pacifying taste. A sampling of the heating-pungent foods includes:· Spices like chili, black pepper, mustard seeds, ginger, cumin, and garlic.· Certain vegetables, like radish and onion. A sampling of the cooling-pungent foods includes:· Spices, including coriander, fennel, basil, and dill.
Pungent ***Katu*** V+ P++ K-	**Heating** (Fire + Air)	Pungent	Spices like chili, black pepper, mustard seeds, ginger, cumin, and garlic. • Certain vegetables, like radish and onion. A sampling of the cooling-pungent foods includes: • Spices, including coriander, fennel, basil, and dill.
Astringent ***Kshaya*** V+ P- K-	Cooling (Air+ Earth)	Pungent	Legumes, beans, and lentils. • Walnuts, hazelnuts, cashews, and pumpkin seed. • Honey and black, green, and white teas. • Sprouts, lettuce, and other green leafy vegetables; rhubarb; and most raw vegetables.
Bitter ***Thikta*** V+ P- K-	Cooling (Air+ Space)	Pungent	Certain fruits, like olives and grapefruits. • Green, leafy vegetables like spinach, green cabbage, Brussels sprouts, and zucchini. • Eggplant, bitter gourd, chicory, chocolate, and coffee. • Certain spices, like turmeric and fenugreek.

Rasa - Taste
Virya - Potency; heating or cooling to the body
Vipaka- Post digestive effect; long term action on the body

Prabhava - Special action
Unique action of a substance after consumption. Eg. **Amla (gooseberry)** is sour and heating but sweet post digestive effect which is cooling.

Fig. 45.2 Six tastes in Ayurvedic nutrition. (Based on data from reference (V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017) and Refs. [15, 18])

and other subtle sites in the body, turning into a toxic, sticky, foul-smelling substance called Ama [19]. These toxins are similar to cholesterol that forms plaque in the arteries and need to be removed by detoxification modalities described as Panchakarma in Ayurveda.

B. Another principle that is observed in Ayurveda is that *"like increases like,"* which means that a food that is dominant in water element will increase water in a Prakruti dominant in a water element like Kapha. The logical intervention would be to restrict foods with that property in the corresponding Prakruti.

45.7 Ayurvedic Concept of Food Is Medicine

Ayurveda does not classify any specific food as a "superfood," as all foods can be modified to fit the individual's needs, based on Prakruti/Vikruti or body type/imbalance. However, there are certain foods that are considered beneficial in many ways for all doshas, and these are supported by plentiful scientific evidence. Figure 45.3 illustrates eight of those foods, although this is in no way a comprehensive list.

Ghee, as described in Ayurveda, is not technically clarified butter, which is made by melting butter available in stores. It is a more complex process that involves extracting the cream from cultured yogurt, making butter from that, then heating it to clarify it, and removing the brown residue by filtering it. This ghee has micronutrients and is called medhya, which is nourishing to the brain. Studies revealed no blood lipids elevated with the consumption of ghee, despite the presence of saturated fat [29].

Uses: It is used as a medium or Anupana for giving herbs, called medicated ghee. Also:

- It is a healthy fat and has a high smoke point, so it's suitable for cooking and frying.
- It can be used as a spread on toast instead of butter.

Fig. 45.3 Food is medicine. (Based on data from Refs. [15, 20–28])

- It is used for frying seasonings and adding them to foods.
- It is commonly used to make nasya for nasal cleansing and for the eyes as well [26].
- Take one spoon of ghee mixed in warm water or warm milk at night to relieve constipation. It helps with oleation therapy [15, 26].

Turmeric, or Curcuma longa, has a bitter taste with heating potency. It contains the diverse nutraceutical curcumin, which has been shown to prevent many chronic diseases – including obesity, diabetes, certain types of cancers, and autoimmune disease – by fighting inflammation [15, 23, 26]. It is a blood purifier and antiseptic, and it is very useful for liver disorders.

It has multifold uses:

- *Cooking:* It is a common spice used in Indian cooking. It can be added to soups, lentils, curry, and rice noodles.
- *Golden milk*: Popular nowadays, this drink is made by boiling 1/4 tsp. of turmeric in a cup of organic milk. You can add raw sugar to it if hot or honey if lukewarm and drink it. A pinch of cinnamon or nutmeg can be added as well and taken in the morning or at night for a good night's sleep.
- Mix 1/4 tsp. of turmeric with lemon juice and honey in warm water and drink on an empty stomach in the morning as a daily detox and to enhance metabolism.
- *For inflammation:* Make a paste of dry roasted turmeric and apply on the area of a sprain.
- *For pimples or acne:* Make a paste of turmeric, sandalwood, and milk. Apply it;
- *For type 2 diabetes:* Mix a tsp. each of turmeric and amalaki powder in water and drink it (A Raut, Ayurvedic approach in chronic disease management, personal communication, 24 Mar 2017).

Tulsi, or holy basil, is bitter and pungent with a heating potency. It is a powerful adaptogenic herb referred to as "queen of herbs" and is revered as a sacred plant with great healing powers. Tulsi has immense benefits for people with respiratory problems, including asthma, allergies, cough, cold, and fever. It is an antibacterial and antiviral herb. The reviewed studies reinforce traditional uses and suggest Tulsi as an effective treatment for lifestyle-related chronic diseases, including diabetes, metabolic syndrome, and psychological stress [15, 22].

Uses and other health benefits per Ayurvedic literature:

- It can be made into a tea for respiratory benefits, either by using the leaves themselves or by steeping Tulsi powder in hot water for 5–10 minutes.

- The leaves can be eaten raw for their medicinal properties and as a mouth freshener.
- The leaves can be crushed and the juice extracted to be used for fever, cough, and cold.
- It is also a water purifier and is considered very auspicious in spiritual practices in India.
- A decoction of Tulsi with ginger juice and honey is good for sore throat.

Fenugreek is pungent in taste and has a post-digestive effect with a heating Virya. It is a native spice of India and South Europe. Fenugreek seeds and leaves are anticholesterolemic, anti-inflammatory, antitumor, carminative, expectorant, hypoglycemic, laxative, parasiticidal, and restorative. They serve as a uterine tonic and are useful for burning sensations. Fenugreek is used by breastfeeding mothers to increase milk production. Fenugreek and alpha-lipoic acid is associated with a blood glucose-lowering effect, according to strong scientific evidence [15, 27].

The seeds and leaves can be used in many ways:

- Soak 1 tsp. of the seeds in water and drink it in the morning on an empty stomach for blood sugar control for diabetics [15, 27].
- The seeds can also be sprouted and eaten as a curry.
- It is used in cooking as well, roasted in oil or dry roasted, or as a powder added to soups, gravies, lentils, mixed grains, etc.
- The leaves can be mixed into the dough to make unleavened bread called paratha.
- A few leaves can be added to lentils or soup as well.

Mint, or pudina, has a sweet and mildly pungent taste with a warming potency and pungent post-digestive effect. Plant-derived natural compounds have the potential to ameliorate the causes and symptoms of neuroinflammation because of their various antioxidant and anti-inflammatory activities, without completely muting the immune defenses. *Scutellaria* is a perennial plant in the mint family that has been used to treat diseases in Asia and Eastern Europe throughout history [21].

Here are some ways it can be used:

- It has antiemetic properties and is used for nausea in the form of a tea or juice in the dosage amount of 10–15 ml.
- It can be used as a mouth freshener.
- Pudina chutney can be made using the leaves.
- It is also added to soups, lentils, curries, etc.

Ginger, also called ardraka (fresh) or shunti (dry), is called Vishwa Bhaishajya, or universal medicine, in Ayurveda. It is a rhizome (root) and considered pungent in taste and heating in potency, but its post-digestive effect is sweet, which makes it very unique. It plays an excellent role in improving digestion by increasing Agni, as well as in respiratory problems and circulation. It is a natural blood thinner, so if one is on warfarin, caution should be exercised in consumption. Studies have shown that ginger has a potential preventive property against some chronic diseases, especially hypertension and CHD, as well as an ability to reduce the probability of illness [28].

Ginger has many uses as food and medicine:

- *Cooking:* It is used in cooking with soups, noodles, rice, curries, and stir-fries.
- Make into an herbal tea by boiling ginger for a few minutes in hot water or adding it to black tea while steeping. Honey can be added if it is warm, not hot.
- *Cough*: 1/4 tsp. each of ginger powder, turmeric, and black pepper mixed with 1 tsp. of honey can be taken at night before bed to help with cough. Or this mixture can be added to 1/4 cup of warm water and taken as a shot [15, 26].
- *Sore throat*: Same as above with ginger, turmeric, and honey.
- *Diarrhea*: Add a pinch of ginger to cooked rice and a tsp. of ghee (A Raut, Ayurvedic approach in chronic disease management, personal communication, 24 Mar 2017).

Black pepper, or Piper nigrum, is pungent and has a heating potency that aids in digestion. It is great for respiratory disorders, for deep cleansing of sinuses, and as a cough expectorant. Piperine, an alkaloid present in black pepper, has many pharmacological effects and health benefits, especially against chronic diseases, such as reduction of insulin-resistance, anti-inflammatory effects, and improvement of hepatic steatosis [20].

Besides uses in cooking, it is also useful in increasing the bioavailability of herbs:

- It is one of the three ingredients in trikatu, which helps with reducing Kapha and burns up Ama (toxins) and is good for obesity [15, 26].
- It makes other herbs in the preparation more bioavailable. For instance, turmeric is more available when taken with black pepper mixed in honey, for coughs and colds.
- It can be used in cooking in many recipes, in powder form, and is part of many cuisines of the world.

Honey, or madhu, is a sweet and viscous liquid produced by bees from the nectar of flowers. It is primarily sweet in taste with a secondary astringent taste which gives it the quality of lekhana, or "scraping out the cholesterol," which gives it its medicinal property. The health benefits of honey range from antioxidant, immunomodulatory, and anti-inflammatory activity to anticancer action, metabolic and cardiovascular benefits, prebiotic properties, human pathogen control, and antiviral activity [15, 26].

Uses and other benefits per Ayurvedic literature:

- It is a sweetener that can be used in different foods. Because of its astringent nature, it is the only sweetener suitable for diabetics, although moderation is key.
- It can be added to warm water and taken in the morning or with a few drops of lemon juice.
- It is used as a medium or anupana for delivery of many herbs.
- *Caution:* There are certain toxic effects with honey if taken with other foods:

Healthy Eating Habits

1. Choose foods as per your body type or Prakruti.
2. Choose foods according to the season.
3. Eat fresh quality foods. Avoid old, stale, processed, canned and microwaved foods.
4. Listen to your hunger signals and do not eat unless hungry.
5. It is advised to sit and eat, not stand and eat for better digestion.
6. Chew well, as suggested 32 times per mouthful. This enables mouth enzymes to work properly.
7. Eat at a moderate speed, do not gobble.
8. Fill one third stomach with food, one third with water and leave one third empty for better digestion.
9. Eat the amount of food you can hold in two cupped hands (Anjalis). Do not over eat as that can expand the stomach and produce toxins in the digestive tract.

Important Tips:

- During meals **DON'T DRINK ICE COLD WATER, JUICE OR DRINK,** sip little warm water between mouthfuls of foods.
- **Honey** should never be cooked as heating honey causes its helpful enzymes to integrate and make it gluey which are toxins called Ama that can clog the subtle channels or strotasmi.

(© 2018 copyright Pushpa Soundararajan, RDN, LD, MBA, AHE, AFNC)

Fig. 45.4 Healthy eating habits. (Based on data from Ref. [31])

- Honey and ghee should NOT be taken in equal amounts [15, 26].
- Honey should NOT be mixed with hot water and consumed because that leads to a toxic substance that is very sticky and very difficult to remove even with detoxification therapy [30].
- Honey should not be heated or cooked with, and any packaged foods made with honey should be avoided [26] (Fig. 45.4).

45.7.1 Ayurvedic Lifestyle

One of more than 82 natural systems of healing worldwide, Ayurveda emphasizes prevention and gives guidelines for how to make your system optimal to prevent any imbalance without falling sick.

According to Vedic system, there are four major goals in life, called Purusharthas:

> *Dharma artha kama mokshanam*
> *Aarogyam mulam Uttamam.* [26]
> Health is the foundation (mulam) to achieve the four goals of life, namely, dharma (right conduct), artha (wealth and prosperity), kama (desires), and moksha (liberation).

An Ayurvedic lifestyle prescription includes dinacharya, or daily routine; *ritucharya,* or seasonal routine; and sadvritta, or mode of conduct, to achieve these four goals of life.

45.7.2 Dinacharya: Daily Routine

Dina means "daily" and charya means "routine" or "regimen." This covers the mental, speech, and physical aspects of well-being that one should follow every day [15].

Figure 45.5 gives a brief summary of the daily routine that one is encouraged to follow.

45.7.3 Ritucharya: Seasonal Routine

Ritu means "season," and charya means "regimen." This routine deals with diet and lifestyle adjustments for the seasonal variations. All activities in the universe are governed by the two energy principles of heat and cold. The ancient Ayurvedic textbooks are tailored toward an Indian climate, which consists of three seasons: winter, summer, and rainy. However, in temperate parts of the world, where cold is a detrimental factor, these two periods follow equinoxes [2]. In the USA, we talk about four seasons. Figure 45.6 gives a brief summary of the four seasons and suggested recommendations.

45.7.4 Sadvritta: Ethical Regimen

The third aspect of lifestyle management is Sadvritta, which means "ethical regimen" [2] or code of conduct. A healthy mind is as important as a healthy body for wellness. Many dos and don'ts are outlined in ancient texts for the right conduct. Practicing them will give balance and peace to the mind.

Fig. 45.5 Dinacharya daily routine

Dinacharya - Prescribed Daily Routine

1. Wake up time: Ninety minutes before sunrise or at least before sunrise.
2. Pray before leaving the bed to start the day.
3. Evacuate bowel and bladder ideally within an hour of waking up.
4. Oral hygiene:
   a. Brush teeth with natural toothpaste or powder which is astringent in nature. (like neem)
   b. Tongue scraping with metal scrapper, preferrabley copper to remove toxins and increase Agni.
   c. Oil pulling or Gandosha: Swish your mouth with sesame oil or coconut oil till it changes color. This exercises gums and jaws and gives strength.
5. Face cleaning: Wash face with warm water for Vata and Kapha or cool water for Pitta. Wash eyes as well.
6. Vyayaama or Exercise: Yoga and Pranayama (breathing). Other forms of exercise can be done like treadmill, bike etc.
7. Abhyanga or Self Massage with sesame oil starting from the head and going down to the feet.
8. Shower or bathe. This can be done before oil massage too if you want to keep the oil in the body.
9. Drink 1–2 glasses of warm water in an empty stomach.
10. Breakfast should be light and eaten only if hungry. Just fruits can be eaten if not hungry.
11. Lunch should be the main meal of the day preferrably between 10 and 2 pm, around noon.
12. Take 100 steps, light walking and then rest (not sleep) for better digestion.
13. Dinner should be very light more like soups eaten between 6 and 7 pm preferably.
14. Go to bed by 10 pm preferably. Staying up late leads into Pitta time which makes you hungry.
15. Meditation and Pranayama before bed helps get a restful sleep.

(© 2018 copyright Pushpa Soundararajan, RDN, LD, MBA, AHE, AFNC)

Fig. 45.6 Ritucharya – seasonal routine. (Based on data from Ref. [2])

45.7.5 Panchakarma, or Ayurvedic Detox Treatment

Panchakarma literally means five actions. Those actions are vamana (induced vomiting), virechana (purgation), nasya (nasal drops with herbs), basti (medicated enema), and raktamokshana (bloodletting, usually using leeches). Although all of these are practiced in India, only the first four are done in the USA. There are several centers in the USA that perform this kind of treatment, and their durations range from 3 days to even a month, depending on need and affordability. The concept behind this unique therapy is to remove toxins (Ama) built up throughout the body from poor diet and lifestyle. The main procedure is called panchakarma. There is a preparatory stage prior to that called purvakarma, which lasts for a week or two as prescribed by the Ayurvedic physician. After the panchakarma, rejuvenating herbs or rasayana are prescribed to be taken, as the body is detoxing during that phase as well. Special restricted diet and lifestyle recommendations are also made, based on the client's needs for maintenance of good health. This whole procedure is administered with the supervision of an Ayurvedic physician who has had extensive training in the field. Specially trained massage therapists also play a vital role in this process [2, 26].

45.8 Disease Management in Ayurveda

The National Health and Nutrition Examination Survey indicates that from 2011 to 2014, the prevalence of obesity was just over 36% in adults and 17% in youth. Obesity-related conditions include heart disease, stroke, type 2 diabetes, and certain types of cancer, all of which are among the leading causes of preventable mortality [32].

Metabolic syndrome, a group of risk factors related to the disorders listed above, bears striking resemblance to the santarpanjanya vikaras (comprised of diseases due to overnutrition and defective tissue metabolism) described in classical Ayurvedic texts. Ayurveda focuses mainly on conservation of health rather than disease eradication. It presumes that improper dietary habits and deranged functions of different sets of Agni (Metabolic fire) give rise to the formation of Ama (reactive antigenic factor), which in turn causes disease [33].

In the management of lifestyle diseases, Ayurveda offers various regimens, including dinacharya (daily regimen), ritucharya (seasonal regimen), panchakarma (five detoxification and bio-purification therapies), and rasayana (rejuvenation) therapies. The sadvritta (ideal routines) and achara rasayana (code of conduct) are of utmost importance to maintain a healthy and happy psychological perspective. Including several of these modalities is very effective in controlling these disorders. Moreover, the application of organ-specific rasayana herbs, which is unique to Ayurveda, helps not only in healing but also in the rejuvenation process [34].

Ayurveda describes metabolism of food in a unique way, from ingestion of food called Ahara to the formation of tissues in the body. There are seven tissues or dhatus that are formed in succession every 5 days. These are rasa (plasma and lymph), rakta (blood, RBCs, and platelets), mamsa (muscle), meda (adipose tissue), asthi (bone), majja (nerves and bone marrow), and shukra (reproductive tissue). The food eaten mixes with the digestive enzymes, and the essence called Ahara rasa gets metabolized with the help of the different dhatu agnis, or digestive fires, to form the seven bodily tissues in the order given. These provide support and strength to the body. These, along with the organs, form an elaborate network of channels called Strotas, to carry the nutrients to the different parts of the body and wastes for elimination. There are 14 such srotasmi described in Ayurveda, similar to the systems in modern medicine. Diseases occur when proper flow is obstructed through these channels. Obesity, as an epidemic in today's society, is discussed first. Weight management can go a long way in controlling many of the metabolic diseases.

45.8.1 Obesity per Ayurveda

The Ayurvedic term for obesity, or overaccumulation of fat under the skin and around certain internal organs, is called Sthaulya. Another name for obesity in Ayurveda is medaroga, as the meda or fat is the main cause of this condition and roga means disease [35]. Charaka Samhita has given the description as large hips, excess bulk over the midsection, pendulous breasts, and too much flesh over the chest [26]. Obesity is divided into central obesity, where the belly is big; truncated obesity, where the breasts are big; and peripheral obesity, where the extremities are large. These conditions are the result of displacement of fat to different regions by Vata energy because of the person's food, lifestyle, and emotions. Therefore, if a person has deep-seated grief and sadness in the lungs, which are Vata emotions, they are carried lower down to lead to chubby thighs [19]. We can deduce from this that some Vata-pacifying techniques may be beneficial in treatment.

45.8.2 Causes of Obesity

In Ayurveda, medaroga is caused by aggravation of Kapha. Kapha is the humor or dosha that is dense, heavy, slow, sticky, wet, and cold in nature. It governs all structure and lubrication in the mind and body, apart from controlling weight and formation of all seven tissues (dhatus).

In a balanced state, Kapha gives nourishment to these tissues through micro-channels. However, when it is aggravated, it leads to production of toxins in the body. These toxins or Ama are heavy and dense in nature and accumulate in weaker channels of the body, causing blockage. In the case of an obese person, toxins accumulate in medovaha strotas (fat channels), thereby leading to an increase in the production of fat tissues, which causes an increase in weight. The other problem that ensues as a result is that these blockages prevent air or vata from moving freely through the channels,

and they get redirected to the stomach. Here they further stimulate the digestive fire (jatharagni) to burn more, like a fan that flames a fire, and thus leads to constant hunger [36]. This makes the person eat more, and this turns into a vicious cycle.

The degree of obesity in a person is dependent on the accumulation of fatty globules or cells. As long as the accumulated fat is stored in the adipose tissue, it does no harm. But when it begins to enter into the cellular elements of the body, especially the muscles, it becomes a source of danger. Since the fat channels get blocked, the next dhatu, which is asthi or bone tissue, is not formed well, and this results in osteoporosis.

As per Ayurveda, common causes of obesity are heavy intake of sweet, cooling, and unctuous food; lack of physical exercise; sleep during the day; lack of mental exercise; and heredity.

Habitual drinking of cold drinks and eating fatty fried foods; eating dairy products such as cheese, yogurt, and ice cream; and consuming excess sugar and carbohydrates are all causative factors [19]. It is believed that "food is the food for the body; love is the food for the soul." When a person is not feeling love within, he or she tends to turn to food to fill that void, commonly referred to as emotional eating in Western society.

Ayurveda approaches these issues from a deeper understanding of digestion, which started the whole process in the first place. If the digestion is improved, then the fat channels will clear up, and then the food that is consumed will be used to nourish all the dhatus instead of being stuck at the meda dhatu level. Clearing the Ama and improving digestion are the major approaches to treatment. Since Vata may also be involved in transporting these fat molecules, a comprehensive treatment could include Vata-pacifying techniques like oil massage, shirodhara (oil dripping over the forehead), yoga, and meditation, to name a few [35] (Fig. 45.7).

Case Study

Pushpa Soundararajan, RDN, LD, AHC, AFNC

A 60 year old Caucasian female with Diabetes, Chronic renal failure Stage 3 and Obesity Grade II (BMI38.2), Fibromyalgia, joint problems, chronic pain, exhausted majority of the time and Constipation came in for Nutrition Counseling.

Anthropometrics: Height: 5'8", Weight: 252 lbs.

Weight history showed she used to be 129 lbs for majority of her life. She claimed to have gained 100 lbs due to Medications Paxil and Prednisone. She does not do any regular exercise but just some routine household chores. She had trouble falling asleep usually woke up exhausted even after 8-10 hours. She said her response to stress was to eat.

She had tried Atkins diet 8 years ago, lost 30 lbs but gained it all back. She tried another commercial diet program 12 years ago but did not notice any change.

Diet Recall revealed eating breakfast and dinner and often skipped lunch. If she did eat lunch it included a sandwich or leftovers. Breakfast usually consisted of cold cereal with almond milk or bagel and cream cheese with iced tea. Dinner included a salad, some vegetables and some pasta with meat. She rarely ate after dinner but if she did she had a craving for sweets.

Ayurvedic Assessment:

It was very clear based on her symptoms she had a Vata imbalance given her choice of cold foods, tiredness and constipation. Her dietary habits and lifestyle contributed to the imbalance and having kidney failure she wanted help with restrictions as well.

Recommendations:

Reviewed renal restrictions from Modern nutrition perspective. Suggested switching to warm water and starting with 1 glass in the morning before breakfast to aid in cleansing and facilitating bowel movement. Recommended eating her main meal at lunch time with cooked foods including small portion of meat, kidney friendly vegetables and limited carbohydrate foods. Suggested dinner of soup or something light with more vegetables and less meat. Counseled on mindful eating, paying attention to hunger cues, avoiding distractions while eating and enjoying her meal and portion control by not going for seconds. Sipping hot water or herbal teas like lemon ginger was suggested for better digestion. Encouraged exercise of walking for at least 15 minutes per day and work up to 30 minutes gradually as medically possible.

Follow Up Visit:

Patient came back in 3 months. She was very happy, energetic and had lost 13 lbs. Her weight was 239 lbs, BMI 36.3 down from 38.2. She said she had made the switch to main meal at dinner, eating only cooked foods, warm water and paying attention to her hunger signals. She said she was very satisfied with lunch and didn't even need any dinner most days. She also had no cravings. She was very upbeat and said she had more energy and felt so good that she is motivated to continue. She did not incorporate exercise as suggested but yet with her Vata getting better she found improvement. Suggested to continue with the dietary regimen, suggested some kidney friendly Ayurvedic recipes with spices and digestive CCF (Cumin, Corriander, Fennel) tea. Encouraged walking even 10 minutes after meals for consistent control of BS levels.

Fig. 45.7 Case study 1

45.8.3 Diabetes and Other Related Disorders

Prameha is the term used for diabetes and other related syndromes. There are 20 types of diabetes identified by Ayurveda. It is a metabolic disorder of agni, the energy of transformation. When there is a dysfunction of the agnis, especially the kloma (pancreas) agni, the carbohydrate metabolism is disturbed [37]. Any of the doshas may be imbalanced, but the first step is always to rebalance the agni to regulate nutrient metabolism and water-electrolyte balance. Dietary and lifestyle changes can go a long way in doing that.

Following are some suggested guidelines that could help kindle the agni and aid in weight loss. Since generally Kapha dosha is disturbed in obesity and other metabolic disorders, these suggestions would be useful. If other doshas are disturbed, adjustments need to be made accordingly. An Ayurvedic practitioner will be better equipped to make that assessment (Fig. 45.8).

45.8.4 Ayurvedic Dietary and Lifestyle Recommendations for Obesity and Metabolic Disorders

1. Generally, a Kapha-pacifying diet is recommended.
2. One can use basmati rice, barley, green gram, red gram, and horse gram.
3. Honey is the only sweetener that is recommended while treating obesity, but it should be original honey, directly collected from honeycombs.
4. Drink warm water instead of refrigerated water.
5. For cooking purposes, use sesame oil or mustard oil with spices like turmeric, black pepper, ginger, and rock salt.
6. Use vegetables with astringent, bitter, and pungent tastes. If you are particular about your weight, it might be helpful to fast for 1 to 2 days a week, or to partially fast while drinking fruit juices, warm water, and honey.

Clinical Case study
Vaidya Ashlesha, Raut BAMS, MD (Ayurveda)

38 year old female, 63 inches tall and weight is 124 lbs with Narcolepsy with Cataplexy (Sleep Paralysis).

Symptoms: Extensive sleepiness during daytime, intermittent uncontrollable episode of falling asleep at workplace, frequent episodes of partial to total loss of muscle tone (Cataplexy). Sleep paralysis was experienced during day- time. She also used to suffer from post- menstrual severe headaches, which further used to trigger her Cataplexy. Symptoms were overwhelming and disturbing her daily life as described by patient. She was treated with many drug prescriptions along with antidepressants from her MD. Patient did not experience significant improvement and decided to try Ayurveda.

Ayurvedic Diagnosis:

Patient's Dosha Prakruti showed the Vata-pitta type. The area of Doshik- imbalance was of strong Vata imbalance covering Sadhak pitta. The dhatu imbalance involved Mamsa dhatu and Rasa dhatu. She also showed signs of AMA (Toxins in Ayurveda) and low Ojas (Vital energy).

Ayurvedic Treatment approach:

Ayurveda treatment included Diet, lifestyle and herbs recommendations. She was started with Amapachaka herbs (Herbs that digest ama- toxins), along with Vata pacifying treatment. Her diet was carefully checked to rule out Vata provoking foods. Also Ojas (Energy) increasing foods were recommended. In lifestyle changes she was given specific Pranayama (Breathing exercise) along with many Apana soothing yoga postures (wind releasing poses). She was encouraged to perform very specific daily abhyanga (Self oil massage). After a period of time she was given authentic Panchakarma treatment, which was followed by Ayurveda Rasayana therapy which included focus on Vata dosha, Rasa and Mamsa dhatu.

Within 3 months significant improvement was noticed, postmenstrual headaches stopped, episodes of cataplexy reduced. After panchakarma treatment her energy level increased and with Rasayana treatment her quality of life improved. The whole treatment took 9 to 10 months but tremendous improvement noticed.

Fig. 45.8 Case study 2

7. Avoid eating substances prepared with refined wheat flour, including white bread, cakes, and pastries; and abstain from dairy products and sweets prepared from milk and sugar.
8. You should also avoid cold drinks, alcohol, and deep-fried foods, and follow a vegetarian diet. If you do eat meat, choose chicken or fish just once a week [38].
9. Follow an active pattern of life by increasing work and mental activity. You should avoid taking too much rest, sleeping during the day (particularly after meals), and bathing with cold water.
10. Vyayama (special exercise) is definitely helpful in burning some calories, but the most important factor is that it brings the body into shape and creates a general feeling of well-being. Walking is good for all doshas.
11. Whatever the ultimate cause of obesity in your case, the immediate cause is energy imbalance, and weight reduction can be achieved only by reducing energy intake or by increasing output or by a combination of the two.
12. Yoga recommendations: Sun Salutation or Surya Namaskar (SN) is a classic yoga exercise consisting of 12 asanas performed sequentially and synchronized with breathing [39]. It is considered a comprehensive and ideal practice for physical and spiritual well-being. SN is performed as a prayer to the Sun, ideally at sunrise and in open air, facing east. It has aerobic and dynamic components and has been shown to improve strength, body composition, and general body endurance. Performing 6–8 rounds will achieve the energy expenditure of light exercise intensity, and a 10-minute practice may improve cardiorespiratory fitness in unfit or sedentary individuals. Fish, camel, cobra, and cow or other chest-opening poses would also be helpful.
13. Pranayama, especially Bhastrika Pranayama (Breath of Fire), will increase the rate at which your body burns off fat.
14. Meditation is also a strong tool in the Ayurvedic lifestyle to cope with various diseases and improve general well-being (Fig. 45.9).

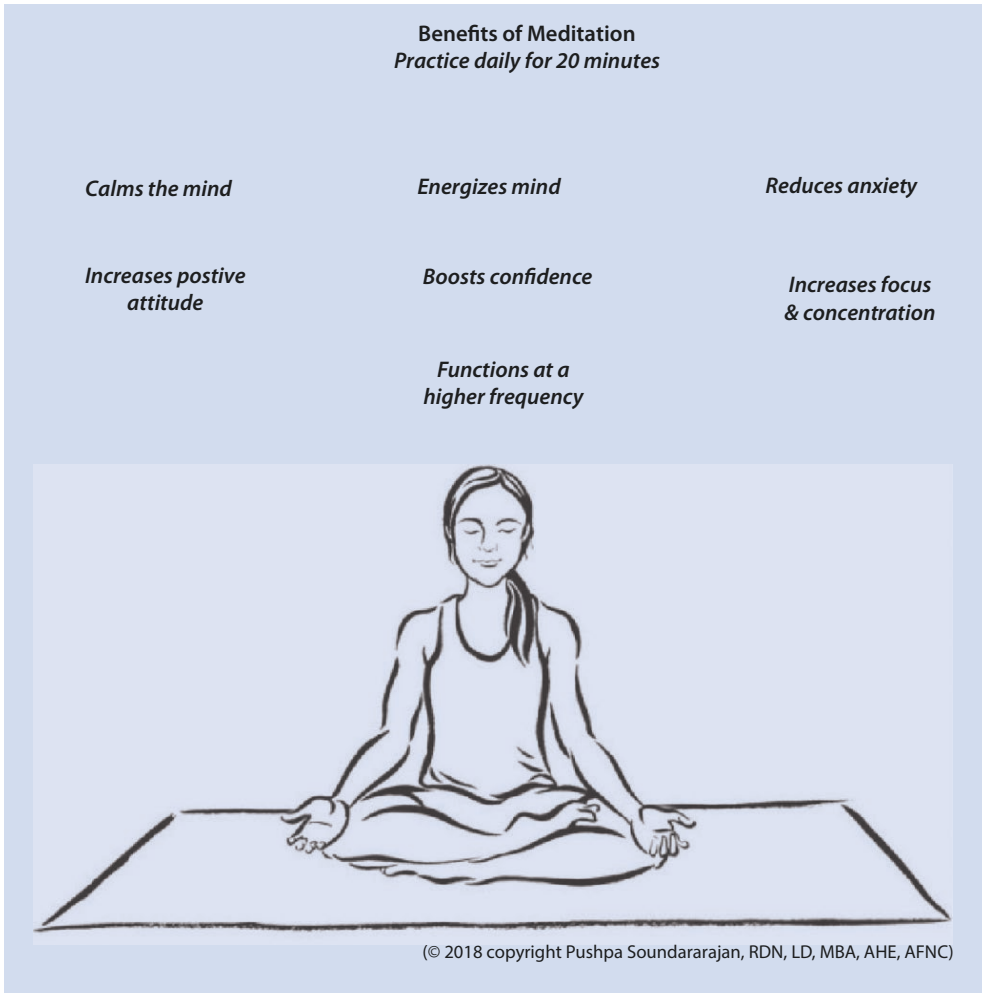

Fig. 45.9 Benefits of meditation: Ancient literature and current scientific evidence suggest that meditation can be a very powerful tool in managing chronic diseases [2, 15, 26, 40]. Potential benefits are listed in the figure

45.8.5 Cancer and Ayurveda

Arbuda is the name given to a malignant tumor or cancerous growth. Traditional Ayurvedic literature has a detailed description of various types of tumors, and the treatment is complicated and based on balancing three doshas, seven dhatus, and three malas (urine, waste, and sweat) [37]. It takes an experienced Ayurvedic doctor to administer treatment effectively (Fig. 45.10).

45.8.6 Integrating Ayurveda in Modern Practice

Integrative health is a system of health in which the intangible as well as the more material aspects of life are given equal importance. Our existence is physical as well as mental, emotional, energetic, and spiritual. Our emotions are intertwined with our physiology. Stress is implicated in 85% of chronic diseases. A healthcare system where therapies are directed to each of these aspects of our existence is called integrative health. This fundamental approach is crucial to life's wholeness. Treating just the physical body with drugs and surgery may be effective, but not enough to solve the problem of chronic diseases. No integrative health system is complete without a consciousness-based model of health and disease. This is what is found in the ancient system of Ayurveda. Integrating Ayurveda with advances in modern medicine will help provide a better healthcare regimen than any one of them practiced separately (MD Jayarajan, Ayurvedic approach in chronic disease management, personal communication, 21 Mar 2017; A Raut, Ayurvedic approach in chronic disease management, personal communication, 24 Mar 2017; V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017).

The Ayurvedic approach consists of diet, lifestyle, and medicine in equal parts. So the integration of the Ayurvedic approach in medical nutrition therapy has great potential. Registered dietitians, nutrition professionals, and other healthcare practitioners can easily apply Ayurvedic principles in their practices. We spoke to several eminent Ayurvedic practitioners around the USA, and they all agreed that holistic and nutrition-focused healthcare practitioners can and should certainly incorporate Ayurvedic principles in their counseling and delivery of nutritional services. As Ayurveda focuses on an individualized approach, its use may provide a strong tool. Interviews were conducted with successful practitioners and eminent faculty at leading Ayurvedic institutions around the country (MD Jayarajan, Ayurvedic approach in chronic disease management, personal communication,

Fig. 45.10 Case study 3

Clinical Case Study
Dr Vijay Jain MD

78 years old male patient with Non-Hodgkins Lymphoma Stage 3.

Ayurvedic diagnosis:
Pitta/vata imbalance with Ama accumulation in the Rakta dhatu (Blood tissue).

Ayurvedic Approach of intervention:
Patient was put on special anti-inflammatory diet in addition to other treatments like lifestyle modification, meditation and pranayama for stress reduction. Patient also underwent a full Panchakarma treatment followed by rasayana therapy with Bhasmas and herbo-mineral compounds. He was in complete remission in six months.

Fig. 45.11 Comparison of Ayurvedic and modern nutrition

Criteria	Modern nutrition	Ayurvedic nutrition
Why do we eat?	Personal preference, habit, body image	To take in Prana to live
Nutrient element	Calories, carbohydrates, protein & fats	Panchamahabhutas or 5 elements (space, air, fire, water and earth)
Main focus for weight loss	Counting calories	Evaluating metabolism based on Agni or digestive fire
Importance give to	Caloric value	Individual Constitution (Prakruti) and imbalance (Vikruti)
Intervention based on	Nutrient deficiency	Balancing Prakruti and Vikruti
Summary	**You are what you eat**	**You are what you digest**

(© 2018 copyright Pushpa Soundararajan, RDN, LD, MBA, AHE, AFNC)

21 Mar 2017; A Raut, Ayurvedic approach in chronic disease management, personal communication, 24 Mar 2017; V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017). They use an integrative Ayurvedic approach in their practice and teaching. Each of these experts emphasized the need to stabilize the disease state prior to beginning treatment. Agni is the hallmark of Ayurvedic nutrition (V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017). Eating healthy foods does not serve you effectively if digestive fire (agni) and digestion, absorption, or assimilation are compromised. In conclusion, integrating Ayurveda with modern nutrition would be beneficial as a holistic treatment modality for patients. ◘ Figure 45.11 summarizes the differences in the two approaches, demonstrating the value in integrating the two in practice.

45.8.7 Comparison of Ayurvedic and Modern Approaches to Nutrition

Take-Home Message

If we healthcare practitioners were to imagine a form of medicine designed especially for twenty-first-century Americans, it might have the following traits:

1. *Preventive:* It would cultivate wellness before illness takes root, strengthening a person's resilience to disease.
2. *Low-intervention*: It would pursue health through diet, exercise, and lifestyle, using drugs and surgery as a last resort.
3. *Affordable*: It would be cost-effective by reducing surgeries and hospital procedures for chronic disease.
4. *Holistic*: It would see a person's body, mind, and spirit – and their environment – as deeply interconnected.
5. *Personal:* Practitioners would build relationships with patients, viewing them as unique individuals.

In short, it would look a lot like Ayurvedic medicine [25], the traditional Indian health system growing robustly among Americans looking for wellness-focused healthcare providers like integrative healthcare practitioners (V Jain, Ayurvedic approach in chronic disease management, personal communication, 4 Apr 2017).

46.1 Introduction

In 2010, the World Health Organization (WHO) announced that, for the first time, chronic noncommunicable diseases have overtaken infectious communicable diseases as the chief causes of mortality worldwide [1, 2]. Cardiovascular diseases (CVD), including coronary heart disease and stroke, are currently the leading cause of death in the world [3]. However, cancer deaths have recently reached an almost equal status to cardiovascular mortality [4]. The most common of these noncommunicable chronic diseases are cardiometabolic disease, cancer, neurological disease, autoimmune disease, metabolic syndrome, diabetes, developmental health conditions, and obesity, which are resulting in unsustainable impacts on global healthcare economies and needless suffering [5–8].

Further, the WHO reports that chronic (noncommunicable) diseases are responsible for 70% of all deaths worldwide, with cardiovascular disease as the primary underlying cause of death. Cardiovascular disease is followed by cancer, respiratory disease, and diabetes. These noncommunicable diseases are also characterized by modifiable risk factors that exist for these conditions [9].

These risk factors include:

- Tobacco use
- Excess sodium intake
- Alcohol use
- Lack of physical activity
- Unhealthy diet

The WHO also lists the metabolic risk factors intimately involved with the development of chronic disease pathophysiology:

- Increased blood pressure
- Obesity or overweight
- Central adiposity with sarcopenic obesity
- Hyperinsulinemia
- Hyperglycemia
- Hyperlipidemia

Characterization of Metabolic Syndrome

- Central adiposity
- Hypertension
- Systemic, chronic inflammation
- Compromised kidney function
- Type 2 diabetes
- Sarcopenia
- Neurodegeneration
- Fetal and infant chronic disease pre-programming
- Increased cancer risk
- Increased cardiovascular disease risk
- Sleep disturbance/apnea
- Increased autoimmune disease risk

These metabolic risk factors – modifiable to different extents with appropriate dietary, physical, and lifestyle interventions – are the same metabolic risk factors associated with the development of cardiometabolic syndrome [10–12] (Tables 46.1 and 46.2).

Table 46.1 Metabolic syndrome: 2017 American Heart Association

Risk factor	Defining level	Exceptions
Abdominal central obesity Waist circumference Men Women	Waist circumference Men > 102 cm (>40″) Women > 88 cm (>35″)	Height <60″ or >74″ Then measure height/weight ratio
Triglycerides (elevated)	Reference range(s) ≤9 years <75 mg/dL 10–19 years <90 mg/dL ≥20 years ≤150 mg/dL	If >150, check Carnitine status to rule out carnitine deficiency Check dietary intake of alcohol, sugar, and sugar-rich foods
HDL (low)	Male <1.03 mmol/l (<40 mg/dl) Female <1.29 mmol/l (<50 mg/dl) Specific treatment for this lipid abnormality	Check HDL/total cholesterol ratio
Hypertension	Systolic >130 Diastolic <85 Treatment of previously diagnosed hypertension	If BP <120/80, check mineral status of sodium and chloride, autoimmune, and thyroid status
Plasma fasting glucose (elevated)	Fasting reference 13–47 mg/dL Non-fasting reference 13–87 Fasting >126 mg/dL diagnosis diabetes	If glucose >5.6 mmol/l or 100 mg/dl, consider oral glucose tolerance test. Compare to HgA1C
Additional insulin resistance markers (not diagnostic for metabolic syndrome)		
HgbA1C (elevated)	HgbA1C normal 4.8–5.6% Hgb/A1C >5.7% prediabetes Hgb/A1C >6.5% diabetes	
Insulin, fasting (elevated)	Reference 2–12, 88–94 µIU/mL	If >10, check clinical waist circumference, body fat %, risk of hyperinsulinemia

Based on data from: Quest Diagnostics, ► www.questdiagnostics.com 2019; American Heart Association, ► www.heart.org; American College of Cardiology, ► www.acc.org [88]

This chapter will present the impact on healthcare of the underlying pathophysiology and nutritional relationships that lead to chronic disease and discuss the current science of chronic metabolic disease processes. These disorders are considered "lifestyle and dietary-related diseases [8, 89]," where the metabolic microenvironment promotes a phenotype characterized by insulin resistance, inflammation, and elevated visceral adipose tissue (VAT). The focus will be on evidence-based nutritional and lifestyle factors that can be individually assessed from where interventions are possible that enable management of the complex human metabolism.

Table 46.2 Body composition measurements

Sarcopenic obesity	Loss of muscle		Independent of BMI
Body type % body fat	**Females**	**Males**	**BMI**
Essential fat % body fat	10–13%	2–5%	All – Independent of BMI
Athletes % body fat	14–20%	6–13%	All – Independent of BMI
Fitness % body fat	21–24%	14–17%	All – Independent of BMI
Acceptable % body fat	25–31%	18–25%	All – Independent of BMI
Obese	>31%		All – Independent of BMI

The practitioner uses a functional systems assessment of the individual to identify metabolic priorities and develop therapies, including the application of nutritional medicine principles to improve health outcomes for the patient.

In addition to the metabolic risk factors listed above, chronic disease is becoming understood to include these related foundational risk factors: abdominal obesity (visceral adipose tissue), sarcopenia, insulin resistance, stress, nutrition, and lifestyle. As this understanding expands, there is increasing recognition of the need to address factors of any success quelling the epidemic of chronic disease. These factors are related to the development of most chronic diseases. In this section of the textbook, various metabolic systems are presented in more detail in the specific chapters. The current protocols of conventional healthcare are discussed, as well as integrative and functional medical nutrition therapy approaches that address the root causes of chronic diseases.

In addition, a growing recognition of diabetes and metabolic syndrome being a mediator of several chronic disease conditions like Alzheimer's, heart disease, osteoporosis, and cancer. They are sometimes referred to as "type 3 diabetes." Intervening with the dietary and lifestyle components of cardiometabolic syndrome may benefit all chronic diseases and can be used as a model therapeutic approach for all chronic diseases.

The societal burden of chronic metabolic disorders is expected to steadily increase. It is projected that 75% of the US population will be obese or overweight by 2030. There are currently 371 million people worldwide who are obese or overweight, and the number is predicted to reach 552 million by 2030. A new case of diabetes is diagnosed in the United States every 30 seconds; more than 1.9 million people are diagnosed each year [90, 91] (Fig. 46.1).

ICD-10 Data

Medical Disorder	*ICD-10*
Metabolic Syndrome	E88.81
Coronary Heart Disease	I25
Hypertension	I10/I16.9
Hypercholesterolemia	E78.0
Hypertriglyceridemia	E78.1
Obesity	E66.9
Hypo HDL cholesterol	E78.6

Chronic Diseases are Diseases of Lifestyle

- Nutrient insufficiency
- Low vegetable intake
- Low omega-3 fat
- Epigenomics
- Oxidative stress
- Poor sleep quality
- Environmental toxins
- Altered microbiome
- Community-socio-genomics

46.2 Pathophysiology: Overview

At the base of many chronic diseases, there are alterations in blood glucose and insulin metabolism, as well as a state of chronic inflammation. These metabolic changes begin to affect the sensitivity of cellular insulin receptors resulting in a growing insulin resistance. Unique to each individual are factors, including nutritional deficiencies and lifestyle choices, that lead to metabolic alterations and that are subject to many influences. Consideration of intra-systemic influences is of central importance when assessing for the etiology of an individual's condition. These influences begin to impact various systems and homeostatic mechanisms, eventually overcoming homeostatic and allostatic controls.

46.3 Homeostasis and Allostasis

Homeostasis may be defined as "the ongoing maintenance and defense of vital physiological variables such as blood pressure and blood sugar [93]". Feedback control, which may be positive or negative, is a core regulatory process that enables homeostasis.

Allostasis is a process that may be thought of as an anticipatory homeostatic mechanism that, in some ways, supplants the classical homeostatic concept of control of systems. Peters and McEwen [94] describe allostasis as an "active process by which living organisms adapt to potential threats to their survival and changes in their environment (often referred to as 'stressors') in order to maintain homeostasis and promote survival." This definition manifests a holistic approach because stressors can be biological, biochemical, and/or psychological, including the concepts of mind-body medicine. A further concept, allostatic load, describes the cumulative effects of physiological stress and disruptions, eventually resulting in a dysregulation of a system. The system whose dysregulation is often the first clinically noted is the cardiovascular system, though pre-existing perturbations can be seen in glucose and lipid control [95] (Fig. 46.2).

46.4 Community and Social Impacts on Psychosocial Determinants of Health

Who your friend, family, or co-worker is can directly affect your health. These are new findings that bring important focus to consider when working with patients to bring into the conversation hearing the patient's story. And if a person does not have meaningful relationships, loneliness can be a primary mediator of illness and have a wide range of negative effects on all chronic diseases (Fig. 46.3).

> These findings indicate that the influence of others' choices on risk-taking behavior is large, direct, cannot be explained by an economic utility model of risky decision-making, and goes against one's own better judgment [97].

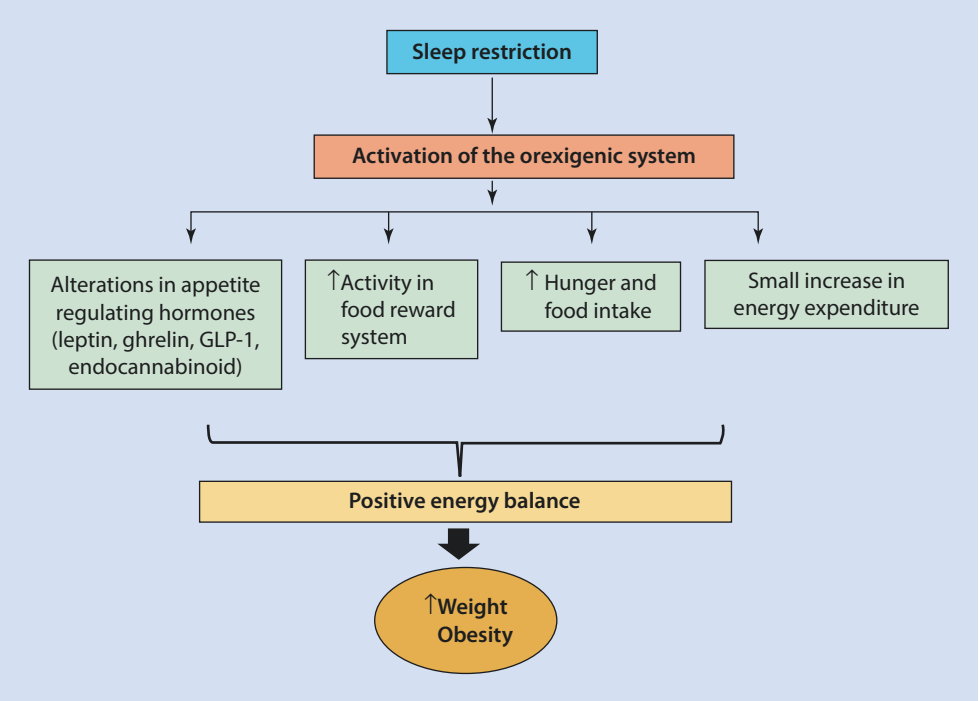
46.5 Inflammation

Swelling, redness, pain, and heat classically characterize inflammation. Loss of function of the tissue or joint may also be involved. This characterization, while valid, primarily focuses on the inflammatory response surrounding a wound or superficial injury. Inflammation involves both the innate and acquired aspects of the immune response and includes a vascular component.

It is important to remember that inflammation is a normal, protective response to injury, but it is the loss of control and prolonged presence of the inflammatory response without resolution that is the underlying pathophysiologic mechanism of damage (see Fig. 46.4).

The inflammatory response involves the cellular and humoral aspects of the immune system and includes endothelial cells, circulating leukocytes and immune and mast cells, and macrophages and lymphocytes embedded within the connective tissue. The extracellular matrix, including glycoproteins, fibrous proteins, and proteoglycans, also plays an important role.

Endothelial cells constitute a selective barrier, controlling the extravasation of leukocytes by the regulation of cellular



Sleep restriction
Activation of the orexigenic system
Alterations in appetite regulating hormones (leptin, ghrelin, GLP-1, endocannabinoid)
↑Activity in food reward system
↑ Hunger and food intake
Small increase in energy expenditure
Positive energy balance
↑Weight Obesity

adhesion molecules. The secretion of various cytokines and colony-stimulating factors regulates immune proliferation.

Neutrophils, macrophages, monocytes, and other immune cells produce vasoactive amines (e.g., histamine, serotonin) and pro-inflammatory cytokines including prostaglandins, platelet-activating factor, growth factors, interleukins (e.g., IL-6), TNF-α, and others. In addition to vasoactive amines and pro-inflammatory cytokines, the complement system, opsonization, phagocytosis, autophagy, and the intracellular release of lysozymes along with reactive oxygen and reactive

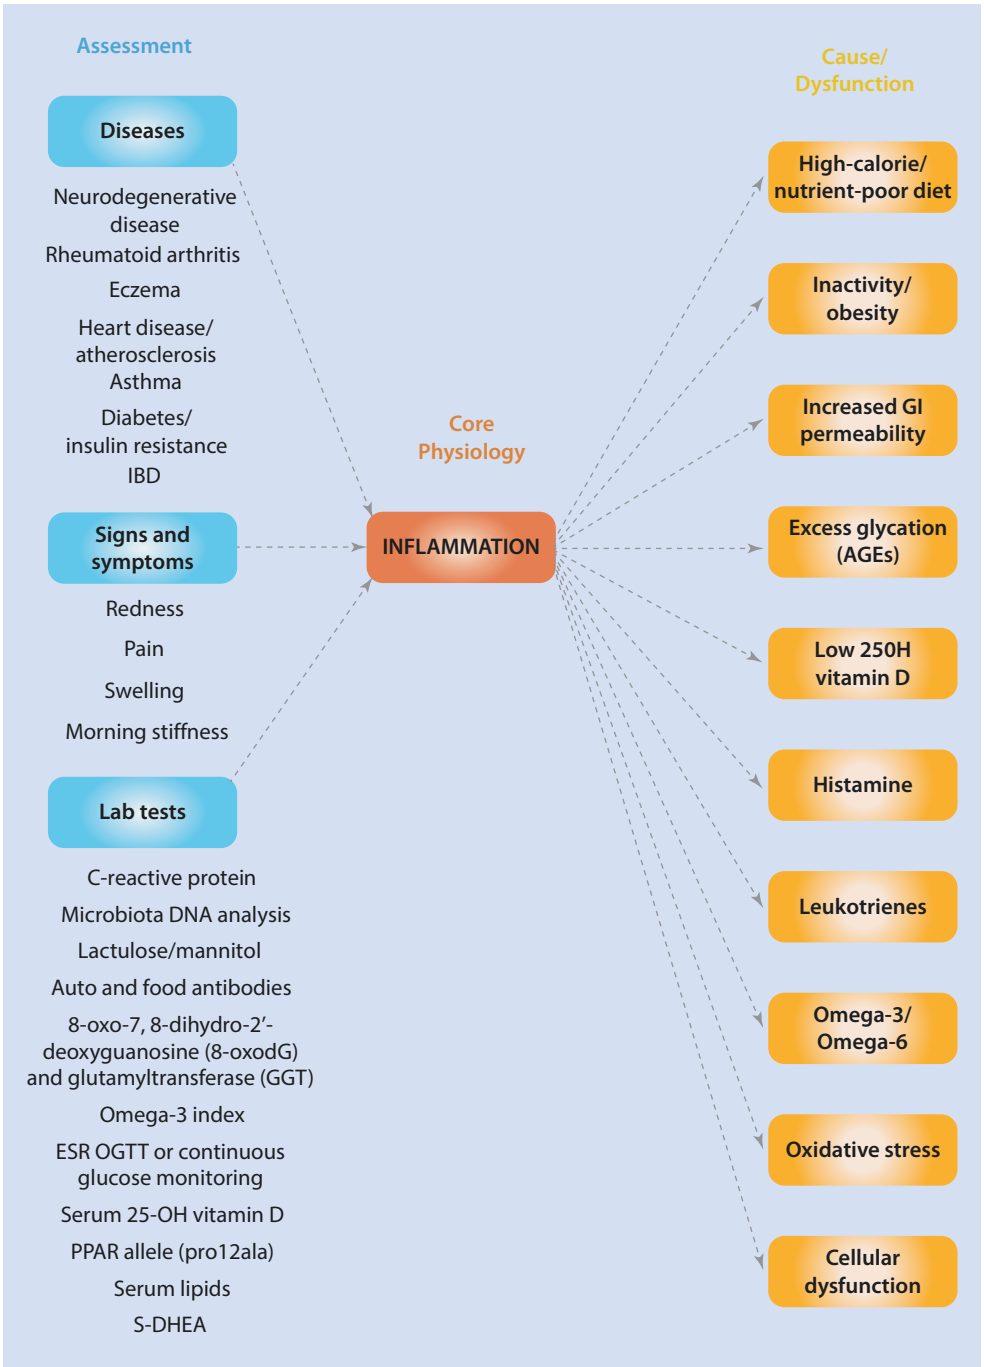

Fig. 46.4 Core physiology of inflammation. (Reprinted from Pizzorno and Katzinger [98]. With permission from Mind Publishing.)

nitrogen species (ROS/RNS) play a central role in the control of inflammation in response to infection with pathogenic organisms.

46

46.6 Inflammatory Mediators

Pro-inflammatory cytokines favor inflammation and include IL-1, TNF-α, IFN-γ, IL-6, IL-8, IL-18, and others. In metabolic syndrome and other disorders associated with adiposity and inflammation, adipocytes produce a variety of pro-inflammatory mediators (e.g., TNF-α, IL-1β, IL-6, IL-8), acute-phase response factors (e.g., C-reactive protein (CRP), ceruloplasmin, ferritin, fibrinogen, plasminogen activator inhibitor-1, haptoglobin, and serum amyloid A). High-sensitivity C-reactive protein (hs-CRP) is a very useful inflammation marker related to infection, trauma, and elevated visceral adipose tissue (VAT) [99]. In addition, hormones such as adiponectin, omentin, and ghrelin, GI-derived hormones (e.g., glucagon-like peptide-1 and other incretins),

and possibly leptin are often elevated during inflammation. The following are cardiometabolic inflammatory markers:

- C-reactive protein with a half-life of 6–8 hours. It is reflective of bacterial infection, musculoskeletal stress/trauma, or high visceral adipose inflammatory cytokine-secreting tissue. It has more recently been considered a prognostic indicator of heart disease when elevated and often referred to as a "cardio CRP" [100, 101].
- Erythrocyte sedimentation rate (ESR): ESR can indicate inflammatory activity often associated with elevated fibrinogen, autoimmune responses, and viral infections. It remains high for an extended time after removal of the inflammatory trigger.
- TNF-α: In adipocytes, TNF-α is a paracrine mediator. TNF-α induces insulin resistance by inhibiting the insulin receptor substrate 1 signaling pathway and induces adipocyte apoptosis [102]. TNF-α is associated with increased body weight and increased leukocytes and triglycerides.
- IL-1β: IL-1 is a family of at least 11 cytokines. IL-1β is also known as leukocyte pyrogen and is produced primarily by macrophages. IL-1β increases body temperature and induces interferon production.
- IL-6: IL-6 is produced by adipose tissue and in skeletal tissue but has context-dependent pro- and anti-inflammatory actions; IL-6 is associated with increased BMI and the development of type 2 diabetes while inversely associated with HDL-C [103].
- IL-8: IL-8 is chemotactic for neutrophils, basophils, and T cells and is released from monocytes, macrophages, neutrophils, and cells of the intestine, kidney, placenta, and bone marrow. IL-8 has been found to be increased in inflammatory conditions, including cardiometabolic syndrome [104].
- Plasminogen activator inhibitor-1 (PAI-1): PAI-1 is an atherogenic adipokine, induced by TNF-α [105].
- Other mediators
  - Toll-like receptors: Toll-like receptors (TLRs) are pro-inflammatory immune receptors. Activation and expression of TLRs follows recognition of pathogen-associated molecular patterns (PAMPs) and endogenous, host-derived ligands. TLR2 and TLR4 are well-characterized inducers of insulin resistance and systemic inflammation [106].
  - Adiponectin: Adiponectin, involved in the regulation of glucose and fatty acid levels, is decreased in obese individuals as well as those with insulin resistance, type 2 diabetes, and coronary heart disease. Lowered levels of adiponectin are seen in cardiometabolic syndrome [107].
  - Leptin: Leptin is a hormone that inhibits hunger and is opposed by ghrelin, which increases hunger. Obesity appears to be related to leptin resistance. Leptin can directly induce IL-6 production and thus, indirectly, hepatic CRP production [108]. Leptin and adiponectin have opposing effects on inflammation: leptin upregulates pro-inflammatory cytokines such as TNF-α and IL-6, while adiponectin downregulates pro-inflammatory cytokines [106].
  - Omentin: Omentin is an insulin-sensitizing adipokine, with reduced expression in obesity, type 2 diabetes, and insulin resistance. Omentin is associated with anti-inflammatory, anti-atherogenic, and antidiabetic properties and appears to be decreased in cardiometabolic syndrome [109].

During inflammatory states, there are also "negative" acute-phase proteins that decrease (e.g., albumin, transferrin, etc.) in response to inflammation. This is especially important to consider with the blood level of albumin, as historically it was a biomarker of nutrition status but is now recognized as a marker of inflammation when low (Fig. 46.5).

46.7 Oxidative Stress

Oxidative stress can be described as the overaccumulation of oxidants versus antioxidants, leading to cellular and tissue damage [111]. Oxidative stress closely correlates with inflammation, and inflammation is closely correlated with oxidative stress [112, 113]. Both reactive oxygen species (ROS) and reactive nitrogen species (RNS) free radicals play a role in the development of oxidative stress. A variety of factors can induce oxidative stress, including inflammation, xenobiotics, poor nutrition (e.g., simple carbohydrates, saturated fats), tobacco use, stress (physical, biochemical, mental, and emotional), and lack of physical activity, among others.

In oxidative stress, the endogenous antioxidant defense systems, which include superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GSHPx), as well as natural antioxidants such as vitamins C and E, plant-derived polyphenols, carotenoids, and sacrificial proteins such as albumin, are overwhelmed, and levels of free radicals (ROS/RNS and others) increase, enhancing the potential for damage ranging from DNA mutations, lipids, proteins, cellular organelles, tissues, and organs.

Oxidative stress has been associated with a growing number of disorders, and the list is larger when inflammation is considered part of the underlying pathology. Oxidative stress with concomitant mitochondrial dysfunction is associated with obesity; insulin resistance; diabetes; cardiometabolic syndrome; neurodegenerative disorders such as Parkinson's disease, Huntington's disease, and Alzheimer's disease; cancer; and aging [114–121].

46.8 Cardiometabolic Syndrome and Comorbidities

In addition to the coexistence of major conditions in cardiometabolic syndrome, this disorder is also associated with psychiatric disorders, autoimmune disorders, rheumatic dis-

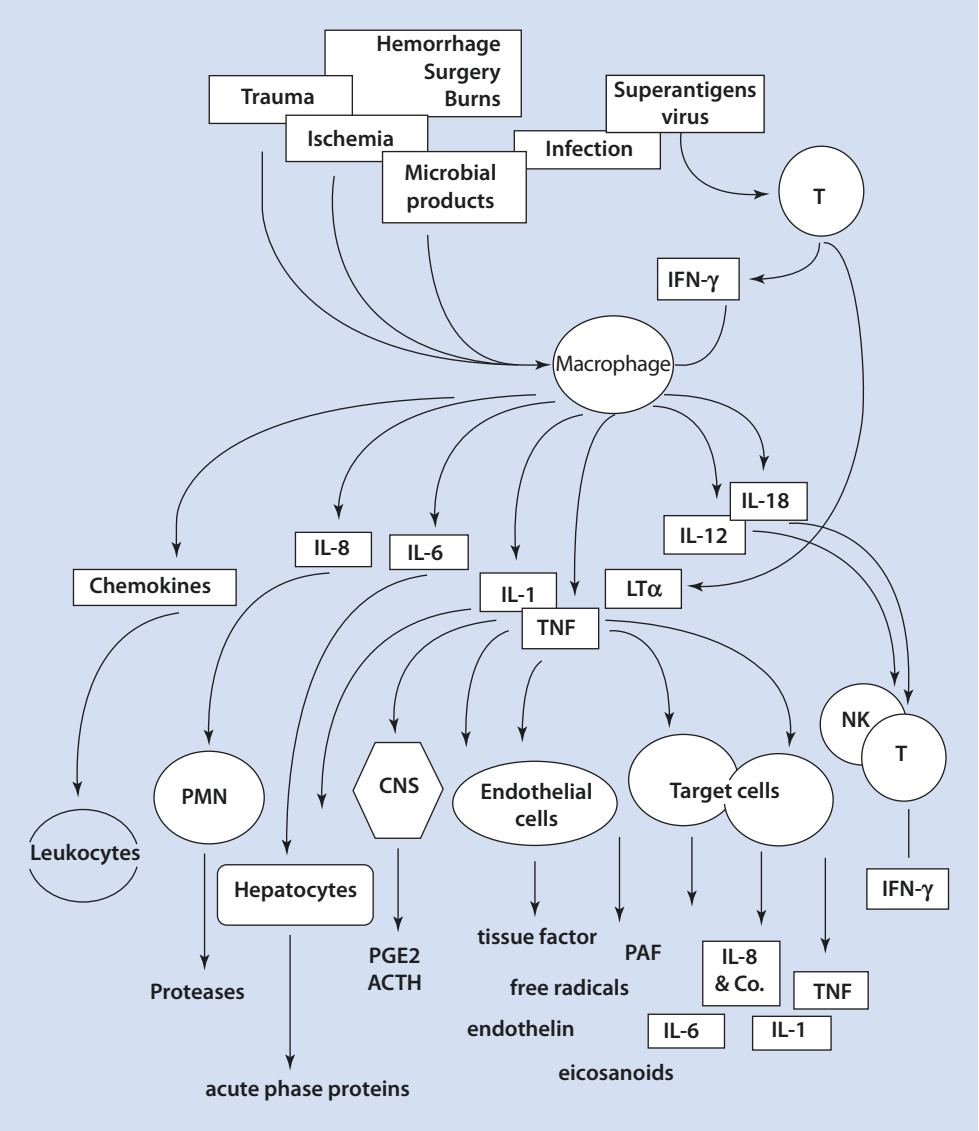

Fig. 46.5 The pro-inflammatory cascade. (Reprinted from Cavaillon and Adib-Conquy [110]. With permission from Springer Nature.)

orders, and endocrine disorders. It is becoming clear that the underlying inflammatory and oxidative stress is at the root of these relationships.

46.8.1 Metabolic Disorder Comorbidities

- Metabolic/cardiometabolic syndrome
  - Diabetes
  - Obesity/sarcopenic obesity
  - Hyperuricemia
  - Hypertension
  - Dyslipidemia
  - Chronic kidney disease
  - Glucose dysregulation
  - Insulin resistance
  - Fatty liver, nonalcoholic fatty liver disease (NAFLD)
  - Acanthosis nigricans, peripheral neuropathy, retinopathy, and hirsutism (seen in patients with insulin resistance)
  - Xanthomas or xanthelasmas (seen in patients with severe dyslipidemia)
  - Erectile dysfunction
- Pain
- Fatigue
- Cardiovascular
  - Heart disease
  - Stroke; ischemic event
- Infection: can promote metabolic dysfunction (see ▶ Chap. 20 – Infection)
  - Periodontitis
  - *Chlamydophila pneumoniae*; promotes increased rate of atherosclerotic plaque formation [122]

- Cancer
  - Solid tumor cancers
  - Hematological cancers
- Neurological
  - Neuropathies
  - Parkinson's disease
  - Alzheimer's disease
  - Seizure syndromes
  - Amyotrophic lateral sclerosis (ALS)
- Endocrine
  - Insulin resistance
  - Gonadal hormone dysfunction
  - Adrenal hormone dysfunction
- Mood and psychiatric disorders

There is a growing body of evidence indicating that Alzheimer's disease is, at its core, a metabolic disease that shares a number of features including insulin resistance, insulin-like growth factor resistance, increased oxidative stress, and local and systemic inflammation [123–128].

Alzheimer's disease is a neurodegenerative disease clinically characterized by the progressive loss of cognitive function and memory. Pathological characteristics include the presence of extracellular amyloid-β (A*β*) found as neuritic plaques and neurofibrillary tangles (NFT) made of abnormal and hyperphosphorylated tau protein. The brains of patients with Alzheimer's disease show increased levels of lipid peroxidation, oxidized proteins, RNA and DNA oxidation, carbohydrate modification, and posttranslational protein modifications, including nitrosylation and carbonylation [129, 130]. Insulin resistance has been shown to increase amyloid-β aggregates and neuritic plaque formation in addition to the decreased utilization of glucose in the CNS. Patients with type 2 diabetes are at an increased risk of developing Alzheimer's disease – the converse is also true [130]. Inflammatory mediators associated with increased adipose tissue including Ilβ, IL-6, and IL-18 [131] as well as TNF-α and adiponectin are believed to contribute to Alzheimer's disease.

46.8.2 Psychiatric Disorders

Patients with schizophrenia have an increased risk of cardiometabolic syndrome, with an overall rate of 32.5% (95% CI 30.1–35.0%) [132]. The highest rates were seen in patients who were prescribed clozapine (51.9%), while the lowest rates were associated with patients on no antipsychotic medications [112]. Patients with bipolar disorder are also at high risk for cardiometabolic syndrome, possibly related to polypharmaceutical treatment [133, 134]. Overall, a recent study found that the pooled prevalence of cardiometabolic syndrome in individuals with severe mental illness, including schizophrenia, bipolar disorder, and major depressive disorder, was 32.6% (95% CI: 30.8–34.4%; n = 52,678) [114]. Highest risk was also associated with the use of clozapine and olanzapine, although the use of clozapine carried a significantly higher risk. Lowest risk was associated with the use of aripiprazole [114]. Studies have indicated that post-traumatic stress disorder (PTSD) also increases the risk of cardiometabolic syndrome [135].

46.8.3 Autoimmune Disorders

Cardiometabolic syndrome is associated with autoimmune disorders such as psoriasis, psoriatic arthritis, rheumatoid arthritis, Hashimoto's thyroiditis, and Graves' disease [136, 137]. Several studies link psoriasis and psoriatic arthritis [138] with cardiometabolic syndrome, though the relationship is not clear. A recent meta-analysis indicated that psoriasis patients are at a greater risk of cardiometabolic syndrome, with a pooled odds ratio (OR) of 2.14 (95% CI 1.84–2.48) [139]. Chronic inflammation in psoriasis is believed to contribute to insulin resistance and an inflammatory cascade which ultimately may result in cardiometabolic syndrome [140].

Systemic lupus erythematosus (SLE) is also linked to an increased risk of cardiometabolic syndrome [13, 141, 142]. Cardiovascular events are a leading cause of mortality in SLE, and it is considered likely that both the inflammatory and autoimmune mechanisms may interact with a variety of factors, including genetic, environmental, and treatment-related factors, and that this interplay may trigger and/or exacerbate damage to the vascular wall [127, 128].

46.8.4 Rheumatic Diseases

Rheumatic diseases, including rheumatoid arthritis [14, 15], osteoarthritis, systemic lupus erythematosus, and ankylosing spondylitis, are associated with an increased risk of cardiometabolic syndrome. Cardiovascular disease in general is associated with nearly 50% increased mortality in those patients with rheumatic diseases [16]. The link between these rheumatic disorders has been related to increased adipose tissue, increased levels of adipokines, increased biomechanical loading (particularly in osteoarthritis), and an overall increased level of inflammatory markers [17]. A recent meta-analysis indicated that the association was somewhat criteria-dependent. If the National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III) criteria were used to diagnose cardiometabolic syndrome, there was an association between rheumatoid arthritis and cardiometabolic syndrome (OR = 1.38, 95% CI: 1.04–1.83, P = 0.02), but this association was less evident when using the International Diabetes Federation (IDF) criteria [18].

46.9 Dietary Considerations in Inflammation, Oxidative Stress, and Cardiometabolic Disorder

The American Heart Association (AHA) recommends regular consumption of fruits and vegetables [19]. The AHA also recommends a diet high in whole grains, low-fat dairy prod-

ucts, skinless poultry, fish, nuts, legumes, and nontropical vegetable oils. The Academy of Nutrition and Dietetics (AND) similarly recommends a diet high in vegetables and fruit [20]. Part of the rationale for these recommendations includes evidence that a diet high in plant antioxidants can reduce mortality from cardiovascular disease [21, 22] and diabetes [23–25, 115]. Plant polyphenols and carotenoids, among other plant constituents, scavenge free radicals and may act indirectly by interacting with signaling cascades and cellular membranes.

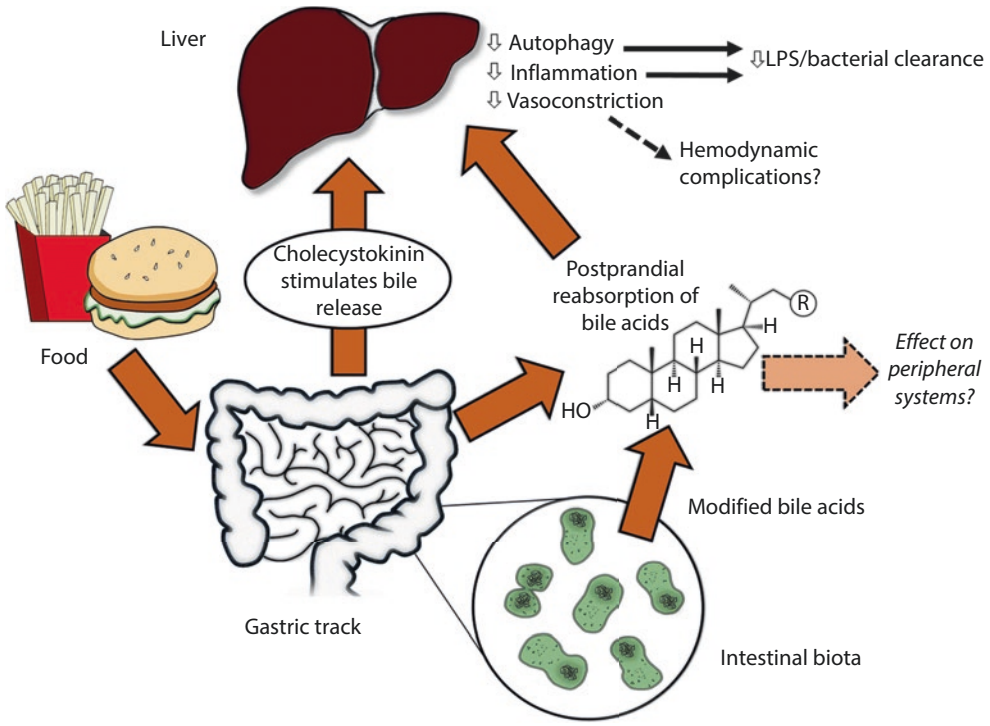
46.9.1 The Microbiome

The microbiome may be defined as the sum total of all microorganisms residing in a host in a symbiotic and commensal relationship. In common usage, the microbiome often refers to the pattern of specific microorganisms, particularly bacteria and some fungi/yeasts, that reside in the human gut. These number over 10^{14} [26].

Methods such as high-throughput gene sequencing, proteomics, metagenomics, and metabolomics have indicated that the specific pattern(s) of microbial distribution play(s) a critical role in health and in the development of cardiometabolic diseases. This pattern, when disturbed, is termed "dysbiosis" and can have a significant and potentially causative impact on overall health. Dysbiosis is associated with cardiometabolic disease, obesity, insulin resistance, dyslipidemia, hypertension, and systemic inflammation [27–30].

Studies in mice fed a high-fat diet show the development of insulin resistance which can be correlated with the patterns of the microbiome [31]. In both genetically obese mice and mice fed a high-fat diet, these changes can be ameliorated by the use of antibiotics [32] with associated improved insulin sensitivity, decreased inflammatory biomarkers, and a reduction in weight gain, supporting the concept that the patterns or composition of the gut microbiome can significantly impact the metabolic phenotype and emphasizing the effect of diet – in this case a high-fat diet – on the microbiome. Obese mice undergoing the transfer of fecal bacteria derived from lean germ-free mice show a normalization of their metabolic phenotype, increased insulin sensitivity, and decreased inflammation and weight loss [33, 34].

Human studies have also found links between the composition of the microbiome with obesity, insulin resistance, dyslipidemia, adipose, and systemic inflammation [36–38] (see ◘ Fig. 46.6). The obese-type microbiome is characterized by a higher *Firmicutes/Bacteroidetes* ratio and higher levels of short-chain fatty acid excretion [39]. These patterns can be altered by dietary factors. An interventional small human study has shown that a high-fiber, strictly vegetarian diet could improve insulin resistance and dyslipidemia and induce weight loss in patients with type 2 diabetes and insulin resistance [40]. Larger five-center interventional studies of individuals at risk of cardiometabolic syndrome (both men and women between the ages of 30 and 65 years, based on BMI, plasma glucose, insulin, triglyceride, and HDL-C levels) showed that the type and quantity of dietary fat and



◘ **Fig. 46.6** The role of bile acids with dietary intake and microbiome. (Reprinted from van Niekerk et al. [35]. With permission from Creative Commons License 4.0: ► https://creativecommons.org/licenses/by/4.0/.)

carbohydrate could alter the profile of fecal bacteria and alter short-chain fatty acid excretion levels [41].

The transfer of gut microorganisms (fecal transfer) is a possible therapeutic tool to treat insulin resistance, type 2 diabetes, cardiometabolic syndrome, and obesity [45]. In a recent study, patients with cardiometabolic syndrome who were overweight received either an allogeneic (from lean, healthy individuals) or an autologous transfer. These patients experienced improved hepatic insulin sensitivity and peripheral insulin sensitivity, particularly after allogeneic transfer [42, 43]. These results could be transitory and depend to a degree on baseline fecal microbial patterns [41, 44].

46.9.2 Chronic Stress and Cardiometabolic Syndrome

Chronic stress, whether physical, mental, emotional or spiritual, results in the hypersecretion of stress mediators, particularly cortisol, and autonomic imbalance. The presence of high levels of glucocorticoids supports the development of central adiposity, low levels of growth hormone, and hypogonadism [45]. Glucocorticoids also stimulate the activities of enzymes involved in fatty acid metabolism, induce preadipocyte differentiation, increase lipid oxidation, and induce the hepatic gluconeogenic pathway. Hypersecretion of glucocorticoids is associated with hypertension, dyslipidemia, visceral obesity, sarcopenia, and insulin hypersecretion and resistance [46, 47, 100]. A high-sugar and high-fat diet, particularly with comorbid chronic stress, has been described as a "more potent driver of visceral adiposity than diet alone, a process mediated by peripheral Neuropeptide Y (NPY)" [48]. NPY is expressed in specific neurons of the brainstem, hypothalamus, and limbic system. An important tract controlling the release of corticotropin-releasing hormone (CRH) is located between the hypothalamic arcuate nucleus (ARC) and the paraventricular nucleus of the hypothalamus (PVH), the major source of CRH. The biological effects of NPY depend on which of five receptors (Y1–Y5) it interacts and may be either anxiolytic or anxiogenic. NPY plays a role in food intake, energy homeostasis, circadian rhythm, and cognition [49]. NPY is increased in acute stress and visceral inflammation, while its expression in chronic stress is not entirely clear [50]. In addition, post-traumatic stress disorder (PTSD) is associated with lowered NPY, increased rates of obesity, and cardiometabolic disorder [51].

An often-overlooked chronic biological stress is the genetic hemochromatosis iron overload possibility for a patient with cardiometabolic syndrome. Iron overload over long term can damage the heart, liver, and kidney, even to the point of requiring organ transplantation. Newer research is associating iron overload with increased risk of Alzheimer's and cancer. For a patient with high hemoglobin/hematocrit and ferritin blood tests, it is prudent to test for the hemochromatosis gene (High Iron Fe (HFE)).

46.9.3 Hypercoagulability

The three factors considered most critical to thrombotic events are hypercoagulability, hemodynamic dysfunction, and endothelial dysfunction. Hypercoagulability may be hereditary or acquired. With acquired hypercoagulability, risk factors include age, immobilization or reduced physical activity (e.g., sedentary), inflammation, obesity, diabetes, pregnancy, hormone replacement therapy, and oral contraceptive use. Cardiometabolic syndrome is characterized by increased levels of clotting factors such as tissue factor, factor VII, and fibrinogen and by both increased plasminogen activator inhibitor-1 and decreased tissue plasminogen activator activity [52]. The cardiometabolic syndrome "presents a prothrombotic state as a result of endothelial dysfunction, the presence of a hypercoagulability state produced by an imbalance between coagulation factors and the proteins that regulate fibrinolysis and increased platelet reactivity" [105].

46.9.4 Insulin Resistance

Insulin resistance describes the lack of responsiveness of cells to the binding of insulin to its receptors. Insulin resistance can also be described as a prediabetic state and is intimately associated with obesity, glucose intolerance, metabolic syndrome, diabetes, cardiovascular disease, hyperlipidemia, as well as a variety of other conditions [53–56].

Insulin resistance is a heterogeneous and progressive clinical condition. It results in increased insulin secretion in a physiological attempt to maintain normal glucose levels. A number of mediators are involved in regulating insulin secretion – these include glucose; free fatty acids; appetite- and fat-regulating hormones including adiponectin, leptin, and ghrelin; GI-derived hormones (e.g., glucagon-like peptide-1 and other incretins); and the autonomic nervous system. Insulin regulation also is dependent on genetic, immunologic, and metabolic factors [57–59]. Dietary and nutritional influences are of obvious importance in the development and progression of insulin resistance.

Insulin resistance is primarily related to poor cell signaling at the insulin receptor on the surface of every human cell. Two things determine this insulin receptor sensitivity:

1. Structure: The structure of the cell bilayer membrane that houses the insulin receptor influences the ability of the insulin receptor's degree of sensitivity. The structure of the cell membrane is made up of 55–75% (depending on cell type) fatty acids and phospholipids. The fatty acids and phospholipids are primarily determined by those that come from diet and the milieu of hormone balance (especially insulin and cortisol), likely related to a person's inflammatory load, and that are most commonly determined by elevated visceral adipose tissue (VAT) that secretes inflammatory molecules.

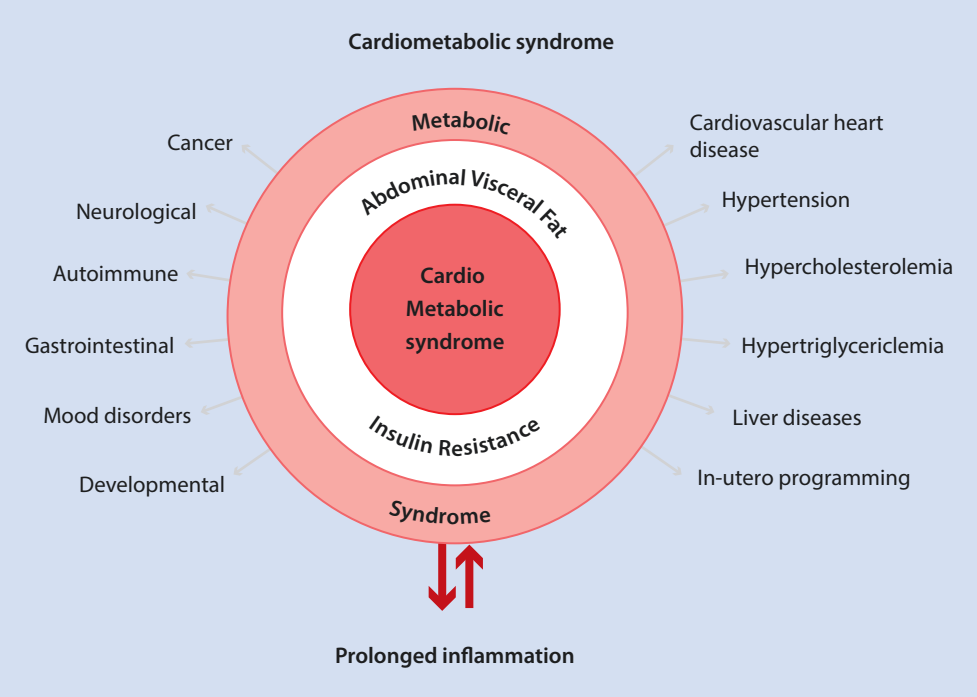


Fig. 46.7 Cardiometabolic syndrome and insulin resistance

2. Function: The dynamic biochemistry and energy flow within the individual's microenvironment by the presence of essential and conditionally essential nutrients and the energy flow largely dependent on a person's mineral status. If there is a significant toxin load (toxic metals, toxic chemicals, EMF exposure), there can be a negative interruption of nutrient flow to maintain healthy tissue. There are a plethora of environmental toxins individuals have been exposed to over the past 50–70 years that override the natural protective detoxification systems of a human and can be a source of metabolic perturbation exhibiting disease conditions like diabetes and metabolic syndrome [60].

Inflammation is a central component of insulin resistance [61, 62]. Both intrinsic and extrinsic factors inhibit insulin signaling. For example, serine phosphorylation of the insulin receptor substrates 1 and 2 by c-Jun N-terminal kinases (JNK) and inhibition of NF-κB (IKK) inhibits insulin signaling. In addition, both JNK and IKK stimulate the production of inflammatory cytokines, which in turn further activate JNK and IKK via autocrine and paracrine pathways. An individual's toxin load is now recognized as a contributor to the inflammation of insulin resistance [63–68]. Inflammation increases the risk of insulin resistance and metabolic syndrome as well as other metabolic conditions by three main pathways:

- Direct inhibition of insulin receptor substrates [69]
- Secretion of inflammatory cytokines [70]
- Recruitment of inflammatory leukocytes [71]

Other pathways involve excess intake of sugars, with a resultant hypertrophy in adipocytes, tissue inflammation, and white blood cell recruitment, increased insulin resistance, increased serum glucose levels, and tissue damage, with ensuing clinical consequences (Fig. 46.7).

46.9.5 Sarcopenia/Sarcopenic Obesity

Sarcopenia is defined as age-related loss of muscle [72]. Sarcopenia, along with cachexia, defined as the loss of weight due to underlying disease, is of great importance in the aging population but is often overlooked [112]. Sarcopenia is associated with a loss of muscle mass and muscle strength, while cachexia is associated with the loss of both muscle and fat mass. In sarcopenia, there is a mismatch between the decline in muscle strength which exceeds the decline in muscle mass.

The atrophy in sarcopenia is related especially to the atrophy of the fast, type II fibers. The number of motor units decrease, and fat is accumulated within the muscle tissues. In the geriatric population especially, inactivity may lead to increased muscle loss, and increased muscle loss may lead to greater inactivity.

Muscle mass represents the balance of protein anabolism and catabolism. Anabolic mechanisms depend in part on the activation of the serine/threonine kinase Akt, insulin-like growth factor-1 (IGF-1), insulin, testosterone, and branched-chain amino acids (BCAA). In addition, exercise and physical mobility can influence muscle mass. Catabolic

mechanisms include the ubiquitin proteasome and caspase pathways as well as the myostatin pathway [73].

In aging, sarcopenia may be related to nutritional factors, genetic factors, autophagy, apoptosis, mitochondrial dysfunction, and possibly inflammation. With respect to nutrition, decreased food intake as well as decreased protein and energy intake can contribute to loss of muscle mass. Nutrients of concern include high-quality protein, vitamin D, vitamin E, and trace minerals such as selenium, carotenoids, and vitamin C [74]. As inflammation is an important underlying mechanism, consideration should also be given to intake of the omega-3 fatty acids.

Mortality risk, independent of obesity, is higher in older women with sarcopenia [75]. Approaches to sarcopenia should always also include a resistance training program to maintain or increase muscle strength. Resistance training is an effective approach, particularly in the elderly [76].

46.9.5.1 Sarcopenic Obesity

Sarcopenic obesity was originally defined as a muscle mass index that is less than 2 standard deviations below the reference gender and age-dependent reference value. An NHANES study defined sarcopenic obesity as the two lower quintiles of muscle mass and the two highest quintiles of fat mass [77]. This corresponds to:

- For men: Muscle mass < 9.12 kg/m^2 and fat mass > 37.16%
- For women: Muscle mass < 6.53 kg/m^2 and fat mass > 40.01%

There are no standard criteria for muscle strength, though grip strength is often tested because it is easier to measure than muscle mass.

Fat mass tends to increase with age, with a peak between 60 and 75 years, while muscle mass tends to decrease beginning in early middle age. This effect is correlated with reduced physical activity, reduced energy intake, and neurologic, hormonal, and environmental signals. As in the case of insulin resistance and obesity, inflammation plays a central role [78, 79].

Evidence from NHANES III also suggests that sarcopenia may be an early indicator of diabetes risk and was associated with increased insulin resistance in the non-obese and the obese. Sarcopenia was associated with dysglycemia in obese individuals, as well [80]. The InCHIANTI study, a prospective study of participants over the age of 65 in the Chianti region of Italy, found that sarcopenic obesity was associated with elevated levels of pro-inflammatory cytokines including IL-6, C-reactive protein, IL-1 receptor antagonist, and soluble IL-6 receptor ($P < 0.05$) [81].

As noted, sarcopenia is associated with increased mortality. Sarcopenic obesity is associated with higher total mortality as well as mortality associated with cardiovascular disease [82]. Thus, building and maintaining muscle mass over time is an important aspect of cardiometabolic health.

46.9.6 Cardiometabolic Syndrome

Metabolic syndrome can be defined as a cluster of abnormalities that increase the risk of cardiovascular disease, stroke, diabetes, nonalcoholic steatohepatitis, and obesity. Metabolic syndrome includes hypertension, hyperglycemia/dysglycemia, increased central obesity, hypercholesterolemia, and hypertriglyceridemia. Other signs and symptoms associated with metabolic syndrome include chest pain, shortness of breath, reduced HDL-C, and symptoms associated with dyslipidemia and insulin resistance.

Diagnostic criteria include three of the following [83]:

- Fasting glucose ≥100 mg/dL (or receiving drug therapy for hyperglycemia)
- Blood pressure ≥130/85 mm Hg (or receiving drug therapy for hypertension)
- Triglycerides ≥150 mg/dL (or receiving drug therapy for hypertriglyceridemia)
- HDL-C <40 mg/dL in men or <50 mg/dL in women (or receiving drug therapy for reduced HDL-C)
- Waist circumference USA ≥102 cm (40 in) in men or ≥88 cm (35 in) in women
- Waist circumference Asian ≥80 cm (31.5 in) in men or ≥70 cm (30 in) in women

Insulin resistance and adipose dysfunction are widely accepted as the underlying pathologic changes in metabolic syndrome [84, 85]. Risk factors include family history, poor nutrition, and low levels of physical activity.

46.9.7 Adipocytes in Cardiometabolic Syndrome

Distribution and dysfunction of the adipose tissue impacts the role adipose tissue plays in the metabolic syndrome: visceral adiposity correlates with inflammation, while subcutaneous tissue does not. There are significant ontogenetic differences between visceral and subcutaneous fat. For example, evidence suggests there are differences in genetic expression in Wilms tumor 1 (Wt1), a gene which codes a zinc finger DNA-binding protein required for development of the genitourinary system and mesothelial tissues. The differential expression of other genes including Wt1 may explain these differences [86]. Overall, it appears that expression of pro-inflammatory genes is significantly greater in visceral adipose tissue as compared to subcutaneous adipose tissue [87].

In addition to its relationship to metabolic syndrome [143], visceral adipose tissue (VAT) and the associated inflammation have been associated with atherosclerosis [144], heart disease [145], asthma [146], reflux esophagitis [147], GI disorders [148, 149], and others.

Adipocytes are the source of many biologically active substances known as adipokines. These include TNF-α [150], resistin [151], leptin [152], adiponectin [153], and plasminogen activator inhibitor-1 (PAI-1) [154]. These adipokines

play a role in the pathogenesis of obesity, diabetes, and cardiometabolic syndrome [103]. For example, the increased production of PAI-1 increases the risk of thrombotic events, while elevated levels of TNF-α are associated with insulin resistance [103, 155–157]. Adiponectin, on the other hand, is associated with increased insulin sensitivity [158, 159].

In vascular diseases, oxidative stress and inflammation play significant roles in the pathophysiology of endothelial dysfunction, the proliferation of vascular smooth muscle cells, and foam cell formation. A recent review emphasized the "sequential and progressive" nature of atherogenesis and involves "cross talks at many levels" [160].

Clinical Presentation: Cardiometabolic Syndrome

George W. is a 57-year-old white male whose chief complaint at presentation is dissatisfaction with his weight. He has not seen a physician for approximately 2.5 years, seeing no need. His waist circumference is 103 cm. His height is 71 inches (180.3 cm) and his weight is 225 pounds (102.1 kg). BMI is 33.2 kg/m^2 with a waist circumference of 36.2 inches (91.95 cm). Patient has no history of tobacco use. Patient reports moderate alcohol use and no recreational drug use. He has in the past used cannabis to "take the edge off" but has not used cannabis in the last 5 years. Patient does not report the use of any medications and supplements or any history of chronic disease, but was in an MVA approximately 3 years ago where he sustained a concussion with an overnight stay in the local hospital. He reports a diet of fast food, high of red meat, processed foods, and few vegetables/fruits. He has a craving for salt- and sugar-rich foods. Patient is recently divorced with three children and has been self-employed as a criminal defense attorney for 22 years. He reports 5–6 hours of disrupted sleep per night.

Blood pressure: 135/85 mm Hg Heart rate: 88

Labs: Complete blood count (CBC): Hgb/Hct 16.5/32; MCV/MCH 101/31

- Thyroid stimulating hormone (TSH), T3/T4, normal
- Complete metabolic panel:
  - Fasting blood glucose (FBG): 110 mg/dL
  - Hemoglobin A_1c: 8.9
  - Lipid panel:
    - Total cholesterol: 238 mg/dL
    - HDL cholesterol: 35 mg/dL
    - LDL cholesterol: 180 mg/dL
    - Triglycerides: 452 mg/dL
    - ApoB: 145 mg/dL
    - LDL-P: 1325
    - hs-CRP: 10 mg/L
    - Fibrinogen: 398 mg/dL
- Nutritional status markers:
  - Vitamin D 25OH: 15 ng/mL
  - Albumin: 3.6 g/dL
  - Retinol-binding protein (RBP): 42 mcg/mL
  - Transferrin: 165 mg/dL
  - Homocysteine: 126 mcmol/L
  - Vitamin B12: 157 pg/mL
  - Omega-3 index: 0.9% (range 2.5–11.8%)
- Other:
  - Adiponectin: 0.78 mcg/mL
- Medical Symptoms Questionnaire/Signs and Symptoms: 92 (goal <50)

Assessment/diagnosis:

- Metabolic syndrome with high FBG and A_1c with potential comorbidities
- Hypertriglyceridemia, hypercholesterolemia (LDL cholesterol, LDL-P, HDL)
- hs-CRP (systemic inflammation)
- Fibrinogen
- Altered nutritional markers depleted
- Adiponectin low

Intervention:

- Structural assessment referral to a cranial-sacral trained practitioner related to MVA

Lifestyle

- Stress management education
- Exercise prescription
- Sleep (goal 7/8 hours per night)

Dietary recommendations: Low carbohydrate, healthy fats, and glycemic carbohydrates in a 40:40:30 ratio. Education on avoidance of processed foods, simple sugars, artificial sweeteners, charred meats, and high-heat processed vegetable oils.

Supplements:

- Multivitamin iron-free with bioactive forms of B complex
- B12 hydroxycobalamin/adenosylcobalamin 1000 mcg/day lozenge/AM
- Berberine 500 mg one capsule with each meal
- CoQ10 200 mg daily near food/meal
- Phosphatidylcholine/phosphatidylethanolamine formula 3000 mg daily (capsules or liquid)
- Magnesium threonate 200–400 mg daily
- Further recommendations after test results

Recommend further blood and urine tests to support nutritional assessment:

- Organic acids (urine)
- Lipoprotein particle lipid panel
- C-reactive protein (CRP)
- Ferritin (to rule out hemochromatosis; if ferritin is high, request HFE genomic testing)
- Methylmalonic acid (MMA) (functional B12 marker)
- After reviewing above tests, may recommend further testing of gut ecology, imaging.

Monitoring/evaluation:

- Review new test results
- Review referral consults
- Monitor anthropometrics, previously abnormal blood tests, signs, and symptoms.

Goals:

- Complete referral consults
- Weight loss BMI 25–27
- Blood labs
- $M < 30$
- Sleep 7–8 hours each night
- Consistent moderate exercise program
- Stress management routine in place

46.10 Anthropometric Assessment Methodologies

Anthropometry is the use of body measurements that can be used as part of a comprehensive nutrition assessment. Anthropometric measurements are influenced by a number of factors including age, nutritional status, genetics, the environment, social influences, lifestyle, and others, but they provide an inexpensive, noninvasive approach to obtaining important information regarding overall health status. Anthropometric assessments provide highly reliable information while avoiding the complexities of newer (and costlier) methodologies [161] (Table 46.3).

- Waist circumference
  - A waist circumference greater than 102 cm (40″) in men and 88 cm (35″) in women is associated with a higher risk of cardiometabolic syndrome, T2D, hypertension, and cardiovascular disease.
- Waist-to-hip ratio
  - The waist circumference is measured just below the ribs, and the hips are measured at the widest portion of the hips. For men, a normal waist/hip ratio is ≤0.90, while for women a normal waist/hip ratio is ≤0.80. Waist/hip ratios ≥1.0 are associated with an increased risk for cardiovascular disease, T2D, and cardiometabolic syndrome.
- Waist-to-height ratio
  - The waist-to-height ratio is a measure of body fat distribution. A healthy waist-to-height ratio ranges from 0.42 to 0.48. A waist-to-height ratio of 0.51 is equivalent to the risk associated with a BMI of 25, while a waist-to-height ratio of 0.57 is equivalent to the risk associated with a BMI of 30.
- Body mass index (BMI)
  - The BMI is weight (in kg) divided by height^2 (m). BMI is an estimate of body fat and can be used to screen for health risks in populations.
- Body fat percentage
  - The body fat percentage is the fat mass divided by the total body mass. The percentage of essential fat is 2–5% in men and 10–13% in women [162].
- Body cell mass (BCM)
  - BCM consists of the total mass of all the cellular elements including tissues of the muscles, organs, and bones, as well as extracellular and intracellular water. BCM decreases in wasting conditions such as AIDS, cancer, and other chronic diseases. The preferred method for the assessment of BCM is bioelectrical impedance analysis.
- Bioelectric impedance analysis (BIA)
  - Bioelectrical impedance is the resistance to electrical flow through body tissues and can be used to estimate body fat and body cell mass. BIA has been validated under a number of conditions and circumstances [163, 164].
- Imaging
  - Computerized tomography (CT) scan
  - Magnetic resonance imaging (MRI)
  - Dual-energy X-ray absorptiometry (DEXA, DXA) can be used to quantify total, subcutaneous, and visceral body fat.

Table 46.3 Body mass index height/weight

BMI	Weight status
Below 18.5	Underweight
18.5–24.9	Normal or healthy weight
25.0–29.9	Overweight
30.0–34.9	Obese: Class I
35.0–39.9	Obese: Class II
≥ 40.0	Obese: Class III

46.11 Assessment of Physical Performance

A number of different tests of physical performance and muscle strength may be used. These include gait speed, the 6-minute walk test, the stair climb power test, and the short physical performance battery (SPPB). The SPPB consists of three separate tests that assess balance, gait, and strength. The individual is tested for their ability to stand with their feet in tandem, semi-tandem, and parallel positions [165].

46.11.1 Biomarkers for Cardiometabolic Syndrome

46.11.1.1 Pro-Inflammatory State

The pro-inflammatory state may be assessed in several ways, but common measures are serum levels of hs-CRP, fibrinogen, IL-6, TNF-α, and leukocytosis.

46.11.1.2 Acute-Phase Reactants of Inflammation

- C-reactive protein high sensitivity
- Ferritin
- Albumin (negative)
- Ceruloplasmin (bound copper)
- Sedimentation rate (ESR)

46.11.1.3 Glucose/Insulin

- Fasting glucose
- Hemoglobin A_1c
- Fasting insulin
- Proinsulin
- Fasting C-peptide
- HOMA-IR

46.11.1.4 Dyslipidemia

- Triglycerides
- HDL
- Triglyceride HDL ratio
- VLDL and LDL
- Lipoprotein (a)
- Lipoprotein particle number and size

46.11.1.5 Visceral Adipose Tissue

- Men
  - Waist circumference (WC) USA >40 inches/102 cm
  - Asian BMI >21 kg/m^2
  - WC levels ≥90 cm men
  - Waist-to-hip ratio: >0.90
- Women
  - Waist circumference >35 inches/88 cm
  - Asian waist circumference ≥ 70 cm women
  - Waist-to-hip ratio: >0.85

46.11.1.6 Hypercoagulation

- Prothrombin time (PT)/international normalized ratio (INR)
- Fibrinogen
- Platelets
- Genomic factor V
- hs-CRP

46.11.1.7 Immune Compromised

- Complete blood count (CBC): white blood cells and differential
- Secretory IgA
- Natural killer cell count and activity
- Protein electrophoresis

46.11.1.8 Blood Labs

- CBC
- Differential: WBC, eosinophils, neutrophils, lymphocytes
- hs-CRP
- ESR/sed rate
- Lipid panel
- Liver enzymes: ALT, AST, Alk Phos, GGT
- Bilirubin, direct and total
- Ferritin
- Vitamin D: 25-OH vitamin D, 1,25 vitamin D
- Vitamin A: retinol
- Homocysteine
- Apo b/apo a1/Apob/apoa1
- Lp(a)

46.11.1.9 Further Testing

- Rheumatoid factor (RF)
- Cytokine panel: IL-8, IL-10, IL-6, IL-2
- Fibrinogen (platelets)
- Antitrypsin
- Organic acids
- Toxic metals
- Cleveland heart labs

46.11.1.10 Imaging: CT/Pet CT Scan/MRI/Ultrasound

- Liver – rule out NASH, cirrhosis, fatty liver
- Tumors
  - Benign: lipoma, fluid-filled cysts
  - Neoplastic: size, location, diagnosis
- Osteopenia/osteoporosis via DEXA bone density
- Joints: osteoarthritis
- Gastrointestinal
- Coronary calcium score
- Vo2max testing

46.11.1.11 Biopsy

Any tumor or lesion of GI inspection

46.11.1.12 Bioelectric Impedance Analysis

- Phase angle
- Capacitance
- Body cell mass
- Intracellular water (ICW)
- Total body water

46.11.1.13 Obesity (See Assessment Sarcopenia)

- Metabolically healthy obese
- Chronic disease obesity
- Increased disease associations with obesity

46.11.1.14 Lifestyle

- Sleep
- Exercise
- Relationships

46.11.2 Diet

Diets which are high in simple carbohydrates (including those high in high fructose corn syrup (HFCS), high ratios of omega-6/omega-3 essential fatty acids, high sodium foods, and food low in polyphenols and both soluble and insoluble fiber are associated with a higher risk of chronic disease [166]. Conversely, diets that are high in vegetables, fruits, lean meats, fish, legumes, nuts, and seeds, high in

omega-3, high in fiber, and low in simple carbohydrates or processed foods tend to be protective against chronic disease [166–168].

46.11.2.1 Nutrient Insufficiencies, Deficiencies, or Excesses

Nutrient

- Vitamin D
- Vitamin A
- Vitamin K1 and K2
- Glutathione
- Essential fatty acids (w3 and w6)
- Beneficial MUFA and saturated
- Phospholipids (phosphatidylcholine, phosphatidylethanolamine)
- Cholesterol/sterols
- Methyl nutrients:
- (B vitamins, trimethylglycine (TMG), phosphatidylcholine (PC)) (not lecithin)
- Magnesium (ensure adequate calcium food or supplement if needed)
- Zinc
- Selenium
- Vitamin C
- Vitamin E: gamma-tocopherol and tocotrienols
- ATP: CoQ10, d-ribose, l-carnitine
- Avoid damaged oils
- Excess calcium can be problematic

46.11.2.2 Dental/Oral Health

- Periodontal tissue disease (indicator for risk of folate, carotenoids, vitamin C deficits) [169]
- Tooth decay
- Amalgam dental material fillings
- Oral galvanization
- Composite dental material fillings
- Temporomandibular joint (TMJ) misalignment
- Tongue depapillation (indicator for poor B vitamin status) [170]

46.11.2.3 Gut Health

- Bowel movement frequency, color, and form
- Fermented food or probiotic intake
- Gastrointestinal symptoms
- Healthy toilet posture (squatting vs. sitting)
- *Lab testing*: Comprehensive Digestive Stool Analysis

46.11.2.4 Renal Health

- Kidney clearance
- Fatty acid composition of renal tubules
- Toxin load
- Electrolyte status

46.11.2.5 Gonadal Health

- Men: prostate, breast
- Women: breast, uterus, ovary, thyroid

46.11.2.6 Physical Activity

- *Health maintenance*
  - Intermittent intense exercise several times a day
  - Reduce sitting for long periods
  - Joyful movement
- *Sports* athletic *performance*
  - (See ▶ Chap. 35)

46.11.2.7 Sleep

- Associations with disease
- Sleep apnea
- Sleep hygiene

46.11.2.8 Happiness

- Relationships
- Community
- Mental health
- Blue zones

46.11.2.9 Loneliness

- Biggest lifestyle factor for decreased lifespan

46.11.2.10 Toxin Load

- Dioxin
- Glyphosate (roundup)
- Endocrine disruptors: BPA [171]

46.11.2.11 Physical Exam (See ▶ Chap. 39 Nutrition Physical Exam)

- Hair/scalp
- Ears
- Face
- Eyes
- Oral cavity: palate, tongue, tonsils, adenoids/throat
- Sinus
- Thyroid, neck, parotid
- Gag reflex, vagal nerve tone

46.11.2.12 Posture and Spinal Alignment

- Injury history: head, neck, birth trauma
- Posture habits
- Headache history

46.11.3 Protocols of Treatment for Chronic Conditions

46.11.3.1 Conventional Treatment

- Rx: statins, metformin, hypertensive meds, omega-3 fish oil, etc.
- Diet: optional
- Exercise: optional, 10,000 steps per day

46.11.3.2 Integrative and Functional Medicine Approaches

- Exercise
- Mediterranean diet/low-carb whole foods/ketogenic or modified ketogenic diet
- Glucose/insulin nutrient support
- Support for detoxification metabolism
- Stress management
- Sleep management
- Rx, if indicated

Healthy Human

- Healthy body fat %
  - Male: 8–16%
  - Female: 16–20%
- Muscle strength
- Healthy blood pressure
- Healthy protective inflammation
- Healthy kidney function
- Managed blood glucose
- Nervous system integrity
- Fetal and infant healthy pre-programming
- Minimal cancer risk
- Cardiovascular integrity
- Retain self vs. nonself
- Sexual vitality
- Healthy sleep

46.12 Conclusion

Metabolic disorders are abnormalities that are not isolated conditions but are metabolically closely linked to each other. The concept of systems biology describes the interrelationship of all body systems that need consideration when assessing an individual's health condition. For the past 100 years, there has been a rise in the incidence of chronic diseases that differ from acute diseases, primarily through the long-term development of disorders in complex ways. During early development of chronic diseases, the symptoms are often unrecognized while metabolic perturbations occur. Newer approaches are recognizing biomarkers of early signs of chronic diseases while they are more easily treated and prevented from developing into a serious disorder. The pathophysiology of chronic diseases is continuing to be better understood, with scientific advancements in biology, physiology, biochemistry, genomics, mind-body, and toxicology that are clarifying important differences from acute to chronic disease. This chapter presented evidence that the cardiometabolic syndrome is an underlying foundation for the development of all chronic diseases throughout the lifespan. Chronic diseases are largely due to influences from diet, lifestyle, genomics, and the environment. Chronic diseases are becoming epidemic globally. This chapter presented the principles and practices of identifying the components of cardiometabolic syndrome to influence medical and health practitioner's clinical practice. This knowledge has the potential to effect changes in clinical implementation to prevent and treat chronic diseases to restore wellness for all individuals and populations.

Learning Objectives

Hypertension

1. Understand the pathogenesis of hypertension and the role of vascular biology, the three finite vascular responses of inflammation, oxidative stress, and vascular immune function, plasma renin activity (PRA), and aldosterone to select optimal integrative antihypertensive therapy to reduce blood pressure and decrease cardiovascular disease.
2. Review diagnostic testing for hypertension: 24-hour ambulatory blood pressure monitor (ABM), endothelial function, and arterial compliance testing.
3. Be able to prioritize and personalize the most important nutrition, nutraceutical supplements, and lifestyle treatments for hypertension.
4. Apply micronutrient testing (MNT) in the treatment of hypertension.
5. Review treatment with nutrition, lifestyle, and nutraceutical supplements.

Dyslipidemia

- Review the underlying causes and mechanisms of dyslipidemia and dyslipidemia-induced cardiovascular disease.
- Understand and apply advanced lipid testing (lipid particle number and size and HDL functionality and quality) for the diagnosis and treatment of dyslipidemia in clinical practice.
- Prioritize effective methods to promote vascular repair, reduce vascular damage, and define the interrelationships of the cardiovascular system, gastrointestinal tract, and microbiome.
- Evaluate nutrition and nutritional supplements to treat dyslipidemia.

Coronary Heart Disease

1. Review the top 5 coronary heart disease risk factors, the details of the correct analysis of each, and the top 25 modifiable key coronary heart disease risk factors.
2. Review and understand coronary heart disease and congestive heart failure clinical presentation, diagnosis, and treatment.
3. Prioritize which laboratory and noninvasive cardiovascular tests should be evaluated in patients in the primary care setting and how to interpret and treat.
4. Review integrative medical treatments with nutrition, nutritional supplements, and drugs for cardiovascular disease.

47.1 Introduction

Cardiovascular medicine needs a complete functional and metabolic reevaluation related to diagnosis, prevention, and integrative treatments. We have reached a limit in our ability to appropriately treat cardiovascular disease (CVD) [1]. Current treatments are not effective in reducing vascular inflammation. CVD remains the leading cause of morbidity and mortality in the United States [2]. Statistics show that we spend approximately $320 billion a year in both direct and indirect costs treating CVD alone [2] and over 2200 US citizens die from stroke or MI each day [2–5]. CHD includes angina, MI, ischemic heart disease, and ischemic cardiomyopathy with both systolic (low ejection fraction) and diastolic congestive heart failure (CHF) with a normal ejection fraction with a stiff and noncompliant left ventricle. The most common cause of CHF in the United States is ischemic heart disease. About 80 percent of CVD (myocardial infarction, angina, coronary heart disease, and congestive heart failure) can be prevented by:

- *Optimal nutrition*
- *Optimal exercise (both aerobic and resistance training)*
- *Optimal weight and body fat (total body fat, visceral fat, and epicardial fat)*
- *Avoiding all tobacco products*

The traditional evaluation, prevention, and treatment strategies for the top five cardiovascular risk factors – hypertension, diabetes mellitus, dyslipidemia, obesity, and smoking – have resulted in what is now referred to as a "CHD gap" [4]. Approximately 50% of patients will have CHD or MI despite having "normal" levels of these risk factors as currently defined in the medical literature [2, 5]. Traditional medicine continues to maintain a cholesterol-centric approach to the management of CHD but does not address the basic etiologies of CHD such as inflammation, oxidative stress, and immune vascular dysfunction. However, there are important details within each of these top five risk factors that are not being measured by physicians and are thus ignored in the prevention and treatment of CHD [2]. In fact, there are 25 top modifiable risk factors (▶ Box 47.1) and at least 395 other CHD risk factors that physicians' either aren't aware of or aren't using appropriate techniques to identify and treat them. Thus, it is imperative that we now begin to examine other methods to prevent and treat CVD [2].

Box 47.1 Top 25 modifiable CHD risk factors

- Hypertension (24-hour ABM)
- Dyslipidemia (advanced lipid analysis)
- Hyperglycemia, metabolic syndrome, insulin resistance, and diabetes mellitus
- Obesity
- Smoking
- Hyperuricemia
- Renal disease
- Elevated fibrinogen
- Elevated serum iron
- Trans fatty acids and refined carbohydrates
- Low dietary omega-3 fatty acids
- Low dietary potassium and magnesium with high sodium
- Inflammation: Increased hsCRP, MPO, interleukins
- Increased oxidative stress and decreased defense
- Increased immune dysfunction
- Lack of sleep
- Lack of exercise
- Stress, anxiety, and depression

- Homocysteinemia
- Subclinical hypothyroidism
- Hormonal imbalances in both genders
- Chronic clinical or subclinical infections
- Micronutrient deficiencies: numerous ones such as low vitamin D and K, etc.
- Heavy metals
- Environmental pollutants

47.2 Revolutionizing the Treatment of Cardiovascular Disease

The blood vessel has three finite responses to a large number of internal and external insults [2]. Those responses are inflammation, oxidative stress, and vascular immune dysfunction. Tracking backwards from those three finite responses brings us to the genesis of CVD, with the goal of starting effective treatments to resolve the downstream mediators and abnormalities.

Cell membrane physiology and cell membrane dysfunction are keys to this treatment strategy. This membrane barrier separates the outside and the inside of every cell, such as the endothelium, enterocyte, the blood brain barrier or any other membrane, and determines all of the signaling mechanisms that occur from the external to the internal milieu [2].

Any cell membrane insult such as high blood pressure, LDL cholesterol, oxLDL, glucose, microbes, toxins, heavy metals, or homocysteine results in a reaction diffusion wave ("tsunami effect") throughout the cell membrane that disrupts the receptors and signaling mechanisms that induce membrane damage and dysfunction [6, 7]. One small insult becomes a heightened response (metabolic memory) to create further cell damage [6, 7]. The blood vessel is really an innocent bystander in a correct but often dysregulated vascular response to these infinite insults.

In the acute setting, any vascular insult results in a correct defensive response by the endothelium. The vascular immune dysfunction, oxidative stress, or inflammatory responses are usually short-lived, appropriate, and regulated [2]. However, chronic insults result in a chronic exaggerated and dysregulated vascular dysfunction with preclinical, then clinical, CVD, due to maladaptation of various systems such as the renin-angiotensin-aldosterone (RAAS) system, sympathetic nervous system (SNS), and others [2].

Most diseases are arbitrarily defined with a specific abnormal level. Hypertension is defined as an arterial blood pressure greater than 140/90 mmHg, dyslipidemia as an LDL-cholesterol level over 100 mg/dL, and glucose intolerance as a fasting glucose over 99 mg/d [2]. However, it is very clear that there exists a continuum of CHD risk starting at lower levels of BP, LDL cholesterol and glucose, as well as for most other CHD risk factors [2]. For example, the blood pressure risk for CVD actually starts at 110/70 mmHg, and the risk for LDL-cholesterol causing reduction in nitric oxide in the endothelium starts at 60 mg/dL, and fasting glucose risk starts at 75 mg/dL [2]. There is a progressive continuum of risk with all of the CVD risk factors and mediators that affect the blood vessel, leading initially to functional abnormalities (endothelial dysfunction), then to structural abnormalities of the vascular (loss of arterial compliance with arterial stiffness, increased pulse wave velocity, increased augmentation index) and cardiac muscle (diastolic dysfunction, left ventricular hypertrophy, reduced ejection fraction), and later to preclinical and clinical CVD, such as MI, CHD, angina, and CHF.

Finally, it is important to understand the concept of "translational vascular medicine." Do the risk factors that are measured actually translate into vascular disease and illness? Vice versa, does the absence of those risk factors actually define vascular health? At this time, we often do not use appropriate or early noninvasive testing of functional and structural markers of endothelial dysfunction or vascular smooth muscle and cardiac dysfunction to identify the vascular effects of CHD risk factors, or the presence of vascular disease. Instead, we are relying only upon risk factors or some risk factor scoring system, such as Framingham, COSEHC (Consortium of Southeastern Hypertension Centers) or Rasmussen CHD scoring. We assume that if patients have risk factors, they also have vascular disease. If they don't, they may have vascular health. It is important to measure sensitive indicators of endothelial dysfunction and vascular structural disease that are induced by the insults. Early detection with aggressive treatment will reduce CVD.

47.2.1 The Endothelium, Endothelial Function, and Endothelial Dysfunction

The endothelium is a very thin lining of vascular cells, which forms an interface between the circulating blood in the lumen and the vascular smooth muscle [2, 4, 8] (Fig. 47.1).

When the endothelium is working correctly (endothelial function) with adequate amounts of nitric oxide, all the blood elements and the vascular smooth muscle remain normal. However, when endothelial dysfunction occurs, the results are inflammation, oxidative stress, immune dysfunction, abnormal growth, vasoconstriction, increased permeability, thrombosis, and ultimately CVD [2, 4, 8, 10].

Figure 47.2 illustrates LDL-cholesterol's role in atherosclerotic plaque formation [12]. Once inside the vessel wall, LDL-cholesterol becomes susceptible to oxidation, glycosylation, acetylation or modifications by free radicals and glucose, etc. [12]. Oxidized-LDL and glycated LDL are toxic to the vessel wall. The modified LDL is consumed by scavenger receptors (SR-A and CD-36) on macrophages to form foam cells. Foam cells are not able to process the oxidized-LDL or modified LDL and continue to accumulate oxidized and modified-LDL. It forms a plaque, which may rupture and cause acute coronary thrombosis. This is the progression that needs to be interrupted. There are actually 45 or more different steps in this process that are important in the treatment of dyslipidemia-induced vascular disease [12].

Vascular disease is a balance of vascular injury (angiotensin II and endothelin) versus vascular repair with endothelial

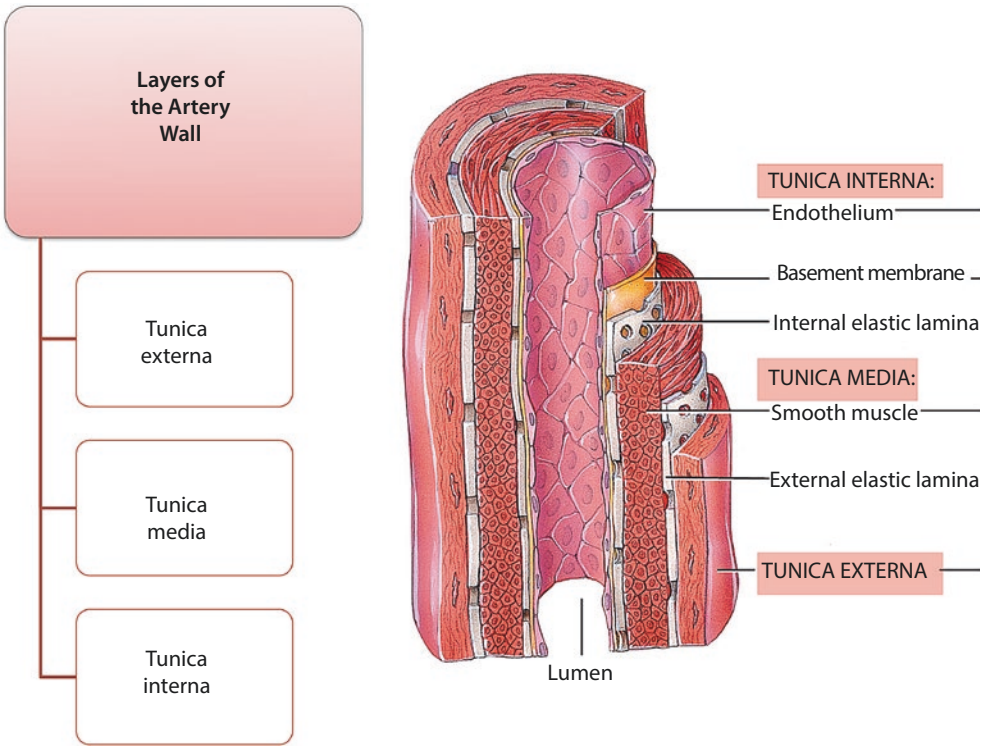

Fig. 47.1 The blood vessel showing the endothelial lining with connective tissue (the intima), vascular smooth muscle (media), and adventitia. Nitric oxide (NO) is released from the endothelial lining. (Reprinted from Tortora and Derrickson [9]. With permission from John Wiley & Sons.)

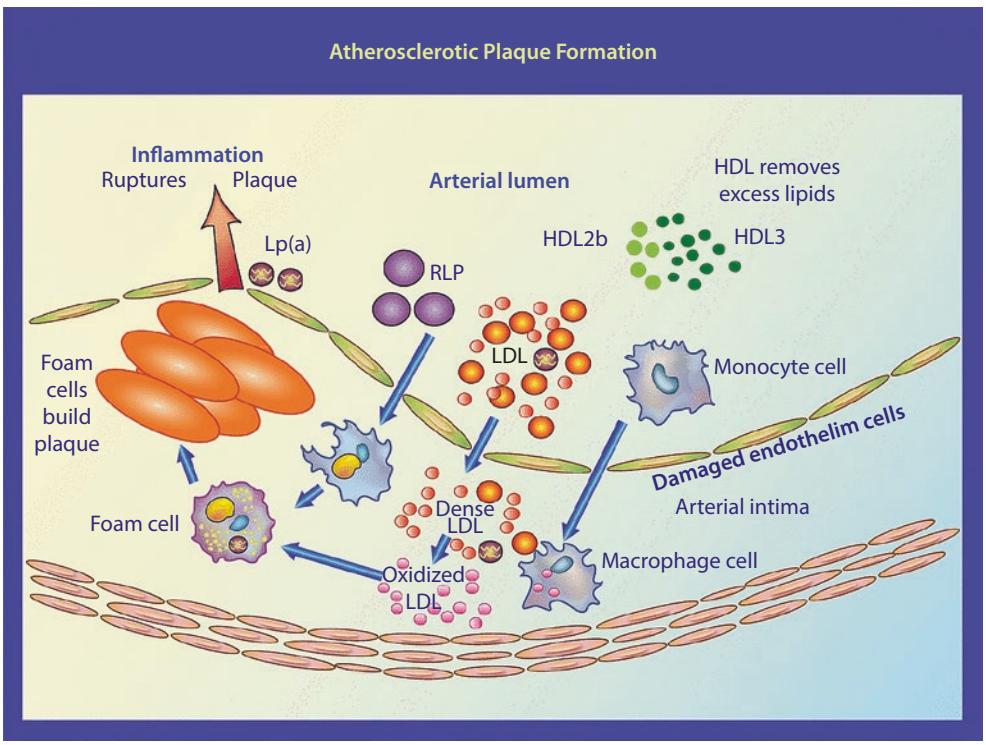

Fig. 47.2 A simplified illustration of atherosclerotic plaque formation in the subendothelial layer of the artery. (Reprinted with permission from Houston [11].)

progenitor cells (EPCs) produced in the bone marrow [2, 4]. The infinite insults result in preconditioned and heightened "metabolic memory" responses that trigger the three finite downstream responses that have a bidirectional communication involving endothelial dysfunction, vascular smooth muscle, and cardiac dysfunction [4, 6]. Once endothelial dysfunction has developed, a smaller insult occurring at a later date can result in a heightened response that induces more vascular damage [4, 6]. The concept of metabolic memory was demonstrated by Youssef-Elabd et al., who found that short-term exposure of adipose cells to uncontrolled levels of saturated fatty acids and glucose leads to a long-term inflammatory insult within adipocytes [6].

47.2.2 The Pathophysiology of Vascular Disease [2, 4]

What are the causes of vascular disease? The major causes are:

- Oxidative stress – reactive oxygen species (ROS) and reactive nitrogen species (RNS) are increased in the arteries and kidneys and with a decreased oxidative defense
- Inflammation – increased in the vasculature and kidneys: increased high-sensitivity C-reactive protein (hsCRP), leukocytosis, increased neutrophils and decreased lymphocytes, and increased renin–angiotensin–aldosterone system (RAAS) in the kidney
- Autoimmune dysfunction – of the arteries and kidneys: increased white blood count (WBC) and involvement of CD4+ (T-helper cells) and CD 8+ (cytotoxic T-cells)

These problems result in abnormal vascular biology with endothelial dysfunction and vascular smooth muscle hypertrophy and dysfunction. Of course, genetics, genomics, and epigenetics also play a role in the pathophysiology of vascular disease [3].

Figure 47.3 offers insight into the infinite insults that bombard the endothelium. These insults are divided into two major categories: biomechanical (blood pressure, pulse pressure, shear stress, and oscillatory pressure within the arterial system – most plaques form at the bifurcation of arteries) and biochemical (e.g., nutritional factors, metabolic, microbes, sterile antigens, and environmental toxins).

Endothelial cells express various receptors that determine the interaction between the insults and the downstream

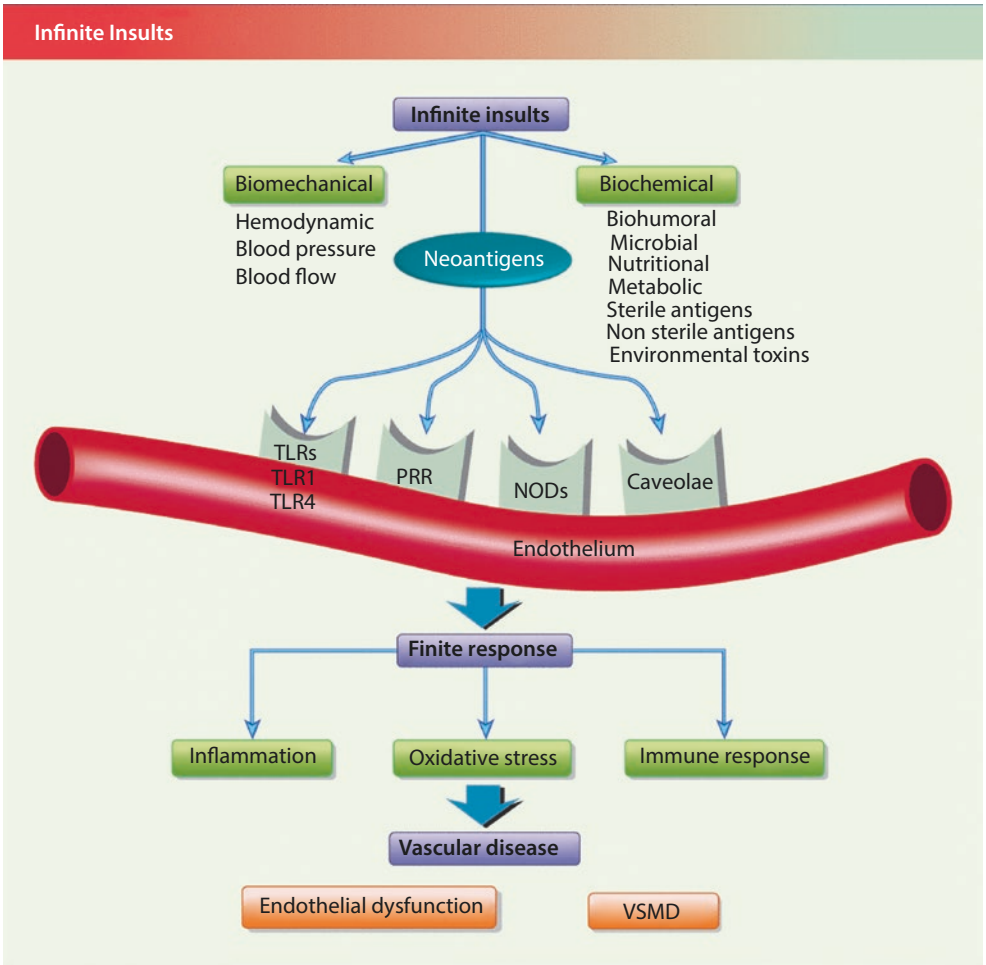

Fig. 47.3 The endothelium is subject to an infinite number of insults but can only elicit a finite number of responses to those insults which include inflammation, oxidative stress, and vascular immune dysfunction. (Reprinted with permission from Houston [11].)

mediators. These include pattern recognition receptors (PRRs), toll-like receptors (TLRs), NOD-like receptors (NLRs), and caveolae [13]. The TLRs and NLRs are membrane receptors that react to external insults with appropriate intracellular signaling that usually induces inflammation, oxidative stress, and immune dysfunction within the cell. The caveolae are membrane lipid microdomains that contain eNOS that determines nitric oxide levels and alterations in blood pressure, inflammation, dyslipidemia, oxidative stress, immune dysfunction, CHD, CVD, and atherosclerosis. The various risk factors and risk mediators attach to one of the receptors in the membrane and then set off a cascade of the three finite responses (inflammation, oxidative stress, and immune dysfunction), which leads to endothelial dysfunction and ultimately CVD [13].

47.2.3 Interrupting the Finite Pathways

The key to the successful prevention and treatment of CVD is both recognition of the risk factors and identification of treatments that will interrupt the pathways that connect the risk factors to these receptors. The TLR 1, 2, and 4 are the most common type of the PRR-TLRs related to the vascular membrane and endothelial dysfunction. The NLRs, NOD 1 and NOD 2, are also a type of PRRs that involve the vascular membrane. The scientifically proven nutraceuticals and dietary factors that accomplish this are listed below [14]:

- Curcurmin (turmeric): TLR 4, NOD 1 (NLR), and NOD 2 (NLR) (these are all PRR) [14]
- Cinnamaldehyde (cinnamon): TLR 4 [14]
- Sulforaphane (broccoli): TLR 4 [14]
- Resveratrol (nutritional supplement, red wine, grapes): TLR 1 [14]
- Epigallocatechin gallate (green tea): TLR 1 [14]
- Luteolin (celery, green pepper, rosemary, carrots, oregano, oranges, olives): TLR 1 [14]
- Quercetin (tea, apples, onion, tomatoes, capers): TLR 1 [14]
- Chrysin: TLR 1 [14]
- Omega-3 fatty acids: Interrupt caveolae lipid microdomains TLRs and NODs, decrease inflammation and hsCRP, lower BP, decrease LDL P, increase LDL and HDL size, improve glycation parameters, decrease immune vascular dysfunction, decrease CHD plaque formation, and improve CHD and CHF symptoms and outcomes [14].

The goal is to use a systematic (dynamic systems biology), functional and metabolic medicine approach to establish cardiovascular ecology, balance, and allostasis (achieve stability through change) and minimize chronic internal and external cardiovascular stressors, mediators, and risk factors that insult the blood vessel. Clinical interventions are needed to reduce the allostatic load, prevent, regulate, and treat the "abnormal" downstream finite responses.

The polygenetic codes for CVD identify 30 separate loci associated with MI and CHD, but most of those loci have nothing to do with the top five cardiovascular risk factors [3]. The majority of those loci deal directly with inflammatory pathways. Evaluation and treatment of only the top five risk factors and how they interact with our genome will never reduce CVD, and the CHD gap will persist.

Atherosclerosis, endothelial dysfunction, and vascular disease are postprandial phenomena [15]. Ingestion of sodium chloride, refined carbohydrates, and some foods containing trans fats may trigger glucotoxicity, triglyceride toxicity, vascular endotoxemia, inflammation, oxidative stress, and immune dysfunction [6, 15]. The data on saturated fats and endothelial dysfunction and cardiovascular disease remain controversial [6, 15]. Furthermore, these responses may be perpetuated long after the original insult with a heightened continued inflammatory response (metabolic memory) [6]. Fortunately, studies have shown that eating a diet that is rich in low-glycemic foods, monounsaturated fats, omega-3 fatty acids, polyphenols, and antioxidants can help to prevent postprandial endothelial dysfunction [12]. Early evidence of CVD in the form of fatty streaks has been documented in children in the first and second decades of life but may actually begin in utero (Fig. 47.4) [2]. The vascular disease is subclinical for 10–30 years or more prior to any cardiovascular event [2, 4, 8]. Patients with CVD may present with substernal chest pain with radiation to the neck, shoulders, arms, or back. Often, dyspnea with exertion may be the only symptom. New onset or severe fatigue, edema, dizziness, or syncope may be present. Women tend to have more atypical symptoms than men. Endothelial dysfunction is the earliest functional abnormality, followed by changes in arterial compliance, stiffness, and elasticity. It is important to begin using technologies that allow earlier identification of cardiovascular dysfunction before any structural changes have occurred.

Figure 47.5 illustrates the vessel changes that occur as CHD progresses. On the left is a fairly normal artery. In the middle, the CHD has progressed from minimal to moderate with the subendothelial layer becoming thick, but the lumen is still the same size. This extraluminal plaque and inflammation could be seen with computed tomography angiogram (CTA) but missed by conventional coronary arteriogram. In the image on the right in Fig. 47.5, there is extensive extraluminal and intraluminal disease.

Lack of the proper type of imaging, ignoring the majority of the other 395 or so CHD risk factors, and not properly evaluating the top five risk factors are some of the reasons for the persistence of the CHD gap [2].

47.3 Hypertension

The majority of patients with hypertension do not have any clinical symptoms until the blood pressure is very high or they have some clinical event such as myocardial infarction, TIA symptoms, stroke, congestive heart failure, or renal failure. If symptoms do occur, they could include chest pain,

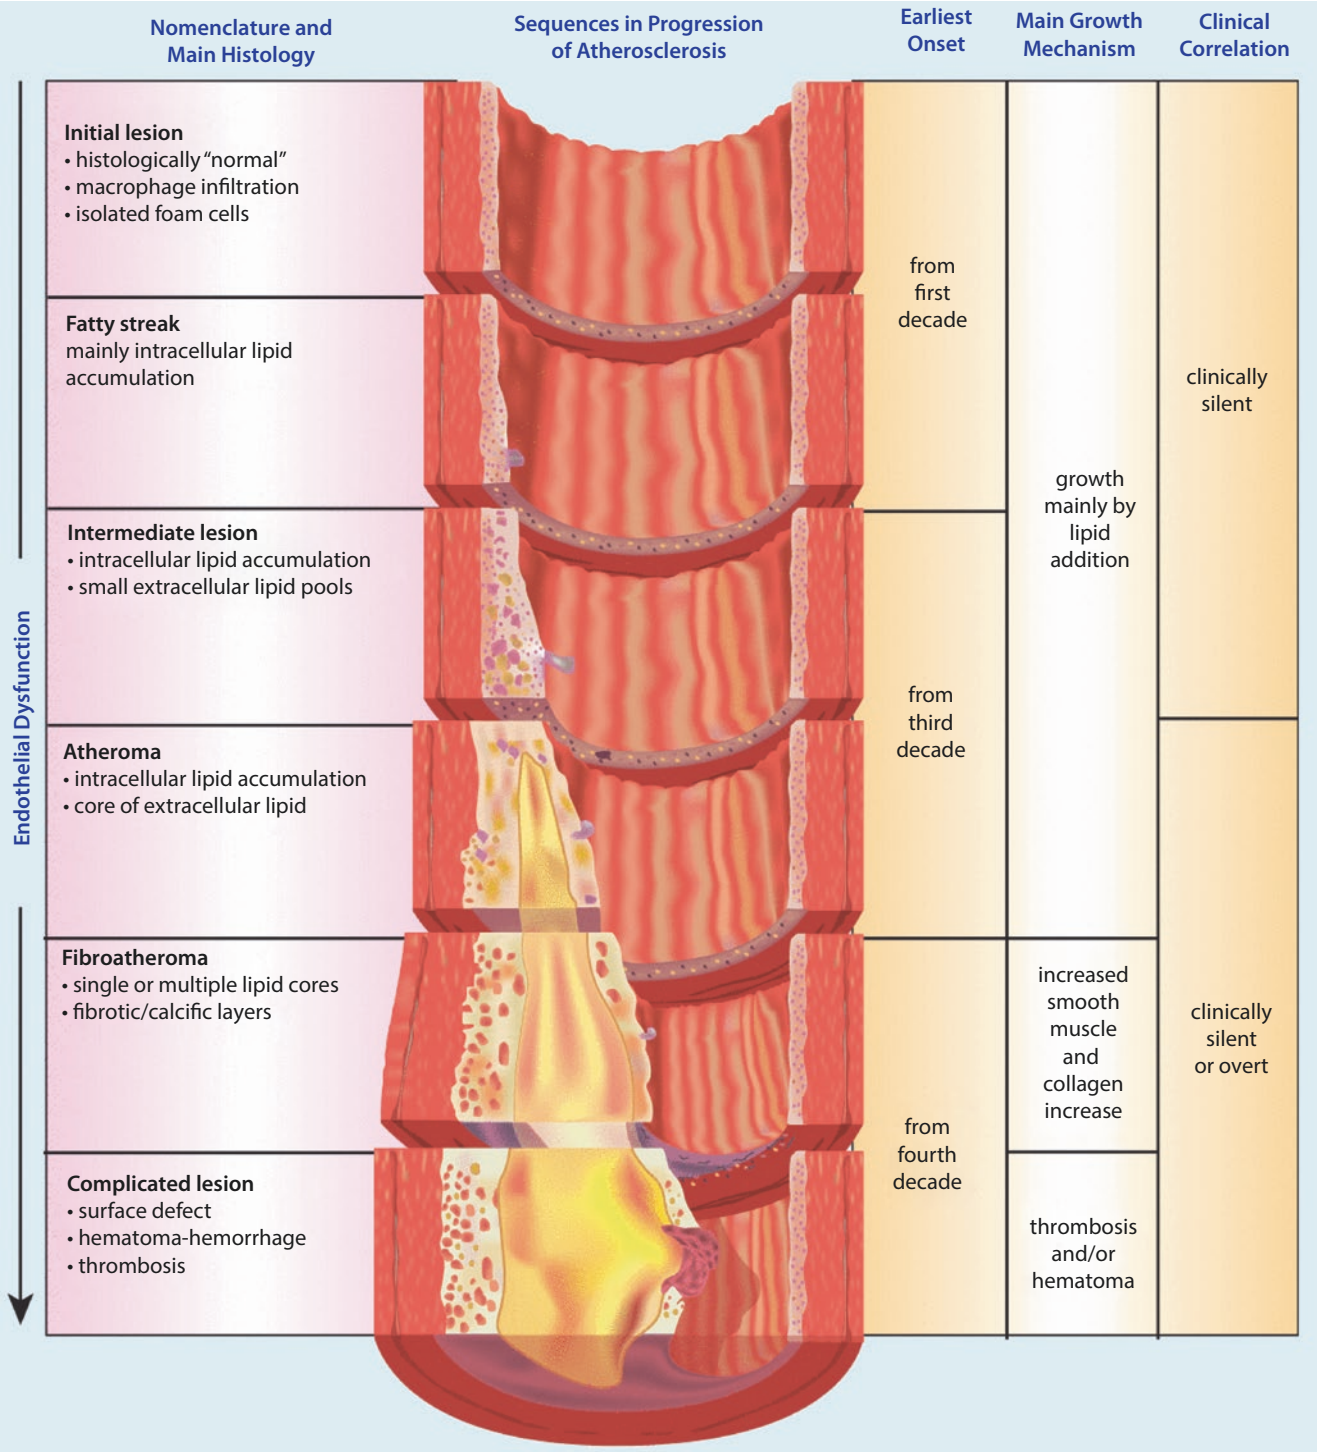

Fig. 47.4 Progression of atherosclerosis from the earlies initial lesion with endothelial dysfunction through the subintimal fatty streak, atheroma, fibroatheroma and final the complex lesion with stable and unstable plaque within the arterial lumen. (Reprinted with permission from Houston [11].)

dyspnea, headache, blurred vision, edema, or dizziness. Only a 24-hour ABM (ambulatory blood pressure monitor) can identify specific BP risks for CVD, such as nocturnal BP, dipping, nondipping, BP surges, BP load, and BP variability. Nondipping is defined as having less than a 10% reduction in BP at night. Nocturnal BP is the primary determinant of CVD, related to BP measurements. The BP load is the number of BP readings over 140/90 mmHg in 24 hours. The normal BP load is less than 15% of the total BP readings. BP surges that are high and rapid between 3 AM and 9 AM, as well as labile or variable BP, will increase CVD [8]. Excessive dipping is associated with an increased risk of ischemic

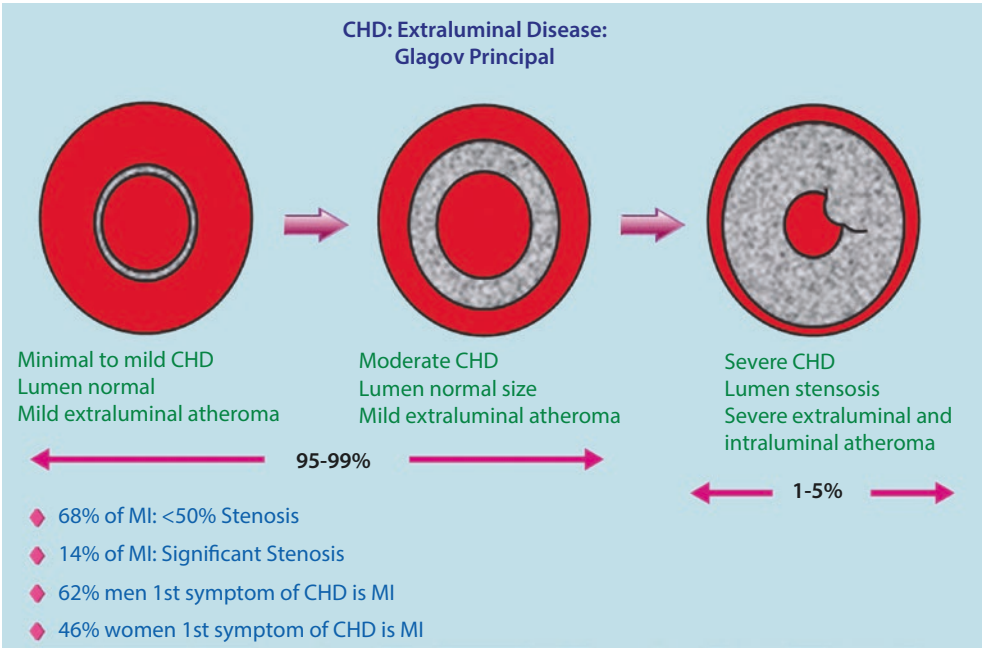

Fig. 47.5 Illustration of the vessel changes that occur as coronary heart disease progresses from an extra-lumenal disease at the beginning to the extra-lumenal and lumenal stenosis. (Reprinted with permission from Houston [11].)

stroke and reverse dipping is associated with an increased risk of intracerebral hemorrhage (ICH). Nocturnal blood pressure is more clinically important than day blood pressure (27/15 mmHg difference is optimal) [8]. Furthermore, morning blood pressure surges (level and rapidity) increase the risk of ischemic stroke, MI, and left ventricular hypertrophy [8]. Hypertension is not a disease; it is a marker for vascular dysfunction. Therefore, it is crucial that it is correctly identified. The following points should always be considered when evaluating blood pressure [8]:

- Normal blood pressure is 120/80 mmHg, but there is a continuum of risk for CVD starting at 110/70 mmHg.
- Each increase of 20/10 mmHg doubles cardiovascular risk.
- Before age 50, the diastolic blood pressure predicts risk best.
- After age 50, the systolic blood pressure predicts risk best.
- 24-hour ambulatory blood pressure monitoring is more accurate than office-based blood pressure measurements and should be the standard of care for defining hypertension and CVD risk.
- Mercury sphygmomanometers are the most accurate. Electronic machines with arm cuffs are good. Do not use wrist or finger monitors.
- Blood pressure load: percent over 140/90 mmHg should be less than 15%.

47.4 Dyslipidemia

Dyslipidemia is asymptomatic until a cardiovascular event, such as angina or MI, occurs. It is one of the top five cardiovascular risk factors, but proper measurement using advanced lipid profiles is rarely ordered to verify risk and optimal treatment [12, 16, 17]. An advanced lipid profile will measure:

- LDL-C total.
- LDL-P particle number (drives CHD risk).
- LDL size (dense type B versus large type A has a greater CHD risk).
- Modified LDL (oxidized, glycated, glyco-oxidized, and acetylated) increase CHD risk.
- Antibodies to oxLDL and modified LDL predict increase in CHD risk.
- Apolipoprotein (APO) B, if elevated, increases CHD risk.
- APO B antibodies and immune complexes increase CHD risk.
- Lp(a) is one of the hidden risk factors for CHD and MI.
- HDL-C total reduces risk for CHD.
- HDL-P particle number reduces CHD risk.
- HDL size (large 2b versus small type 3) lowers CHD risk.
- Dysfunctional HDL reduces reverse cholesterol transport and increases CHD risk.
- Pro-inflammatory and pro-atherogenic HDL increases CHD risk.
- Myeloperoxidase (MPO) and dysfunctional APO A increase oxidative stress, inflammation, and CHD risk as well as plaque rupture and hypertension.
- Low APO A increases CHD risk.
- Low paraoxonase (PON)-1 and PON-2 in HDL increases CHD risk.
- Increased APO-CIII in LDL or HDL increases CHD risk.
- Serum-free fatty acids, if elevated, increase insulin resistance, glucose, and CHD.

- VLDL (especially large VLDL) and triglyceride (TG) total increase thrombosis and CHD risk.
- Large VLDL increases CHD and risk for thrombosis.
- VLDL-P particle number increases CHD risk.
- Remnant particles increase CHD risk.

The primary driving cardiovascular risk related to LDL-cholesterol is the LDL-particle number (LDL-P and apolipoprotein B particles) [12]. HDL-P (particle number) is most protective, with larger HDL type 2b being a second important protective mechanism [12]. Larger number and size of HDL are more efficient at reverse cholesterol transport, and more protective to the vascular system in numerous other ways. It is also important to analyze dysfunctional HDL [12, 16, 17]. Patients who have a HDL of 85 mg/dL or more often have dysfunctional HDL that is not protective against CHD and MI [16, 17]. VLDL, triglycerides, and remnant particles are very atherogenic and thrombogenic [12].

47.5 Insulin Resistance, Metabolic Syndrome, Dysglycemia, and Diabetes Mellitus

A fasting blood sugar (FBS) of greater than 75 mg increases CHD by 1% per increase of 1 mg/dL and induces endothelial dysfunction [2]. If a patient has a FBS of 100 mg (often considered a normal level), the risk of CHD is increased by 25% [2]. A 2-hour glucose tolerance test (GTT) over 110 mg increases CHD by 2% per 1 mg/dL increase in glucose [2]. The current definition of an abnormal 2-hour GTT is >140 mg. If a patient's result is 140 mg, which again is currently classed as "normal," CHD and MI are increased by 60%. Hyperinsulinemia is also an independent risk factor for CHD [2]. Insulin resistance creates inflammation, reduces nitric oxide levels, and causes endothelial dysfunction and vascular disease through the mitogen-activated protein kinase (MAPK) pathway, which is atherogenic and induces hypertension. In contrast, the phosphatidylinositol 3-kinase (PI3K) pathway is anti-inflammatory, antihypertensive, and anti-atherogenic [2]. It is important to measure all glycation parameters including fasting glucose, 2-hour GTT, insulin levels, C-peptide, glycated serum protein, adiponectin and proinsulin, depending on the clinical setting [18].

Obesity with increased levels of inflammatory and oxidative stress-related adipokines contributes to CHD. Measurement of not just body weight but BMI and body composition with visceral fat total and regional body fat, epicardial fat (with chest CT scan), and lean body mass will help predict CHD risk [18].

The top 25 other CHD risk factors are listed below in ▶ Box 47.1. Some of the most neglected and important CHD risk factors to evaluate include gender-specific hormones, thyroid function, toxins, homocysteine, and vitamin D. In the other sections that follow, I will present algorithms, protocols, and treatments for hypertension, dyslipidemia, endothelial dysfunction, and coronary heart disease. Fortunately, there are a number of advanced biomarkers and noninvasive tests to determine vascular pathology before it actually starts [2] (▶ Boxes 47.2 and 47.3).

A discussion of these techniques is beyond the scope of this chapter. However, I would urge the reader to investigate these technologies, particularly EndoPAT, which is very accurate at assessing endothelial function and diagnosing endothelial dysfunction, computerized arterial pulse wave analysis (CAPWA) for endothelial function and arterial compliance, carotid intimal medial thickness (IMT) and plaque, magnetic cardiography (MCG) and cardiac CT angiograms (CTA) and CAC for cardiac calcium scoring [2, 8, 18–21] (▶ Box 47.3). The EndoPAT is the most cost-effective and accurate noninvasive test to identify early endothelial dysfunction and predict future CVD and CHD. This test, along with 24-hour BP, advanced lipid testing and glycation measurements are the best initial ways to evaluate the CV patient and are very cost-effective.

Diagnosis, prevention, and treatment of cardiovascular disease, coronary heart disease, hypertension, dyslipidemia, and diabetes mellitus can now be refined by adding selective cardiovascular genetics with the CHD risk factors, biomarkers, and noninvasive and invasive cardiovascular tests mentioned above (▶ Box 47.4).

Box 47.2 Noninvasive vascular testing for cardiovascular disease

- EndoPAT (endothelial dysfunction, augmentation index, and heart rate variability)
- CAPWA (computerized arterial pulse wave analysis)
- Mobile 0 graph for central and brachial BP, AI, PWV
- 24-hour ABM
- HRV: Heart rate variability and HRRT (heart rate recovery time)
- EKG: Electrocardiogram
- Chest X-ray
- TMT (treadmill test)
- CPET: Cardiopulmonary exercise test
- MCG (magnetocardiography)
- Carotid IMT/duplex
- CT angiogram (CTA)
- Sleep studies for obstructive sleep apnea (OSA)
- CAC (coronary artery calcium scoring)
- Cardiac MRI (CMRI)
- ECHO: Rest and exercise
- ABI: (ankle brachial index): Resting and exercise
- Retinal scan and OPA (ocular pulse amplitude)
- Cardiac PET, SPECT
- FDG-PET/CT: Vascular inflammation/plaque/biologic activity
- PET/CT/F-NaF for coronary plaque/inflammation/morphology
- PET/MRI for coronary plaque morphology and inflammation
- IVUS: Intravascular ultrasound

Box 47.3 Other comprehensive lab testing for cardiovascular disease

- Advanced lipid testing
- 24-hour ABM
- PRA and aldosterone
- Dysglycemia labs: Adiponectin, FBS, 2 hr. GTT, insulin, proinsulin, C-peptide, HBA1C, and glycated serum protein (GSP)
- BIA with total fat, regional fat, and LMM
- CT scan of chest for epicardial fat
- Markers for inflammation, oxidative stress, and immune function
- Micronutrient tests
- Thrombosis markers
- Renal function markers: CrCl (creatinine clearance), MAU (microalbuminuria), cystatin C, and SDMA (symmetric dimethyl arginine)
- Toxicology, heavy metals, POPs screen, organocide
- Omega-3 index
- Telomere test
- CV genetic SNP testing with Apo E genotypes with cardia-X
- CV genetic expression testing: Corus
- Gluten testing
- CBC with differential
- Urinalysis
- CMP 12
- APO B and APO AI and AII
- Free T4,T3, TSH, RT3, thyroid antibodies
- Magnesium
- Iron, TIBC, and ferritin
- Fibrinogen
- hsCRP
- Homocysteine
- Uric acid
- Microalbuminuria
- GGTP (gamma glutamyl transpeptidase) and hepatic profile
- Myeloperoxidase (MPO)
- Plasma viscosity
- Vitamin D3
- Hormone profile: Free testosterone, SHBG, estradiol, estriol, progesterone, DHEA, and DHEAS

Box 47.4 Cardiovascular genetics

1. 9p21 (GG/CC): CHD, MI, ASCVD, DM, IR AAA, thrombosis, plaque rupture, inflammation, and intracranial aneurysms
2. 6p21.4: CHD, MI, DVT)
3. 4q25: Atrial fibrillation, long QT, and PR intervals
4. ACE I/D (DD allele): HBP, LVH, CRF, MAU, nephro angiogenesis, carotid IMT, MI, and CHD.
5. COMT: Catecholamines, CHD, MI, HBP, ASA, and vitamin E responses.
6. 1q25 (GLUL): CHD in DM, enterocytes, and ED
7. 7 APO E: Dyslipidemia, CHD, MI, nitric oxide, statin response.
8. MTHFR: Methylation (1298C and 677 T): hypertension, CHD, MI, CVA, thrombosis, homocysteine, ED.
9. CYP 1A2: Caffeine, HBP, MI, aortic stiffness, PWV, AI, tachycardia, arrhythmias, vascular inflammation, catecholamines.
10. Corin: Hypertension, CHF, volume overload, sodium sensitive, CVD, CRF, preeclampsia), ANP, and BNP.
11. CYP 11 B2 (TT allele): HBP, aldosterone and response to spironolactone.
12. Glutathione peroxidase: CHD, MI, hypertension, LVH, CHF, glutathione, ALA 6 alleles, selenium.
13. ADR B2: HBP, PRA, inflammation and DASH diet with ACEI, ARB, or DRI.
14. APO A1: Lipids, HDL, CHD, MI, obesity.
15. APO A2: Lipids, HDL, CHD, MI, obesity.
16. APC C 3: Dyslipidemia, CHD, MI, dysfunctional HDL, inflammation, DM.
17. CYP 4 A11: Hypertension, ENaC and sodium, volume overload, CHD, and amiloride.
18. CYP 4F 2: Hypertension, ENaC and sodium, volume overload, CHD and amiloride.
19. AGTR1 (ATR1AA): HBP, ARBs, and potassium..
20. NOS 3: Nitric oxide, hypertension, MI, CHDCVA, thrombosis, ED, oxidative stress, inflammation.
21. SCARB1: Lipids, dysfunctional HDL with high HDL, CHD, MI.

47.6 Nutritional Interventions

47.6.1 Mediterranean Diet (TMD: Traditional Mediterranean Diet) [22–30]

In the 4.8-year primary prevention (PREDIMED), the rate of major cardiovascular events from MI, CVA, or total CV deaths was reduced by 30% with nuts and 30% with extra virgin olive oil (EVOO). The reduction in CVA was 39% ($p < 0.003$) with a 33% reduction from EVOO and a 46% reduction from nuts. The reduction in MI was 23% ($p = 0.25$) with a 20% reduction from EVOO and a 26% reduction from nuts. Total CV deaths were reduced by 17% ($p = 0.8$) [22–25]. New onset type 2 diabetes mellitus was decreased by 40% with EVOO and 18% with mixed nuts [22–25]. This reduction was associated with decreases in hsCRP and IL-6.

The high content of nitrate (NO3), at an average of 400 mg per day, is converted to nitrite (NO2), which eventually forms nitric oxide. Also, the increased amount of omega-3 FA, good omega-6 FA, and polyphenols (such as quercetin, resveratrol, and catechins, in grapes and wine) provide many of the beneficial outcomes in CHD.

Secondary prevention post-MI in the Lyon Diet Heart Study demonstrated significant reductions in all events, including cardiac death, nonfatal MI, unstable angina, CVA, CHF, and hospitalization at 4 years using the Mediterranean-style diet supplemented with alpha-linolenic acid, compared to a prudent western diet. Compared to the control, the Mediterranean-style diet demonstrated a 76% lower risk of cardiac death and nonfatal MI during the study period. Olive oil was associated with a decreased risk of overall mortality and an important reduction in CVD mortality in a large Mediterranean cohort of 40,622 subjects. For each increase in olive oil by 10 g, there was a 13% decrease in CV mortality. In the highest quartile of olive oil intake, there was a 44% decrease in CV mortality. One of the mechanisms by which the TMD, particularly if supplemented with virgin olive oil at 50 g per day, can exert CV health benefits is through changes in the transcriptomic response of genes related to cardiovas-

cular risk that include genes for atherosclerosis, inflammation, oxidative stress vascular immune dysfunction, type 2 diabetes mellitus, and hypertension. This includes genes for ADR-B2 (adrenergic beta 2 receptor), IL7R (interleukin 7 receptor), IFN gamma (interferon), MCP1 (monocyte chemotactic protein), TNFα (tumor necrosis factor alpha), IL-6 (interleukin 6), and hsCRP (high-sensitivity C reactive protein**).** In summary, the TMD has been shown to have the following effects**:**

- Lowers blood pressure
- Improves serum lipids: lowers TC, LDL, TG, increases HDL, lowers oxLDL and Lp(a), improves LDL size, and lower LDL P to less atherogenic profile
- Improves T2 DM and dysglycemia
- Improves oxidative defense and reduces oxidative stress: F-2 isoprostanes and 8OHDG
- Reduces inflammation: lowers hsCRP, IL 6, sVCAM, sICAM
- Reduces thrombosis and factor VII after meals
- Improves BNP
- Increases nitrates/nitrites
- Improves membrane fluidity
- Reduces MI, CHD, and CVA
- Reduces homocysteine

47.6.2 DASH Diets (DASH 1 and 2)

The DASH (Dietary Approaches to Stop Hypertension) diets reduce BP and CHD. Both DASH 1 and DASH 2 emphasize fruits, vegetables, whole grains, beans, fiber, low-fat dairy products, poultry, fish, seeds, and nuts but limit red meat, sweets, and sugar-containing beverages, while increasing the intake of potassium, magnesium, and calcium – and including variable restriction in dietary sodium [31, 32]. Both DASH diets reduce blood pressure within 4 weeks by about 10/5 mmHg or more, which is at least as effective as one antihypertensive medication. In the Nurses' Health Study, adherence to the DASH dietary pattern was associated with a lower risk of CHD by 14% in those with the highest adherence to the diet [33].

47.6.3 Portfolio Diet [34, 35]

The first Portfolio diet study consisted of 34 patients with dyslipidemia treated with three diets for 1 month, each in random order [34]:

- Control Diet: very low saturated fat
- Diet 2: control diet, plus lovastatin 20 mg
- Diet 3 (Portfolio): plant sterols, soy foods, almonds, viscous fibers, okra, eggplant

The results showed:

- Control Diet: reduced LDL 8.5%
- Diet 2: reduced LDL 33.3% and TG 11%
- Portfolio Diet: reduced LDL 29.6% and TG 9.3%

The second Portfolio diet study [35] was performed over a 6-month period with 351 subjects [34]. It included a low saturated fat diet as control, which reduced LDL-C by 3%. The dietary portfolio with variable counseling showed an LDL reduction of 13.1%. The dietary portfolio with two clinic visits resulted in an LDL decrease of 13.1%. The dietary portfolio with seven clinic visits had an LDL reduction of 13.8%.

47.7 Conclusions

The top five cardiovascular risk factors, as they are currently defined, are not an adequate explanation for CHD. In order to close the CHD gap, the top 5 risk factors must be better defined while assessing the top 25 modifiable risk factors and the other 395 risk factors and mediators. Early detection and aggressive prevention and treatment of cardiovascular disease are needed to identify functional CV disease and early CVD risk biomarkers before any cardiovascular structural changes occur or clinical disease becomes manifest. Improved utilization of new laboratory techniques are required, such as the advanced lipid profiles, 24-hour BP monitoring, and specific tests to identify inflammation, such as hsCRP; oxidative stress such as oxLDL and myeloperoxidase; and immune vascular dysfunction such as thyroid antibodies and other immune markers. In addition, vascular translational medicine will need to be evaluated with new imaging technologies, such as EndoPAT, CAPWA, carotid IMT, MCG, and CT angiogram.

In order to truly revolutionize the treatment of CVD, new therapies will need to involve management of the pathophysiologic risk factors, mediators and their downstream effects, as well as the finite vascular responses. This will be achievable by using a combination of targeted personalized and precision treatments with genomics, proteomics, metabolomics, nutrition, nutraceutical supplements, vitamins, minerals, antioxidants, anti-inflammatory agents, anti-immunological agents, and pharmacologic agents. Future studies must begin to measure all of the pertinent risk factors that have been reviewed here to correlate their direct relationship with CHD. Only by addressing all of these factors will we be able to decrease or halt subsequent vascular damage.

Case Presentations

Hypertension

Clinical History, Physical Exam, and Laboratory

- A 55-year-old black female with new onset hypertension
- BP 148/94 mmHg in office, averaged with BP readings x 3
- 24-hour ambulatory BP monitor: Mean BP 146/92 mmHg, BP load 52%, AM surges, nondipper
- FH negative for hypertension and CHD. Nonsmoker, no ETOH, no caffeine
- PE normal. Normal weight and body fat
- Lab normal except for microalbuminuria (MAU) of 66, FBS 104 mg/dL, and TG 298 mg/dL
- EKG mild left ventricular hypertrophy
- PRA 0.20 ng/ml/hr. (low)
- Plasma aldosterone: 10
- ARR (Aldo/renin ratio): 50
- Micronutrient deficiencies: GLA (gamma linoleic acid), vitamin D (25 ng/ml), zinc, magnesium, and lipoic acid

Concepts of Diagnosis and Treatment

- Patient has low renin hypertension (LRH).
- Endothelial dysfunction by EndoPAT at 1.44. Normal is >1.67.
- Her genetic profile (SNPs) for hypertension is negative.
- Use nutraceuticals and/or drugs that work in LRH.
- DASH 2 diet with 50 g of carbohydrates.
- Combined aerobic and resistance exercise 6 days per week at 60 minutes per session.
- GLA 500 mg twice per day.
- Vitamin D3 at 4000 IU per day.
- Zinc 50 mg per day.
- R-Lipoic acid 100 mg per day with biotin 2 mg per day.
- Magnesium chelates at 500 mg twice per day.
- Omega-3 fatty acids at 1.5 g bid (DHA and EPA).
- Replete nutrient deficiencies: GLA (gamma linoleic acid), vitamin D, zinc, magnesium, and lipoic acid.
- Start high-dose treatment with nutritional supplements that improve LRH: GLA (gamma linoleic acid), vitamin D, zinc, magnesium, and lipoic acid or others.
- Treat the insulin resistance and hypertriglyceridemia.
- Improve MAU.

Results

- 6 weeks: BP 126/84 mmHg.
- 3 months: BP 118/78 mmHg, 24-hour ABM is normal with mean BP 116/76 mm Hg, BP load <5%, no AM surges, normal dipping pattern.
- FBS 88 mg/dL.
- TG 110 mg/dL.
- MAU 34.
- Vitamin D3 62 ng/dl.
- MNT normal for nutrient deficiencies.
- EndoPAT is increased to 1.96.
- LVH on EKG unchanged.

Dyslipidemia

Clinical History, Physical Exam, and Laboratory

- A 38-year-old white male in for physical exam.
- Family history is positive for CHD early in life (age below 50 years).
- Normal weight, nonsmoker, excellent diet, and exercise program.
- History and PE are normal.
- All labs are normal, including a routine lipid profile. Note the normal TC, LDL, HDL, and TG.
- Expanded lipid profile done below (Fig. 47.6a, b):
- Lp(a) is 120 (normal is <30).
- hsCRP is 1.5 (borderline).
- Treatment: Should this patient be treated?

Treatment and Results at 2 Months

- Niacin B3 1000 mg bid
- NAC 1000 mg bid
- Omega-3 FA 4 g per day
- Vitamin C buffered at 5000 mg per day
- Lysine 1000 mg per day
- Proline 500 mg per day
- Red yeast rice at 800 mg hs
- Berberine 500 mg HS
- Pomegranate seeds ¼ cup bid
- LDL: 70–55 mg%
- LDL(p): 999–710
- LDL size: 20.3–22
- HDL: 41–50 mg%
- HDL 2b: 16–38 mg%
- TG: 70–55 mg%
- Lp(a) from 120 to 70

Coronary Heart Disease

Clinical Presentation, History, Physical Exam, and Laboratory

- A 58-year-old white male attorney.
- CC: fatigue for 8 years and mild DOE with steps and inclines only for 6 months. No chest pain. Mild memory issues for 5 years. Frequent URIs for 6 years. Erectile dysfunction for 4 years.
- PMH: negative except for GERD for 5 years, history of EBV and hepatitis A.
- Nonsmoker, 4 cups of coffee per day, one glass of red wine per day.
- Stressful job.
- Married with four children.
- Good diet. Eats lots of chicken and rice.
- Exercises 4 days per week for 1 hour without symptoms.
- Medications: nexium 40 mg per day for 5 years and Cialis 5 mg per day.
- No allergies.
- FH positive for hypertension, dyslipidemia, DM, CHD, and CVA.
- BP 142/88 mmHg HR 78.
- 6 ft. 1 inch Weight 220 pounds.
- WC 40 inches.
- Body Fat 25%.
- HEENT: mild glossitis.
- Cardiac: no murmur, rubs, or gallops.
- No edema.
- Skin: dry without rash.
- Otherwise normal exam.
- CHEM 12 normal except FBS of 102 mg/dL (high).
- CBC: PCV 38 (low) with MCV 104 (high).
- MAU 340 mg.(high), Cystatin C elevated at 1.7 (1.04).
- Homocysteine 12 (high).
- Fibrinogen 490 (high).

- hsCRP 3.0 (high).
- Ferritin: 162 (high).
- 2 h GGT 182 mg/dL (abnormal).
- HBAIC 6.2 (high).
- MNT: low in B 12, chromium, pantothenic acid, Co AQ 10, copper, vitamin C, and vitamin D.
- B 12 level 143 (low).
- Vitamin D 15 ng/ml (low).
- TFTs normal except for TSH of 3.4 (high)/positive TPO antibodies.
- Coenzyme Q 10 1.5 ug/ml (low).
- LPP advanced lipid profile: LPP 891, dense LDL, low HDL 2b.
- Genotype: heterozygote hemochromatosis, 2 SNPs for MTHFR (677 and 1298), Apo E 4/4, 9pq21, heterozygote SOD and GSH, homozygote CYP A12.
- ADMA elevated.
- Adiponectin low.
- MPO high at 730.
- Increased 8-0hdG and MDA with low PAO (plasma antioxidant capacity).
- GGTP 82 (elevated).
- OxLDL 99 (elevated).
- Hormones normal: free testosterone and DHEAS.
- Toxin screen: positive for arsenic.
- Gluten sensitivity: negative.
- Positive IGG for EBV and hepatitis A.
- TMT shows ventricular quadrigeminy, anterior and lateral ST depression of 1–2 mm.
- EndoPAT: endothelial dysfunction at 1.44, augmentation index is increased (stiff arteries with increased pulse wave velocity), and HRV is abnormal.
- CWPWA: C1 6 (low), C2 5 (low).
- Carotid duplex: increased IMT with less than 50% plaque bilateral.
- ECHO: normal EF, mild PI.
- MCG: abnormal/positive.
- Retinal scan: Grade 1 KW changes.
- 24-hour ABM: BP average 134/86 mm Hg, nondipper, BP load 35% over 140/90 mm Hg.
- Left main had 50–60% stenosis.
- Left anterior descending: multiple stenosis at 35%, 60%, and 95% high-grade obstruction.
- Left circumflex had 50% stenosis.
- Successfully stented the LAD 95% obstruction.

Treatment

- Mediterranean diet, stopped all caffeine, increased dark green leafy vegetables to eight servings per day with beets.
- Cardiac rehab and then ABCT exercise interval aerobics and resistance exercise.
- Stress management and relaxation therapy and HRV breathing training.
- Crestor 10 mg HS, berberine HCL 500 mg bid, niacin 500 mg hs with food and with quercetin 500 mg.
- Metoprolol 25 mg bid.
- ASA 81 mg per day.
- Quinapril 80 mg HS and melatonin 3 mg hs.
- Armour thyroid 60 mg per day.
- B-12 lozenges sublingual 1000 mcg/day.
- Vitamin D3 10,000 IU per day for 1 month and then 4000 IU per day.
- Chromium 800 ug per day.
- Coenzyme Q 10200 mg per day.
- B complex with methyl folate 5000 ug per day.
- Vitamin C 500 mg bid with copper 1 mg/zinc 50 mg per day.
- R lipoic acid 100 mg, NAC 1000 mg, and whey protein 40 g for glutathione.
- Oral chelation for arsenic.
- Omega-3 FA 5000 mg, vitamin K 2 MK 7200 mcg, Kyolic garlic 600 mg bid, curcumin 1000 mg bid, magnesium chelates 500 mg bid, and Epsom salts bath.
- Phlebotomy for hemochromatosis.
- Probiotic 50 billion cfu per day with glutamine 1000 mg bid. Stopped PPI.

6-Month Results

- All symptoms resolved
- Weight 195 lbs., WC 34 inches, 20%
- BP 122/78 mm Hg, dipper, HR 62 b/m
- All labs normal
- LPP 608, LDL type A, HDL 2b and HDL P normal
- MNT normal
- EndoPAT normal 2.66 and CAPWA normal
- TMT normal

Algorithms, Protocols, and Treatments

Hypertension

- Get appropriate labs with PRA and aldosterone to determine renin status.
  - High PRA: High renin hypertension. Start Natural ACEI, ARB, DRI, or BB
  - Low PRA: Low renin hypertension. Start Natural diuretic or CCB
- Use combinations of supplements to achieve BP goal using office readings and 24-hour ABM.
- Stop all drugs that induce hypertension.
- Exclude all secondary forms of hypertension, especially OSA (obstructive sleep apnea).
- Start DASH 2 diet with high potassium and magnesium and low sodium intake.
- Start weight loss program.
- Start supervised exercise program.
- Stop alcohol.
- Stop all tobacco.
- Stop caffeine, if slow metabolizer.
- Sleep 8 hours per night.
- Employ relaxation techniques.
- Reassess BP at 4 weeks and adjust supplements and protocols.
- BP goal is based on 24-hour ABM.

Treatment

Nutraceutical Supplements for Hypertension

Many of the natural compounds in food, certain nutraceutical supplements, vitamins, antioxidants, or minerals function in a similar fashion to a specific class of antihypertensive drugs. Although the potency of these natural compounds may be less and it may take longer to work than the antihypertensive drug, when used in combination with other nutrients and nutraceutical supplements, the antihypertensive effect is magnified.

Natural Diuretics

- Vitamin B-6 (Pyridoxine): 200 mg per day
- Taurine: 2–3 g twice per day

- Celery: one to two sticks per day
- GLA: 1000 t0 2000 mg per day
- Vitamin C (Ascorbic Acid): 500 mg per day
- Potassium: 5–10 g per day
- High Gamma/Delta tocopherols and tocotrienols: 250 mg per day
- Magnesium 500 mg chelated form twice per day
- Protein: high-quality organic protein at 1.5 g per kg per day
- Fiber 50 g of mixed fiber per day
- Coenzyme Q-10: 100–200 mg per day
- L-Carnitine: 2–6 g per day
- Hawthorn berry extract standardized: 2 per day

Beta-Blockers (BB)
- Hawthorn

Central Alpha Agonists (CAA)
- Taurine: 2–3 g twice per day
- Potassium: 5–10 g per day
- Zinc 50 mg per day
- Na^+ restriction to 2000 mg per day
- Fiber: fiber 50 g of mixed fiber per day
- Protein: high-quality organic protein at 1.5 g per kg per day
- Vitamin C: 500 mg per day
- Vitamin B-6: 200 mg per day
- Coenzyme Q-10: 100–200 mg per day
- Celery: one to two sticks per day
- GLA/DGLA: 1500–3000 mg per day
- Aged Kyolic garlic: 600 mg twice per day

Direct Vasodilators
- Omega-3 FA: 4–5 g per day
- MUFA (omega-9 FA): 50 g per day of EVOO
- Potassium: 5–10 g per day
- Magnesium 500 mg chelated form twice per day
- Soy: fermented soy
- Fiber 50 g of mixed fiber per day
- Aged Kyolic garlic: 600 mg twice per day
- Flavonoids
- Vitamin C: 500 mg per day
- Vitamin E: Gamma/delta tocopherol: 200–500 mg per day
- Coenzyme Q-10: 100–200 mg per day
- L-Arginine: 5–10 g per day as food or supplement
- Taurine: 2–3 g twice per day
- Celery: one to two sticks per day

Natural Calcium Channel Blockers (CCB)
- Alpha Lipoic Acid (ALA): 100–200 mg per day
- Magnesium: 500 mg chelated twice per day
- Vitamin B-6 (Pyridoxine) 200 mg per day
- Vitamin C 500 mg per day
- Vitamin E: high gamma/delta E with alpha tocopherol at 200–500 mg per day
- (↑ cytosolic Mg++ with ↓ Ca++), also diuretic
- N-Acetyl cysteine (NAC) 500–1000 mg twice per day
- Hawthorn standardized extract
- Celery one to two sticks per day
- Omega-3 fatty acids (EPA + DHA): 4–5 g per day
- Aged Kyolic garlic: 600 mg twice per day
- Taurine: 2–3 g twice per day

Natural Angiotensin-Converting Enzyme Inhibitors (ACEI)
- Aged Kyolic garlic: 600 mg twice per day
- Wakame seaweed: 3–4 g per day
- Tuna protein/muscle
- Sardine protein/muscle
- Hawthorn berry
- Bonito Fish (dried): 1500 mg per day
- Pycnogenol: 200 mg per day
- Hydrolyzed whey protein: 40 g per day
- Sour milk and milk peptides
- Gelatin
- Sake
- Omega-3 FA: 4–5 g per day
- Chicken egg yolks
- Zein
- Dried salted fish and fish sauce
- Zinc: 50 mg per day
- Melatonin: 3–6 mg at night
- Pomegranate: ½ to one cup per day
- Quercetin: 500–1000 mg twice per day
- Berberine: 500 mg twice per day

Natural Angiotensin Receptor Blockers (ARB)
- Potassium: 5–10 g per day
- Taurine: 2–3 g twice per day
- Resveratrol: 250 mg trans resveratrol per day
- Fiber: 50 g mixed fiber per day
- Aged Kyolic garlic: 600 mg twice per day
- Vitamin C: 500 mg per day
- Vitamin B-6: (Pyridoxine) 200 mg per day
- Co Enzyme Q-10: 100 t0 200 mg per day
- Celery: one to two sticks per day
- Gamma-linolenic acid (GLA and DGLA): 2–3 g per day

Dyslipidemia
- Identify underlying causes of dyslipidemia, remove, and treat them. These include poor micronutrient and macronutrient intake, toxins, and infections as well as other causes, such as hypothyroidism, obesity, smoking, and lack of exercise.
- Evaluate global CV risk with risk a scoring system.
- Evaluate for concomitant CHD risk factors.
- Measure noninvasive vascular testing such as EmdoPAT, CAPWA, and coronary artery calcium score and repeat testing in 6 months.
- Evaluate also carotid artery duplex, ECHO, EKG, exercise treadmill test, ABI at rest and exercise.
- Use advanced lipid testing to measure all particle sizes and particle numbers and Lp(a) and repeat testing in 2 months.
- LDL-P drives CHD risk.
- Reverse cholesterol transport, HDL-P, and HDL functionality drives reduction in CHD risk.
- HDL is often dysfunctional with inflammation and oxidative stress.
- HDL levels over 85 mg/dL are often dysfunctional.
- Measuring MPO and hsCRP help define dysfunctional HDL.
- Use scientifically proven nutraceuticals with the 45 different mechanisms of action to reduce dyslipidemia-induced vascular disease. Think/treat beyond just numbers. Look at mechanisms.

General Treatment Considerations

1. PREDIMED diet.
2. High-quality organic protein, especially fish.
3. Reduce refined carbohydrates to 50–75 g per day or less.
4. Eight servings of vegetables per day.
5. Four servings of berries or other low glycemic fruits per day.
6. Omega-3 fatty acids.
7. Monounsaturated fatty acids such as olive oil, olives, and mixed nuts. Consume 40 g of EVOO (extra virgin olive oil) per day.
8. Reduce saturated fats.
9. Eliminate trans fats.
10. Mixed aerobic and resistance training.
11. Ideal body weight and composition (BF for women <22% and less than 16% for men). Reduce visceral fat.

Nutritional Supplement Treatment

Supplements and Dose

- Red yeast rice: 2400–4800 mg at night with food.
- Plant sterols: 2.5 g per day.
- Berberine: 500 mg per day to twice per day.
- Niacin (nicotinic acid B3): 500–3000 mg per day as tolerated pretreated with quercetin, apples, ASA. Take with food and avoid alcohol. Never interrupt therapy.
- Omega-3 fatty acids with EPA/DHA at 3/2 ratio: 4 g / day with GLA at 50% of total EPA and GLA and gamma/delta tocopherol.
- Gamma delta tocotrienols: 200 mg hs.
- Aged garlic-Kyolic standardized: 600 mg twice per day.
- Sesame: 40 g per day.
- Pantethine: 450 mg bid.
- MUFA: 40–50 g per day (EVOO 4 tablespoons/day).
- Lycopene: 20 mg per day.
- Luteolin: 10 per day.
- Astaxanthin: 15 mg per day.
- Trans-resveratrol: 250 mg per day.
- NAC: 500 mg twice per day.
- Carnosine: 500 mg twice per day.
- Citrus bergamot: 1000 mg per day.
- Quercetin: 500 mg twice per day.
- Probiotics standardized: 15–50 billion organisms bid.
- Curcumin: 500–1000 mg twice per day.
- EGCG: 500–1000 mg bid or 60–100 ounces of green tea/day.
- Pomegranate: ½ to one cup of seeds/day or 6 ounces of juice per day.

Endothelial Dysfunction

Concepts

- The nitrate-nitrite NO pathway in which endogenous nitrate (NO3-) undergoes reduction to nitrite (NO2-) and then to NO in various tissues, including blood with the production of bioactive NO that is important for ED and CVD.
- Vegetables are the primary source of nitrates (80–85%).
- This is the alternate pathway to the arginine NO path.
- Nitrate-to-nitrite reduction is carried out by commensal bacteria present on dorsal surface of tongue and GI tract and requires healthy microbiome and gastric acid.
- Increased with low oxygen.
- Decreased with mouthwash and GI disease and use of PPIs and H2 blockers that reduce gastric acid.
- Conversion to NO by deoxyhemoglobin, xanthine oxidoreductase, deoxymyoglobin, protons, vitamin C, and polyphenols.

Protocol

1. EndoPAT for endothelial function, augmentation index, and heart rate variability (HRV).
2. CAPWA: computerized arterial pulse wave analysis for arterial compliance.
3. ADMA (asymmetric dimethyl arginine): competitive inhibitor of nitric oxide. One of the best markers for nitric oxide bioavailability.
4. SDMA (symmetric dimethyl arginine): competes with arginine for cell uptake.
5. Nitro-species in erythrocytes: most sensitive marker of nitric oxide.
6. BH4 (tetrahydrobiopterin): primary cofactor for eNOS to make nitric oxide. BH4 is cofactor for conversion of phenylalanine and tyrosine to DOPA, dopamine, NE, and EPI. Low CNS NT lead to hypertension and CVD. BH4 is cofactor for conversion of phenylalanine to tyrosine and thyroid hormones. Hypothyroidism leads to hypertension and CVD. BH4 is cofactor for conversion of L-tryptophan to 5HTP and if deficient increases kynurenate and quinolinate which stimulate glutamate NMDA receptor to increase CNS inflammation (and neurodegeneration) which increases BP and CVD risk.
7. BH2: oxidized form that provides no protection from CHD and is not active as eNOS cofactor.
8. BH2/BH4 ratio.
9. DDAH (dimethyarginine dimethylaminohydrolase): breaks down ADMA and increases NO.
10. Citrulline: increase production of nitric oxide with arginine.
11. Arginine: precursor for nitric oxide via eNOS.
12. Arginase 1: breaks down arginine and reduces NO.
13. Nitrates and nitrites: alternate pathway via food and oral microbes to produce nitric oxide.
14. Folate: cofactor for eNOS to make nitric oxide.
15. MTHFR.
16. Vitamin B 12: cofactor for methylation and improves endothelial function. Lowers homocysteine with other B vitamins.
17. Homocysteine.
18. Neopterin (macrophages, CMI, CVD, and autoimmune).
19. Biopterin.
20. Neopterin/biopterin ratio: normal is 0.5–6.0 (marker for CVD, vascular disease, inflammation, and autoimmune.disease).

Treatment

1. If EndoPAT is low or ADMA and SDAM are high, start treatments below first:
   - Beetroot extract with arginine, citrulline, and hawthorn
   - PREDIMED diet
   - VasculoSirt
   - Methyl folate

2. Repeat ADMA, SDMA, and EndoPAT in 4–6 months. If still abnormal, add the following to the initial treatment: Vitamin C 1000 mg bid, omega-3 fatty acids at 5 g per day (EFA-Sirt Supreme 5 BID), resveratrol 250 mg per day) and Kyolic Aged garlic extract (AGE): 600 mg twice per day and Co Q 10200 mg per day.

Coronary Heart Disease

1. EndoPAT
2. EKG
3. Magnetic resonance EKG
4. chest x-ray
5. Echo
6. Computerized arterial pulse wave analysis
7. Treadmill exercise test
8. Exercise echo as indicated
9. Nuclear medicine scans as indicated
10. Coronary artery calcium score
11. Computerized CT angiogram as indicated
12. MRI and MRI of heart as indicated
13. 24-hour Holter monitor as indicated

Treatment

- DASH diet
- Mediterranean diet with EVOO
- Nut consumption: 20% reduction death with 7 servings per wk
- Vitamin D3 4000IU per day
- Vitamin C 500 mg per day
- Beetroot extract with arginine, citrulline, and hawthorn
- Dietary nitrate at 0.1 mmol/kg of body weight per day (high intake of F and V) reduces DBP 3.5 mm Hg
- Effect is potentiated by Vitamin C and polyphenols
- 500 mg beetroot juice with 45 mmol/L of 2.79 g/L of inorganic nitrate lowers BP 10.4/8.1 mm Hg, inhibits platelet aggregation by 20% and increased FMD 30%
- Lycopene 20 mg per day
- Omega-3 fatty acids 5 g per day EFA-Sirt Supreme
- Polyphenols, flavonoids, and flavonoid-rich foods. Best data with flavones and flavonols
- Resveratrol: 250 mg trans form per day
- Grape seed extract: 500 mg twice per day
- EGCG: 500–1000 mg twice per day
- Co Enzyme Q 10: 100 mg twice per day
- Cacao and dark chocolate: 30 g per day
- Tea and catechins
- Curcumin: 1000–2000 mg twice per day
- Berry anthocyanins and pomegranate seeds
- Orange juice and hesperidin
- Wine polyphenols
- Rhodiola extract: 200–500 mg/day
- Kyolic Aged Garlic extract (AGE): 600 mg twice per day
- VasculoSirt

Congestive Heart Failure

3. EndoPAT
4. EKG
5. Magnetic resonance EKG
6. Chest x-ray
7. Echo
8. Computerized arterial pulse wave analysis
9. Treadmill exercise test
10. Exercise echo as indicated
11. Nuclear medicine scans as indicated
12. Coronary artery calcium score
13. Computerized CT angiogram as indicated
14. MRI and MRI of heart as indicated
15. 24 hour Holter monitor as indicated
16. NT-proBNP and BNP: BNP and CVD Risk
17. Galectin-3

Treatment

1. PREDIMED diet.
2. High-quality organic protein, especially fish.
3. Reduce refined carbohydrates to 50–75 g per day or less.
4. 8 servings of vegetables per day.
5. 4 servings of berries or low-glycemic fruits per day.
6. Reduce fruit juices.
7. Increase fiber to 50 g per day.
8. Omega-3 fatty acids.
9. Monounsaturated fatty acids, such as olive oil, olives and mixed nuts.
10. Reduce saturated fats.
11. Eliminate trans fats.
12. Mixed aerobic and resistance training.
13. Ideal body weight and composition (BF for women less than 22% and less than 16% for men). Reduce visceral fat. Increase lean muscle mass.
14. Sleep 8 hours per night.

Specific Nutritional Supplements

1. Co Enzyme Q 10: 200–300 mg bid
2. D-Ribose: 5 g tid
3. Taurine: 3 g bid
4. Carnitine: 3 g bid
5. Magnesium: 500 mg bid of chelated magnesium
6. Vitamin K2 MK 7: 200–400 micrograms per day
7. Aged Garlic Kyolic: 600 mg bid
8. Omega-3 fatty acids: EFA-SIRT SUPREME
9. B vitamins mixed and thiamine: 200 mg per day

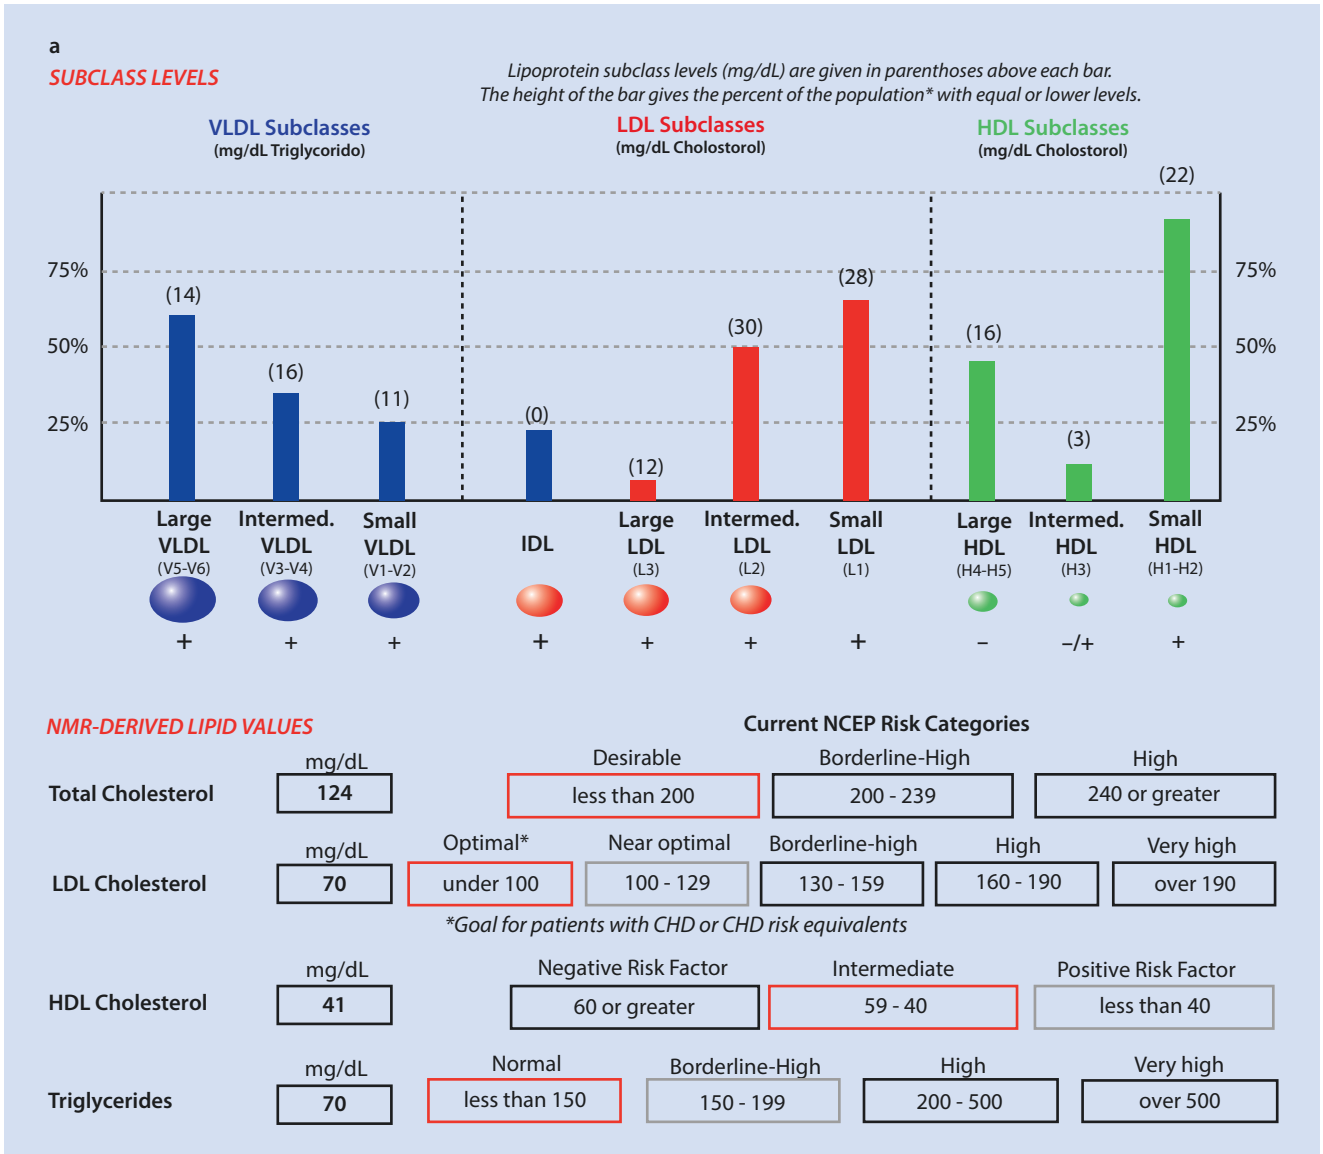

Fig. 47.6 **a** This is the VAP (vertical analytic profile) advanced lipid test indicating the various particle sizes of HDL, VLDL, and LDL. **b** This is the VAP (vertical analytic profile) advanced lipid test giving the actual LDLP number as well as VLDL and HDL

Learning Objectives

- Alteration of the gut microbiome by the modern Western lifestyle is responsible for the rise of food immune reactivities and autoimmunities.
- Exposure to xenobiotics, genetically modified foods, food hybridization, and industrial food additives contributes not only to microbiome alteration but also to the surge of food immune reactivities and autoimmunities.
- Molecular mimicry or cross-reactivity between different foods and human tissue is an additional mechanism for the rise of autoimmunities.
- Detoxification and implementation of dietary protocols based on food-targeted tissue antigens are a strategy to reduce autoimmune reactivities.

48.1 Introduction

In our companion chapter (► Chap. 19), we established that the breakdown or failure of immune tolerance due to an unfavorable lifestyle can result in immune reaction to dietary components. Here we will explain different mechanisms that result not only in food immune reaction but possibly also in autoimmunities. For the sake of discussion, I am asking the following questions:

- Why are allergies and food immune reactivities on the rise?
- Why are autoimmune diseases reaching epidemic proportions?

The answers to these interrelated questions are discussed below.

48.2 The Hygiene Hypothesis

A 28-year-old idea claims that the modern lifestyle of Western societies, the widespread use of antibiotics, a zeal for cleanliness, and a lower number of children per family have purged the growth dynamics of gut microbiota and shifted the development of the immune system from Th1 to Th2 imbalances, setting the stage for the possible development of allergy and asthma.

The hygiene hypothesis states that the rise in allergy and asthma that has been observed in affluent countries since the Second World War is caused by reduced "infectious pressure" from the Western lifestyle environment. The mechanism behind this association has been linked to an imbalance in the immune system, favoring pathogenic Th2 immunity in the absence of counterbalancing Th1 immunity, natural killer T cells, or regulatory T cells that are often induced by infections [1, 2]. A recent investigation [3] provided evidence that environmental protective factors can also influence the threshold for allergen recognition by suppressing the activation of epithelial cells (ECs) and dendritic cells (DCs) via induction of the ubiquitin-modifying enzyme called A20. This regulatory mechanism is also seen in the gut, where colonizing microbiota induce the expression of A20 shortly after birth, thus dampening overt inflammatory reaction to the commensals. It is well known that growing up on a farm and being exposed to the farm microbiome or their antigens protects many individuals from allergy, hay fever, and asthma. It seems that chronic exposure to low doses of bacterial antigens activates regulatory T cells, suppressing Th2 immunity to house dust mites and preventing allergy and asthma. Thus, the farming environment protects from allergy by modifying the communication between epithelial cells and DCs through A20 induction [3].

48.3 Alteration of Human Gut Microbiome by Western Diet

Many years ago when I took my clinical microbiology course and started growing different bacteria in the lab, I asked the question why we needed so many different media and why we couldn't have just one medium on which all bacteria could grow. The answer to this question was very simple: because each bacterium thrives on different nutrients. For example, some bacteria grow on simple media such as nutrient agar; others, such as *Enterobacter*, love to grow on agar and sugar and others on agar and potato, agar and rice, agar and soy, agar and beef extracts, or agar and blood. Some fastidious bacteria will not grow without the addition of heart or even brain tissue to the basic agar medium. The best way to explain this is that we are what we eat, and that is why diet alters the human microbiome and why there is such a huge difference in the microbial communities of different populations [4, 5]. There is growing concern that the current prevailing lifestyle trends of modern civilization, most notably the high-fat/high-sugar "Western diet," have negatively altered the genetic composition and metabolic activity of the resident microorganisms in the human gut. Such diet-induced changes to the gut microbiomes are now suspected of contributing to growing epidemics of chronic illness in the developed world, including obesity, inflammatory bowel disease (IBD), and other autoimmunities [6–8]. It has been shown [9] that the short-term consumption of diets composed entirely of animal or plant products alters the microbial community structure and overwhelms interindividual differences in microbial gene expression. The animal-based diet increased the abundance of bile-tolerant microorganisms (*Alistipes*, *Bilophila*, and *Bacteroides*) and decreased the levels of *Firmicutes* that metabolize dietary plant polysaccharides (*Roseburia*, *Eubacterium rectale*, and *Ruminococcus bromii*). The differences between herbivores and carnivores were mirrored in microbial activity, reflecting trade-offs between carbohydrate and protein fermentation. Foodborne microbes from both diets transiently colonized the gut, including bacteria, fungi, and even viruses. Finally, increases in the abundance and activity of *Bilophila wadsworthia* on the animal-based diet

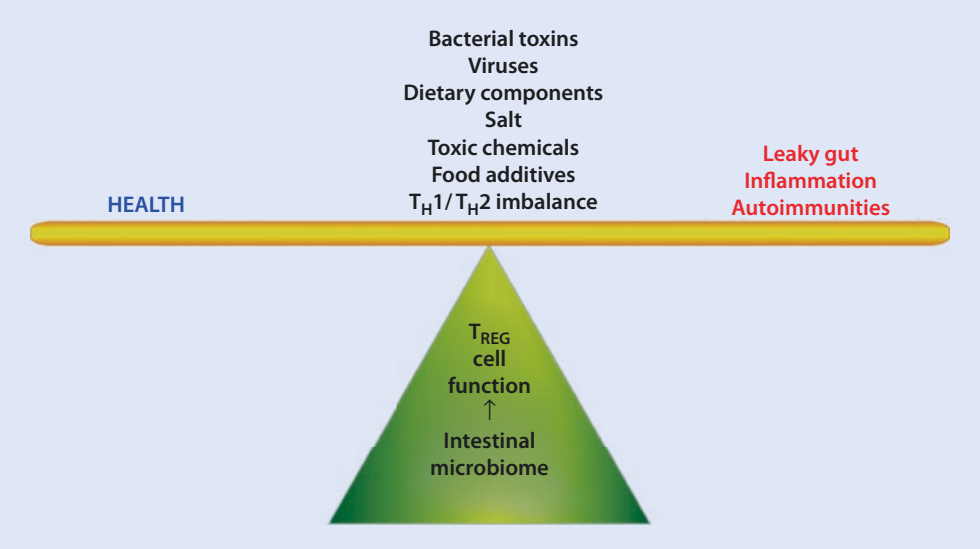

Fig. 48.1 The host-microbiota homeostatic balance

support a link between dietary fat, bile acids, and the outgrowth of microorganisms capable of triggering gut barrier disruption inflammation and autoimmunities, including IBD and celiac disease (CD) [9, 10].

This is because intestinal dysbiosis is a hallmark of several immune disorders, including IBD and CD. Increased levels of pathobionts may activate the pro-inflammatory pathways that trigger a breakdown in food tolerance and promote the onset of disease. This, in turn, further drives the gut microbial community toward a state of dysbiosis, resulting in a vicious circle that disrupts the host-microbiota homeostatic balance [10] (see Fig. 48.1).

Environmental triggers such as viral infections have been proposed to have a role in the pathological role of CD. In support of a relationship between environmental triggers, CD, and non-celiac gluten sensitivity (NCGS), reovirus infection has been shown to trigger inflammatory responses to dietary antigens and to be involved in the development of celiac disease [11]. This is because the reovirus, a so-called avirulent pathogen, can disrupt intestinal immune homeostasis at inductive and effector sites of oral tolerance by suppressing peripheral regulatory T cell (pTreg) conversion and promoting Th1 immunity to dietary antigens. Initiation of Th1 immunity to dietary antigens was dependent on interferon regulatory factor 1 and dissociated from suppression of pTreg conversion, which was mediated by type 1 interferon. The finding of this study supports a role for infection in addition to dietary protein in triggering the development of autoimmune disease [11]. According to the hygiene hypothesis, the increasing incidence of autoimmune diseases in Western countries may be explained by changes in early microbial exposure, leading to altered immune maturation. This is mainly due to microbiome lipopolysaccharide immunogenicity, which may contribute to autoimmunity in humans [12]. For example, the *Bacteroides* species in the microbiota of children from countries with high susceptibility to autoimmunity produce a type of lipopolysaccharide (LPS) with immunoinhibitory properties. These properties may preclude early immune education and contribute to the development of type 1 diabetes and other autoimmune disorders. Therefore, early colonization by microbiota with a capacity of changing the Th1/Th2 balance may be responsible for a lack of immune fitness in many children and adults in Western societies.

48.4 Xenobiotic Residues in Food Commodities

Unfortunately, during the past several decades, we have been presented with the incorrect notion that the chemical insecticides applied to the plants, fruits, and vegetables we eat will not penetrate them but will be washed away. Similarly it is widely believed that when chemicals in our air, food, and water get into our body, they will be out within 24 hours. However, in reality, chemicals originating from the environment or applied to different products form a stable bond with food proteins and other macromolecules. Similarly, some chemicals, after entering the human body, directly or indirectly manage to bind to albumin, hemoglobin, and other tissue proteins. This process – the binding of low-molecular-weight chemicals to proteins or chemical reactivity to proteins – is called haptenation. Haptens such as pesticides must complex with proteins and form neo-antigens in order to be recognized by the immune system. It is during this immune recognition of chemicals bound to human tissue that the immune system will attack the tissue-bound chemicals, setting the stage for autoimmunities [13–16].

One of the best examples of a chemical binding to human body proteins such as albumin or hemoglobin is aflatoxin (see Fig. 48.2). Aflatoxins, especially aflatoxin B1 (AFB_1), are potent carcinogens produced by strains of fungi such as

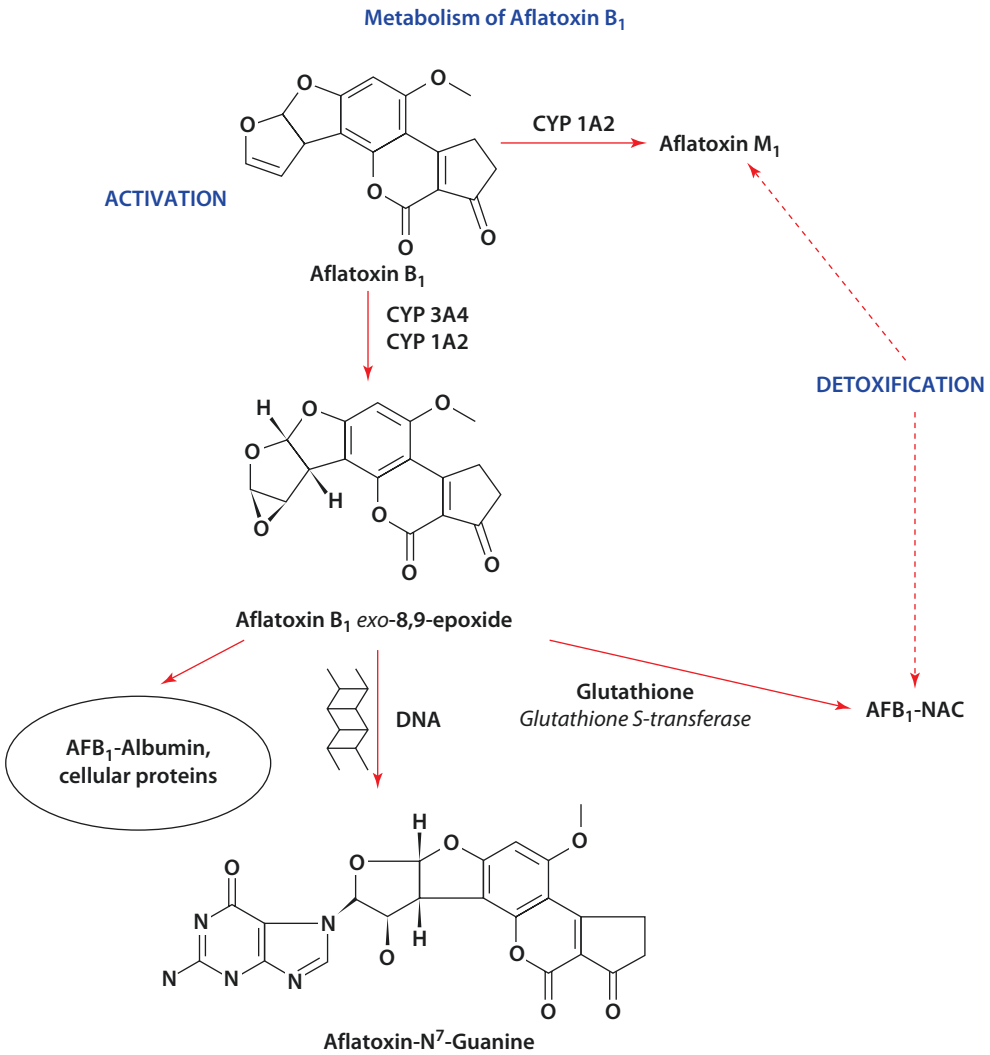

Fig. 48.2 Neo-antigen formation between aflatoxin, proteins, and DNA results in antibody production against DNA and proteins, setting the stage for autoimmunities

Aspergillus flavus. This organism grows on important food groups such as peanuts, other ground nuts, maize, and other oilseeds, and the toxin contaminates these foods. Consumption of these aflatoxin-contaminated foods results in high levels of AFB_1, proteins, and DNA adducts, which are the mechanisms responsible for the induction of immune dysfunction and cancer. In many countries there is not much data available regarding exposure to aflatoxin, but in Ghana, when AFB_1-albumin adducts were measured in 61 participants, 100% of them had very high levels [17].

Aflatoxin can form neo-antigens with cellular proteins and DNA; immune response to this combination in certain individuals may result in antibody production against it. In our own study from 2015 [16], we aimed to examine the percentage of blood samples from 400 healthy donors in which chemical agents mounted immune challenges and produced antibodies against HSA-bound chemicals. In fact, we found that at 2 SD above the mean of the participants, 17% produced IgM and 10% produced IgG against aflatoxin-HSA. Furthermore, when we measured these antibodies against 11 other chemicals bound to HSA or neo-antigens – such as formaldehyde-HSA, isocyanate-HSA, trimellitic anhydride-HSA, dinitrophenyl-HSA, bisphenol-A-HSA, tetrabromobisphenol-A-HSA, tetrachloroethylene-HSA, mercury-HSA, mixed heavy metals-HSA, parabens-HSA, and pyrethroid-HSA – in the same 400 subjects, elevation in IgG ranged from 8% to 22%, while IgM ranged from 13% to 18%. We concluded that this protein adduct formation could be one of the mechanisms by which environmental chemicals induce autoimmune reactivity in a significant percentage of the population [16]. Therefore, these types of studies prove the concept that chemicals are not in and out; some percentage of chemicals or their metabolites bind to human tissue antigens and set the stage for autoimmune attack and even cancer. Therefore, a xenobiotic-bound residue is a residue which is associated with one or more classes of endogenous macromolecules. It cannot be disassociated from the natural macromolecule using exhaustive extraction or digestion without significantly changing the nature of either the exocon or the associated endogenous macromolecules

[13]. This change in the endogenous macromolecules by a toxic chemical seems to be responsible for the rise of food immune reaction, allergies and autoimmunities. Therefore, it is the opinion of the senior author of this chapter that the mere detection of chemicals in urine or blood has no pathological significance; the human body has an enormous body burden of chemicals as an ongoing state, and detected chemical levels in blood would indicate exposure to the chemicals, while detection in urine would indicate their excretion or elimination from the body. It is only when the same chemicals or metabolites form neo-antigens with human proteins that they have the capacity to induce autoimmunities. Consequently, measurements of antibodies against chemicals bound to human albumin is the proper indication of the body burden of chemicals. The senior author has developed tests for these chemical antibodies that are offered as a panel from an independent laboratory.

48.5 Genetically Modified Foods

Genetically modified foods (GM foods) are foods that had changes introduced into their DNA using genetic engineering methods. Put another way, they are foods into whose organism genome more genes were introduced in order to confer them with new traits. Genetically modified in crops include corn, soybeans, canola, cotton, fruits, vegetables, and many more. Crops are modified to be resistant to pathogens and herbicides and for better nutrient content or even to increase their shelf life. For instance, *Bacillus thuringiensis* (Bt) is a Gram-positive soil-dwelling bacterium known to have insecticidal properties, used as a biological pesticide. Bt genes are now used in the genetic engineering of plants so that the crop itself will produce pesticides, eliminating the need for pesticide spraying. According to the USDA, the number of fields that used genetically engineered organisms exceeded 17,000 by September 2013 [18]. Without getting into the politics of GM foods, as an immunologist I firmly believe that any changes in DNA molecules also cause changes in RNA and protein structures, and it is for this exact reason that the changes in protein structures of food proteins may cause failure of the tolerance mechanism to the new antigenic materials, resulting in food immune reaction, allergies and autoimmunities (see Fig. 48.3).

Food immune reaction, Allergies and Autoimmunities

Fig. 48.3 How change in DNA can lead to food immune reactivities and autoimmunities

Although combining genetically modified plants with pesticide-associated GM foods allows the protection of desirable crops from pests and weeds by making them insect-resistant or by reducing the desire for nutrients [19], there is a huge concern about the direct threat of genes and residues derived from herbicide-resistant GM crops such as glyphosate and its metabolites. Glyphosate [N-(phosphonomethyl) glycine] is a nonselective herbicide used for the control of a variety of weeds on non-crop land as well as in a great variety of crops. An enzyme named 5- enolpyruvylshikimate-3-phosphate synthase required for the synthesis of many plant metabolites, including some amino acids, is the major target of glyphosate action. Glyphosate binds to this plant enzyme, interferes with its metabolism, and eventually causes cell death. Glufosinate [ammonium DL-homoalanin-4-yl(methyl)phosphinate] is known to be a broad spectrum contact herbicide that is also used to dry out or desiccate crops before harvest. Glufosinate inhibits the activity of the enzyme glutamine synthetase, which is necessary for the production of amino acid glutamine or Q, therefore leading to a decrease in the level of glutamine and cell death [20, 21]. Truncated Cry1Ab gene encoding Cry1Ab toxin is an insecticide produced by the previously mentioned soil bacterium and biological pesticide *Bacillus thuringiensis*, which has been genetically transferred into the maize genome in order to make it more insect-resistant, especially against Lepidoptera infestation [22]. Upon the application of Cry1Ab, it is solubilized by the gut proteases of insect larvae, and then it binds to specific receptors on the brush border of epithelial cells, leading to disruption of the epithelial barrier and larval death [23, 24]. The mechanisms of these chemicals or toxins – especially the binding of glyphosates and glufosinate to plant enzymes, neo-antigen formation, and their interference with amino acid synthesis or the binding of Cry1Ab toxins to the brush border proteins of epithelial cells – raise the following serious questions for immunologists:

- Is there a relationship between the use of these xenobiotics in our food, changes in the human microbiome, and many gut-associated disorders in children and in adults?
- Is there any correlation between the rise of CD, NCGS, Crohn's disease, ulcerative colitis, small intestinal bacterial overgrowth (SIBO), IBS, and the increased use

of genetically modified foods and their associated toxins?
- What is the relationship between GMO-associated xenobiotics in humans and the epidemic of metabolic syndrome and obesity that affects up to 30% of the world population?
- How about the autoimmune epidemic that currently affects 10% of the world population?
- And finally, is there any relationship between the use and consumption of GMO-associated xenobiotics by humans, cardiovascular disease, neurodegenerative disorders, and cancer?

Only these types of questions can pave the way for more research and hopefully the eventual removal of all xenobiotics from our environment, particularly from our foods, since the basis of better health is prevention. There is an urgent need to find an economical and effective way to grow crops and produce food without glyphosate, glufosinate, Cry1Ab-toxin, and other xenobiotics. In search of answers to these valid questions, I came across a very fascinating review article by Anthony Samsel and Stephanie Seneff published in the *Journal of Biological Physics and Chemistry 2016* [24]. In this article I found the answer to the above questions by learning about the mechanism by which these chemicals can replace amino acids such as glycine and glutamine and form new proteins, both in plants and in human tissue. The study showed that many enzymes in plants and in the human body are targets of structural modification. Therefore, this xenobiotic-induced modification of enzymatic structure is the additional mechanism by which our immune system attacks food or tissue proteins that it normally would tolerate or ignore. This may explain the rise of food immune reactions and autoimmunities in epidemic proportions in the industrialized world [24]. In support of this concept, a summary of this 36-page article is provided here:

» Epidemiological studies have revealed a strong correlation between the increasing incidence in the United States of a large number of chronic diseases and the increased use of glyphosate herbicide on corn, soy, and wheat crops. Glyphosate, acting as a glycine analogue, may be mistakenly incorporated into peptides during protein synthesis. A deep search of the research literature has revealed a number of protein classes that depend on conserved glycine residues for proper function. Glycine, the smallest amino acid, has unique properties that support flexibility and the ability to anchor to the plasma membrane or the cytoskeleton. Glyphosate substitution for conserved glycines can easily explain a link with diabetes, obesity, asthma, chronic obstructive pulmonary disease (COPD), pulmonary edema, adrenal insufficiency, hypothyroidism, Alzheimer's disease, amyotrophic lateral sclerosis (ALS), Parkinson's disease, prion diseases, lupus, mitochondrial disease, non-Hodgkin's lymphoma, neural tube defects, infertility, hypertension, glaucoma, osteoporosis, fatty liver disease and kidney failure. The correlation data together with the direct biological evidence make a compelling case for glyphosate action as a glycine analogue to account for much of glyphosate's toxicity. Glufosinate, an analogue of glutamate, likely exhibits an analogous toxicity mechanism [24].

48.6 Food Hybridization and Change in Amino Acid Sequences of Proteins

Due to the extensive hybridization of wheat and a possible change in the amino acid sequences of wheat proteins, we use wheat as the classical example of protein modification and oral tolerance breakdown, leading to an increase in the prevalence of an autoimmune disease in the gut called celiac disease (CD).

The wheat that is universally consumed today is far different genetically from the simple grain man used to eat. Like most modern food plants, it has been modified to increase productivity, yield, nutrient content, and longevity. With all this genetic tampering, it is little wonder that the immune systems of some individuals are sometimes unable to recognize wheat as a harmless and supposedly beneficial food staple. Gluten proteins from wheat can induce CD in genetically susceptible individuals. Specific gluten peptides can be presented by antigen-presenting cells to gluten-sensitive T-cell lymphocytes, leading to CD. A significant increase in the prevalence of CD has been observed during the last few decades. This may be partly attributed to an increase in awareness and to improved diagnostic techniques, but increased wheat and gluten consumption is also considered a major cause. One should also consider the possibility that the genetic modifications made to today's wheat may have made it intolerable to some segment of the population.

To analyze whether wheat breeding contributed to the increase of the prevalence of CD, Van den Broeck et al. [25] have compared the genetic diversity of gluten proteins for the presence of two CD epitopes (Glia-9 and Glia-20) in 36 modern European wheat varieties and in 50 landraces representing the wheat varieties grown up to around a century ago. Looking back over the last five decades, several trends are apparent in wheat consumption: an increase in CD- related T-cell stimulatory epitopes in wheat, an increase in the use of gluten in food processing, and an increase in the consumption of processed foods. Given the relation between the incidence of CD and exposure to cereals, it cannot be ruled out that an increased content of T-cell stimulatory epitopes has also contributed to the increased prevalence. Considering the epitope impact of CD patients of the major immunodominant Glia-α9 epitope, it is concluded from these data that in general the toxicity of modern wheat varieties has increased. It stands to reason that reduction of T-cell stimulatory epitopes in wheat may directly contribute to increasing the quality of life of many individuals. Further the application of advanced breeding technologies, including resynthesizing of hexaploids and specific gene silencing, will additionally be

helpful [25]. This increase in the toxicity of modern wheat varieties and its impact on alpha-gliadin epitope may be one reason for oral tolerance failure to these new peptides and the increased prevalence of food immune reaction and autoimmunity, such as celiac disease and other associated autoimmunities. Wheat hybridization and its effect on the amino acid sequences of alpha-gliadin is only an example of changes in the protein structure. These changes may apply to other hybridized products whose AA sequences may have changed for better or worse.

48.7 Industrial Food Additives

The role of environmental triggers in the development of autoimmune disease (AD) is becoming clearer year after year [26, 27]. Epidemiological data provide strong evidence of a steady rise in AD throughout Westernized societies over the last three decades. Multiple sclerosis, type 1 diabetes, inflammatory bowel diseases (mainly Crohn's disease), systemic lupus erythematosus, primary biliary cirrhosis, myasthenia gravis, autoimmune thyroiditis, hepatitis, rheumatic diseases, bullous pemphigoid, and celiac disease are several examples [28–33].

For example, in the USA, type 1 diabetes increased 3–4% per annum, and undiagnosed CD mortality increased by fourfold [34, 35]. When autoimmune diseases were grouped as a major disease class, the highest net increase percentage per year was noted in the neurological autoimmunities (14%), with gastrointestinal autoimmunities at 6%, endocrinological autoimmunities at 5%, and rheumatological autoimmunities at 3.5%. This rise in the incidence of AD was associated with the percentage increase per year of industrial food additive usage as described in an elegant review article [36]. In that review it was hypothesized that commonly used industrial food additives abrogate human epithelial barrier function, thus increasing intestinal permeability through the open tight junction, resulting in the entry of foreign immunogenic antigens and activation of the autoimmune cascade [36]. The following paragraphs will deal with eight nutritional ingredients being increasingly added during industrial food processing that find their way to market shelves. These food additives have the capacity to affect the gut microbiome, inducing leaky gut, changing the integrity of the immune system, and impacting overall human health.

48.7.1 Salt

Salt is considered a silent killer. Excessive consumption is associated with hypertension, strokes, left ventricular hypertrophy, renal diseases, obesity, renal stones, and stomach cancer. Overconsumption of salt is very real, crossing multiple populations and demographics, ages, gender, and countries. Unfortunately, sodium intake around the world is five- to tenfold in excess of physiological need, and its indirect use is dominated by the sodium added to manufactured foods. Cereals and baked goods are the single largest contributors to dietary sodium intake in UK and US adults. In Japan and China, the largest source remains salt added at home and in soy sauce. The salt content in processed foods can be more than 100 times higher than that in similar homemade meals [37]. However, while everyone feels that they already know about the harmful effects of salt and are apparently willing to risk their health for added flavor, they might think twice if they actually knew about the impact that excessive consumption of salt has on their immune system. Excess intake of salt can affect the innate immune system, in particular macrophage function, and affects the differentiation of naïve $CD4^+$ T cells. Under normal conditions, the naïve T cells have a significant plasticity that, depending on the presence of different cytokines, enables them to differentiate into the various types of T helper cells. High concentrations of salt – in addition to change in osmolarity, the influence of IL-23 receptor signaling, and the activation of various enzymes – drive the expression of Th17-associated cytokines and the formation of the pathogenic Th17 phenotype. This immune pathway plays a pivotal role in autoimmune disease [26]. Such increased salt concentrations were shown to drive neuropathy in a mouse model of multiple sclerosis by the induction of pathogenic Th17 cells [38] (see Fig. 48.4).

48.7.2 Sugars

The increase in the availability of sweeteners, especially sugar, during the past four decades has contributed significantly to the epidemic of obesity not only in the USA and central Europe but also in countries that used to adhere to the Mediterranean diet [39].

Glucose is a known absorption enhancer. A major portion of intestinal glucose absorption occurs through tight junctions (TJ), not by saturable transcellular active transport. This requires increased junctional permeability, a very high intraluminal glucose concentration, and a sufficient osmotic gradient to promote volume flow [40]. Glucose increases permeability and produces changes in the distribution of the main protein of the TJ in the human cell line Caco-2, indicating intercellular leakage. This effect of sucrose on increased intestinal permeability to macromolecules has been shown in patients with Crohn's disease and with a higher intake of sugars and refined carbohydrates [41]. Therefore, we should not be surprised that the overconsumption of sugar is partially responsible for changes in the microbiome, inflammation, and autoimmunities.

48.7.3 Emulsifiers or Surfactants

Emulsifiers, also known as surfactants, are a group of substances that stabilize an emulsion; they do this by concentrating at the interface between oil and water and reducing the surface of interfacial tension. Emulsifiers are considered to be the fastest-growing segment of the food additive industry.

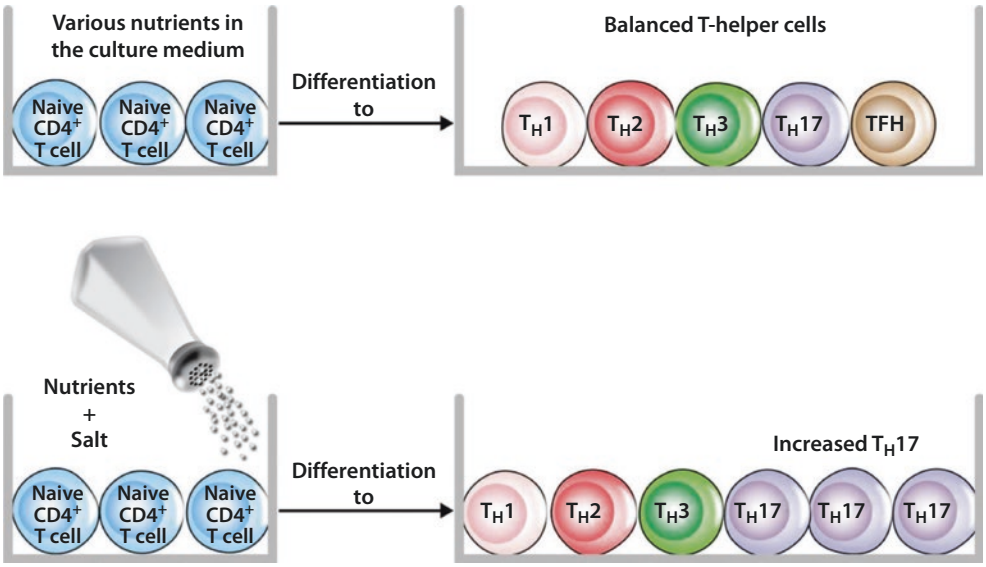

Fig. 48.4 High concentrations of salt affect the differentiation of naïve T cells toward pathogenic Th17 cells

They are widely used in butter, margarine, ice cream, liquors, meat, gums, coffee, beverages, dairy, confectionery, baked goods, fat, oil, sauces, chocolate, and many other products. The emulsifier market is largely driven by diglycerides and derivatives, lecithin, and stearoyl lactylates. Other emulsifiers include polyglycerol esters, polyglycerol polyricinoleate, polysorbate, and sucrose esters [42, 43]. Numerous synthetic surfactant food additives have been shown to increase intestinal permeability through paracellular and/or transcellular mechanisms; some of these additives were also shown to inhibit P-glycoprotein, which is known as a membranous transport protein. For example, sucrose monoester fatty acids, which are major and potent surfactants used in the food industry, including in infant formula, induce actin disbandment and structural separation of TJ or enhanced permeability to large macromolecules. Surface-active compounds, like oleic and docosahexaenoic acids, compromise the integrity of the intestinal epithelium and enhance the paracellular absorption of unwanted molecules. Moreover, self-microemulsifying systems used to improve drug delivery via a microemulsion achieved by chemical rather than mechanical means were found to open the TJ and change the distribution of ZO-1 and actin and therefore play a significant role in the induction of autoimmunities. In Japan, a major player in the food industry's utilization of emulsifiers, a positive correlation was shown between the annual sales of emulsifiers for food and beverage production and an increased incidence of Crohn's disease [44, 45].

48.7.4 Organic Solvents

Organic solvents are a group of liquid chemicals that are capable of dissolving other substances. Gluten, for instance, is not water-soluble, but the addition of alcohol makes it completely soluble. Many proteins can likewise be dissolved in hexane, acetone, toluene, turpentine, benzene, or dimethyl sulfoxide. Organic solvents are considered toxic chemicals and are dangerous to human health and as such are labeled as poisons. They are used for solubilization, extraction of active ingredients, or removal of unwanted substances. For example, for the extraction of 60 million tons of soy oil and other edible oils, hexane extraction technology is used. This extensive use of solvents in the food industry was reported by one study as a serious risk factor for autoimmune diseases including multiple sclerosis, systemic sclerosis, vasculitis, and liver autoimmunity [46]. The author concluded that individuals with non-modifiable risk factors for autoimmune disease should avoid any exposure to organic solvents in order to prevent the risk of developing autoimmune disease.

48.7.5 Nanoparticles

Nanoparticles are very small molecules, those with dimensions between 1 and 100 nm. Due to their tiny size, such materials usually acquire unusual chemical and biological properties and functions; they are prepared by nanoprecipitation of poly(lactic-co-glycolic acid) as carrier material and surface-modified by methoxy poly(ethylene glycol) and chitosan. While nanomolecules offer solutions to technological problems that cannot be achieved by conventional systems, the future impact of these nanofood particles on human health is not yet clear. Many reports confirm that nanoparticulate systems with unique properties can increase the transport of poorly water-soluble compounds across the GI barrier by enhancing paracellular transport via opening of the TJ and enhancing permeability. For example, thiolated chitosan is used for enhancing gut permeability and mucoadhesivity and increasing the intestinal absorption of active agents. Permeation studies have shown that nanoparticles open the tight junction through ZO1 redistribution, F-actin reorganiza-

tion, claudin-4 downregulation, and enhancement of the paracellular permeation of macromolecules [47–49].

Because of this, there are health concerns associated with increasing the oral bioavailability of bioactive components that exhibit deleterious effects when consumed at excessive levels. If one of these bioactive components normally has a very low bioavailability, its absorption by the human body can be increased substantially by encapsulating it within lipid nanoparticles; it could subsequently have unexpected toxic effects. Nanotechnology usage in the food sector has been hindered by concerns about the safety of the engineered nanoparticles, as well as ethical, policy, and regulatory issues [50]. Their safe use in food requires knowledge of their absorption, distribution, metabolism, excretion, and toxicological profiles. Even though the FDA is currently monitoring developments in this relatively new field with undeniably exciting possibilities, the truth is that the safety of extensive use of nanomaterials is still largely unknown.

48.7.6 Microbial Transglutaminase (Meat Glue, Food Glue)

Transglutaminases form a group of enzymes belonging to the class of transferases. Transglutaminases catalyze the formation of an isopeptide bond between two different proteins by cross-linking glutamine to lysine. In the human body, transglutaminase-2 is involved in celiac disease, transglutaminase-3 in dermatitis herpetiformis, and transglutaminase-6 in gluten ataxia [51].

Transglutaminase is also biosynthesized by microbes such as *Streptoverticillium* SP. This transglutaminase is named microbial transglutaminase (mTG), more commonly called "meat glue." mTG has become a very useful tool for modifying the functionality of many food proteins in food products [52]. The extensive use of mTG in the food industry, whether to glue two different pieces of meat or other food components together, became possible due to transgenic procedures and mass production using microbes [53, 54]. Currently this enzyme is applied to a variety of food products and occupies a significant segment of the food industry. Its purposes include improvement of the texture, appearance, hardness, and preservability of meat; increased hardness of fish products; improved quality and texture of milk and dairy products; decreased calories and improved texture and elasticity of sweet foods; and protein film stability and appearance and improved texture and volume in the bakery industry. The amount of mTG used for each kilogram of food is about 50–100 mg; this means that on the average every one of us is exposed to about 15 mg of mTG each day [36]. In patients with intestinal permeability to large molecules, this daily exposure to mTG is enough to be detected by the immune system and to result in the production of IgA, IgG, or IgM antibodies against it. These antibodies may cross-react with human transglutaminases that play a role in CD, NCGS, dermatitis herpetiformis, and gluten ataxia. Furthermore, the mTG antibodies may contribute to false-positive results in CD and NCGS. Indeed, in our laboratory we performed tests for IgG and IgA transglutaminase antibodies on many blood specimens; we detected antibodies against tTGs, but not against any components of wheat proteins. Therefore, this autoimmune reactivity against human tTGs could be due to extensive consumption of mTG by individuals with leaky gut syndrome. In this regard some observations about the role of mtG in increased intestinal permeability are presented:

- mTG may change the balance of the microbiome, and the subsequent release of toxins could increase intestinal permeability to macromolecules, including mTG.
- By mediating nonspecific linking of sulfur containing amino acids, cysteine, and methionine, mTG contributes to enhanced TJ permeability.
- The cross-linking of different proteins by the use of meat glue or food glue acts as a major modifier of the physicochemical structure, antigenicity, and other characteristics of food proteins, which may make them more resistant to digestive enzymes.
- mTG has the ability to catalyze lipidation of proteins, thus providing them with emulsifying activity [42]. Moreover, mTG induces cross-linking of various dietary proteins originating from casein, pork myofibrils, peanut, and fish, which has been shown to improve their emulsifying capacity.
- mTG is also used as biological glue, in cross-linking nanoparticles, and in delivery systems. The potential of the nanoparticles as the enhancers of intestinal permeability was discussed in an earlier section.
- Multiple mTG-linked proteins, in bread and other food products, have the capacity to break the oral tolerance mechanisms, resulting in possible CD, NCGS, and other food immune reactivities [55–59].
- mTG is used in a vast array of food products, from steaks to sushi to faux crab, to hold pieces of food together to achieve a more appealing appearance. In the case of steaks, miscellaneous pieces of meat are mixed together with meat glue and placed on fat, then vacuum-packed together, and left overnight. A cross-section cut from the resulting mass the next morning looks convincingly like a ribeye steak.

48.7.7 Food Colorants

The way food looks has a lot to do with how much we want to eat it. It should surprise no one, then, that food manufacturers and purveyors go to a great deal of trouble to make the food we buy from them look appetizing. Foods with bright colors and fresh-looking appearances appeal to our senses, but in most cases these are achieved with artificial food colorants. Food dyes are made from petroleum – hardly an appetizing idea. Synthetic food colorants are cheaper, more easily available, and last longer than natural colors, and they can achieve hues not possible naturally. But as the use of artificial food coloring has increased through the years, so has the reported incidence of many allergic and other immune-

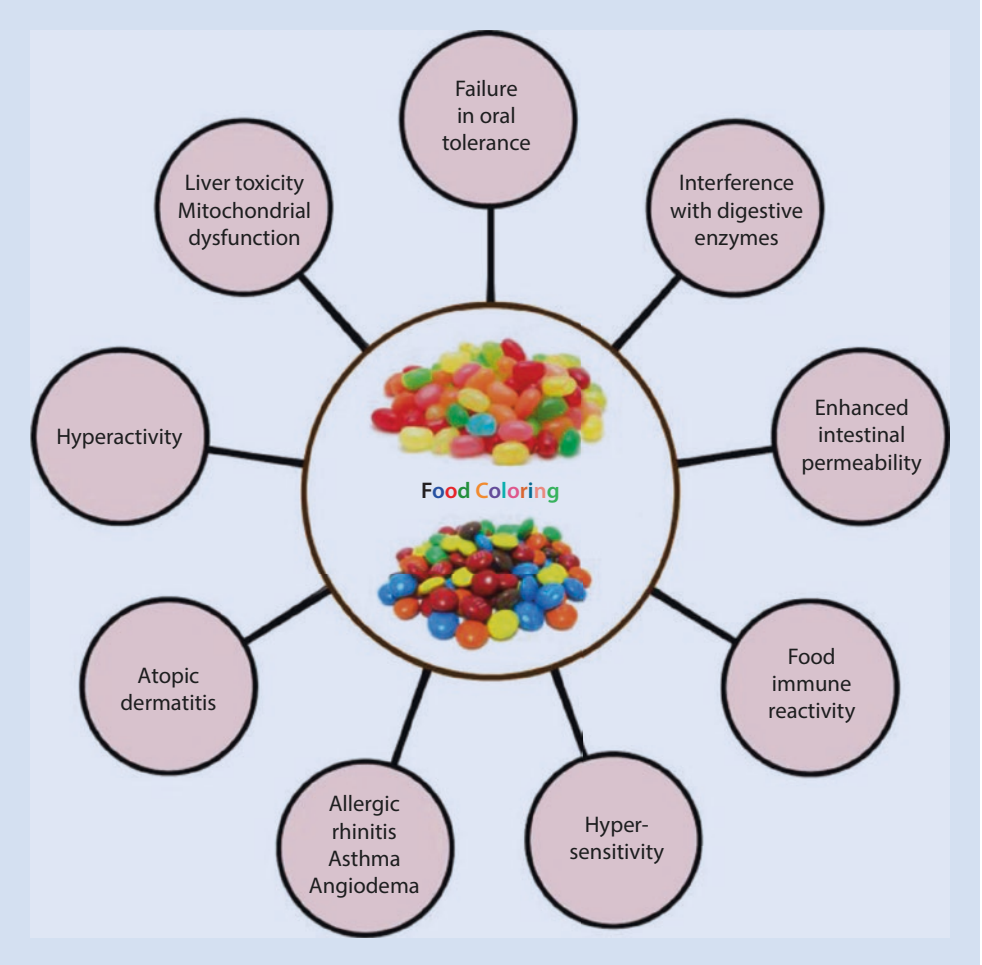

Fig. 48.5 Food colorants may make foods like Snow White's poison apple: beautifully delicious to look at but deathly toxic on the inside. Above are disorders that have been linked to food colorants

reactive disorders. In the past 50 years, the amount of artificial food colorants in food has increased by 500%. Alarmingly, there has also been an accompanying increase in child behavioral problems such as ADHD, ADD, and aggression. The molecules of food dyes are small and are difficult for the immune system to defend against. They can also bind to food or body proteins, and thus disguised are able to slip past the barriers and disrupt the immune system in various ways. They can activate the inflammatory cascade; they can induce intestinal permeability to large antigenic molecules; and they can lead to cross-reactivities, autoimmunities, and even neurobehavioral disorders (see Fig. 48.5). This is not as shocking as the legal amounts of artificial colorants actually allowed by the FDA in the foods, drugs, and cosmetics that we consume and use every day [60]. Even though the Color Additive Amendments of 1960 required that only color additives listed as suitable and safe could be used in foods and had no Generally Recognized as Safe (GRAS) or grandfather provision, in effect all color additives at the time were actually provisionally approved in order to avoid a ban of all colorants, which were then largely untested [61]. The consuming public unfortunately is still largely unaware of how widespread the use of food colorants is or the fact that their consumption carries the possibility of developing one of these devastating diseases:

- Failure in oral tolerance
- Interference with digestive enzymes
- Enhanced intestinal permeability
- Live toxicity
- Mitochondrial dysfunction
- Food immune reactivity
- Hypersensitivity
- Atopic dermatitis
- Allergic rhinitis, asthma, angioedema
- Neurobehavioral disorders
- Interference with neurotransmission
- Reproductive abnormalities

48.7.8 Gums

You shouldn't think of gums as just something kids chew or that unpleasant gunk that won't come off your shoe. Gums make up perhaps the most widely used and traded category

of non-wood plants that are not consumed directly as foods, fodders, and medicines. In 1993 alone the world market for gums as food additives was about 10 billion US dollars. They have been used for thickening and stabilizing since ancient times and enjoy widespread use in everything from food to pharmaceuticals to printing and adhesives. There are different kinds of gums. Seed gums come from plant seeds and have versatile applications in paper, textiles, petroleum, drilling, food, pharmaceutics, cosmaceutics, explosives, and many more. Exudate gums come from plant sap and were used as far back as 5000 years ago as thickening and stabilizing agents. Marine gums come from seaweed and are used in a variety of foods such as "ready-mix" cakes and "instant" pie fillings. Microbial gums are sometimes referred to as "synthetic gums" since they are fermented from plants by bacteria and are the products of biosynthesis. Most gums are composed of complex and variable mixtures of oligosaccharides, polysaccharides, and glycoproteins with an extremely high-molecular-weight polysaccharide attached to a hydroxyproline-rich polypeptide backbone that accounts for about 2% of the molecular size. The result diagrammatically looks something like a bottlebrush (see Fig. 48.6). As opposed to food colorants, gum molecules are huge (200–2000 kDa), comprising from 4000 to 40,000 amino acids. Their molecular structure is similar to those of a number of common foods, so there is a possibility of cross-reactivity. Gums are generally recognized as safe by the FDA, but they do have a troublesome history of association with sensitive or allergic reactions [62]. To investigate the possible immunogenic effects of these supposedly safe gums on the general population, our own lab conducted a study using the sera of 288 nominally healthy individuals aged 18–65 years obtained from a commercial source [62]. The sera was screened for IgG and IgE antibodies against extracts of mastic gum, carrageenan, xanthan gum, guar gum, gum tragacanth, locust bean gum, and β-glucan, using indirect enzyme-linked immunosorbent assay (ELISA) testing. Of the 288 samples, 4.2–27% of the specimens showed a significant elevation in IgG antibodies against various gums. For the IgE antibody, 15.6–29.1% of the specimens showed an elevation against the various gums. A significant percentage of the specimens, 12.8%, simultaneously produced IgE antibodies against all seven tested extracts (see Table 48.1). The results showed that there may be apparently healthy individuals who may actually suffer from hidden food immune reactivities and sensitivities to gums. These findings indicate not only that is there a significant percentage of the healthy population exposed to various gum products but also that these individuals immunologically react against them and produce IgE-mediated and non-IgE-mediated immune reactivity.

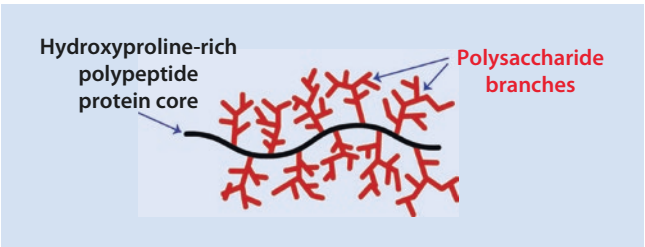

Fig. 48.6 The bottlebrush structure of gums. Most gums are composed of complex and variable mixtures of oligosaccharides, polysaccharides, and glycoproteins with an extremely high molecular weight polysaccharide attached to a hydroxyproline-rich polypeptide backbone that accounts for about 2% of the molecular size

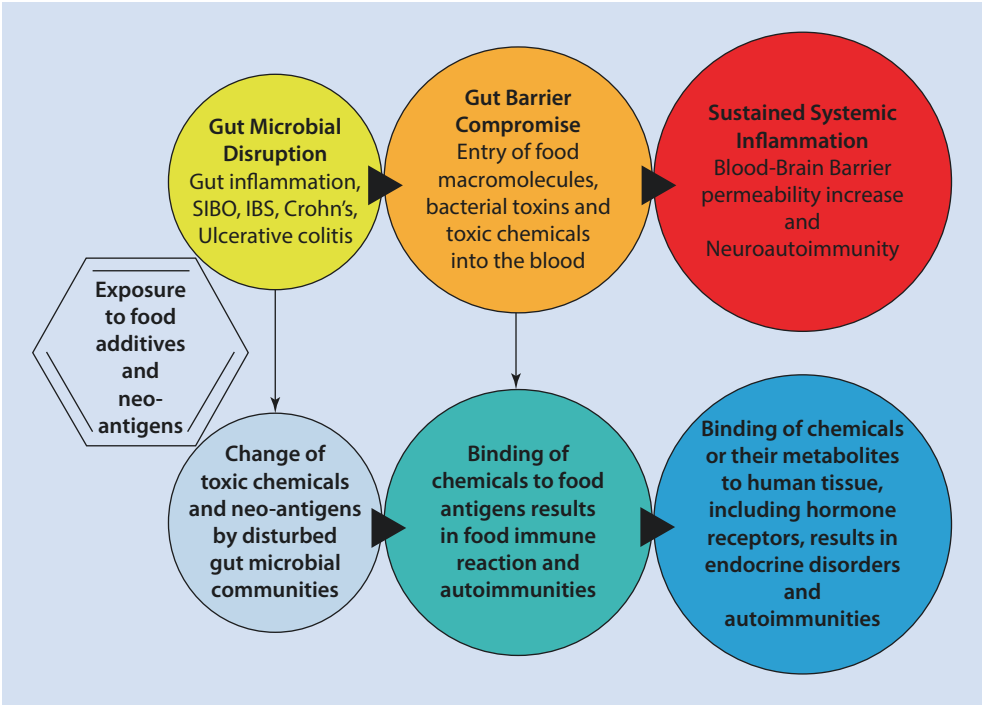
48.7.9 Mechanisms of Food Additive-Induced Inflammation and Autoimmunities

The use of food colorants, gums, meat glue, food glue, organic solvents, glucose, salt, emulsifiers, and nanoparticles is extensively increasing from year to year. This widespread rise in the use of food additives may be for the improvement of food quality, as the manufacturers claim, but there is one thing to consider. All these food additives not only increase intestinal permeability and the transfer of macromolecules into the circulation but also contribute to neo-antigen formation, oral tolerance failure, and chemical and food immune reactivities. In fact, tight junction dysfunction, zonulin release, and the production of occludin/zonulin antibodies and other tight junction proteins have been described in autoimmune diseases [36, 63–66].

It is hypothesized that commonly used industrial food additives cause failure in the oral tolerance mechanism and abrogate human intestinal barrier function. This results in the entry of foreign immunogenic antigens, including neo-antigens, into the circulation, resulting in the production of antibodies against them and activation of the autoimmune cascade (see Fig. 48.7). While we are enhancing our knowledge about the mechanism responsible for the contribution of food additives to intestinal permeability and autoimmunities, exposure to food additives should be a part of the medical history taken from individuals with possible

Table 48.1 % Elevation in IgG and IgE antibodies against various gum antigens in 288 healthy subjects at 2 SD above the mean

Antibody	Mastic gum	Carrageenan	Xanthan gum	Guar gum	Gum tragacanth	Locust bean gum	β-Glucan
IgG	42/288 (14.6)	78/288 (27)	30/288 (10.4)	12/288 (4.2)	15/288 (5.2)	33/288 (11.5)	18/288 (6.2)
IgE	84/288 (29.1)	57/288 (19.8)	48/288 (16.6)	51/288 (17.7)	48/288 (16.6)	45/288 (15.6)	66/288 (22.9)



Gut Microbial Disruption
Gut inflammation, SIBO, IBS, Crohn's, Ulcerative colitis
Gut Barrier Compromise
Entry of food macromolecules, bacterial toxins and toxic chemicals into the blood
Sustained Systemic Inflammation
Blood-Brain Barrier permeability increase and Neuroautoimmunity
Exposure to food additives and neo-antigens
Change of toxic chemicals and neo-antigens by disturbed gut microbial communities
Binding of chemicals to food antigens results in food immune reaction and autoimmunities
Binding of chemicals or their metabolites to human tissue, including hormone receptors, results in endocrine disorders and autoimmunities

Fig. 48.7 Mechanism of food additive-induced gut inflammation, barrier disruption, food immune reaction, endocrine disorders, and autoimmunities

autoimmunities. This can facilitate the implementation of a program to decrease exposure to food additives and other chemicals in order to improve a patient's chance to recover from devastating and life-altering autoimmune diseases.

48.8 Mimicry or Cross-Reactivity: The Mechanism Responsible for Immune Reactivity and Autoimmunities

48.8.1 Cross-Reactivity Between Wheat and Human Tissue

As an immunologist, although I was familiar with and studied molecular mimicry or cross-reactivity between pathogens and human tissue [67], I have to admit that at one time I was not very knowledgeable about the cross-reactivity of food proteins with human tissue antigens. However, in 2002, I became familiar with an article in which investigators used commercially available IgA antigliadin antibody to show reactivity with human cerebellar and rat CNS tissue by indirect immunohistochemistry [68, 69]. They demonstrated that IgA antigliadin antibody reacted strongly with both rat and human cerebellar tissue. Furthermore, sera from 12 of 13 patients with gluten ataxia were able to strongly stain Purkinje cells. With this indirect evidence, it was suggested that patients with gluten ataxia have antibodies against Purkinje calls, and humoral immune responses are involved in the pathogenesis of gluten ataxia [69]. However, this cross-reaction between cerebellar tissue, Purkinje cells, and gliadin was done by using impure commercially available whole rabbit serum made against the gliadin molecule and not against its immunodominant peptides. My colleagues and I conducted our own study using affinity-purified antibodies made against the gliadin peptide and demonstrated its reactivity against the recombinant brain protein of Purkinje cells [70]. We showed that the molecular target for these antibodies was an epitope consisting of six amino acids (VPLLED) expressed predominantly in neuroectodermal tissue, as well as in α-gliadin peptide. We concluded that molecular mimicry between gliadin and cerebellar peptide may be a mechanism by which dietary peptides induce autoimmunity. Furthermore, we used highly specific monoclonal antibody made against α-gliadin peptide and reacted it against 180 food and 24 human tissue antigens [71].

We demonstrated a significant cross-reactivity between α-gliadin 33-mer and human tissues, including cytochrome p450, glutamic acid decarboxylase, collagen, ovary, thyroid peroxidase, asialoganglioside, myelin basic protein (MBP), cerebellar tissue, and synapsin [71] (see Fig. 48.8). With the degree of cross-reactivity that has been shown between gliadin and neuronal tissues, healthcare professionals can link gluten reactivity to autoimmune reactivities that target the nervous system.

A different study was able to establish that gliadin peptides carrying the QQQPFP epitope interact directly with actin or smooth muscle, which can alter the actin cytoskeleton and possibly contribute to autoimmune reactivity to actin [72]. Thus, untreated patients who continue to consume wheat will have circulating IgG and IgA antibodies to gliadin, which can cross-react with human tissue and lead to autoimmunity within and beyond the gut. Moving away from the

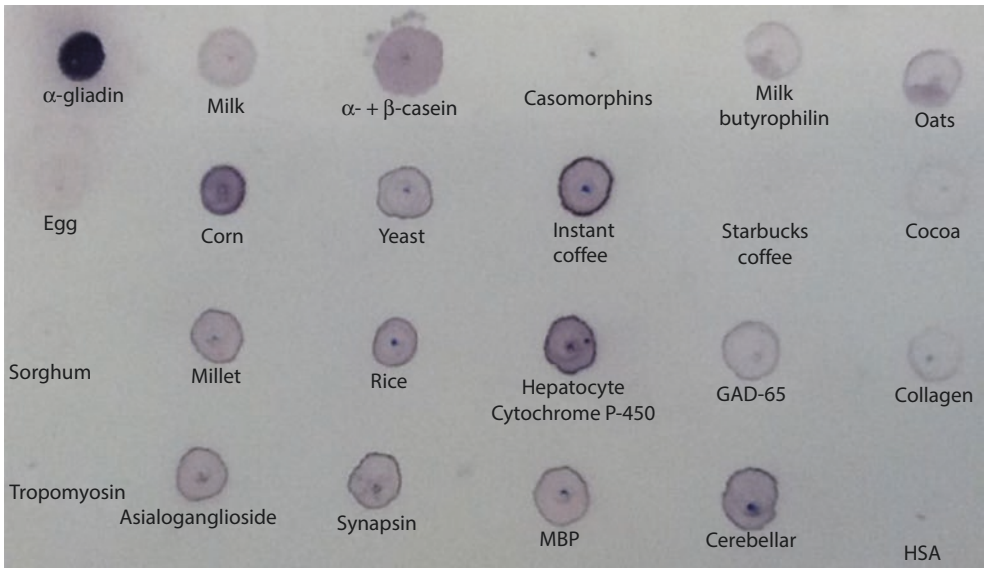


Fig. 48.8 Reaction of polyclonal anti-α-gliadin 33-mer to gliadin and various tissue and food antigens by dot blot

gluten family of proteins found in wheat, it is important to discuss yet another wheat trigger of autoimmunity, wheat germ agglutinin (WGA). According to Freed [73], WGA has the capacity to bind to multiple tissues in the body, from the stomach and colonic mucosa to myelin. WGA has an affinity for human tissues. It binds to the tissue, sometimes generating a neo-antigen. The immune system identifies the WGA bound to tissue, where it does not belong, and begins the process of eliminating the WGA. In the attempt to destroy the WGA, tissue is also broken away and enters the bloodstream. Tissue proteins in the circulation ignite production of antibodies against the tissue. Soon, autoantibodies begin attacking the tissue to which the WGA was bound. Untreated patients who continue to consume wheat will have circulating WGA, which can bind to human tissue and lead to autoimmunity within and beyond the gut.

48.8.2 Cross-Reactivity of Dairy with Human Tissue

Currently, public attention seems to have shifted focus from the old "star" of problematic foods, dairy, to the new media darling, gluten. However, dairy still tops the list of antigenic foods, especially for children. In studies previously reviewed by the senior author of this chapter, researchers found that early consumption of cow's milk may present a risk for the development of certain autoimmune diseases, such as Behcet's disease, CD, Crohn's disease, lupus, uveitis, and type 1 diabetes (see Fig. 48.9). They also concluded that exposure to cow's milk can activate immune responses that lead to autoimmunity.

In the case of diabetes, the protein β-casein peptide in cow's milk has been shown to have antigenic similarity to islet cell autoantigen [74] (see Fig. 48.10); thus, cow's milk may trigger diabetes in some individuals and different autoimmunities in others. Milk has far-reaching effects. It has been shown that increased milk consumption correlates with a higher incidence of multiple sclerosis (MS). Furthermore, in a comparison of MS mortality rates to food consumption, a high correlation between milk consumption and MS mortality has been found [75–79].

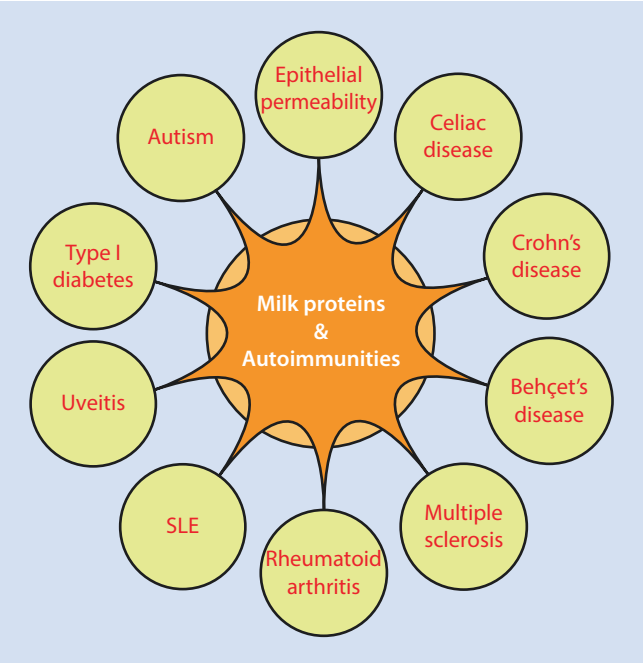

Fig. 48.9 Milk-related autoimmunities. Milk proteins have been linked to a variety of disorders that affect different tissues and organs. SLE = systemic lupus erythematosus

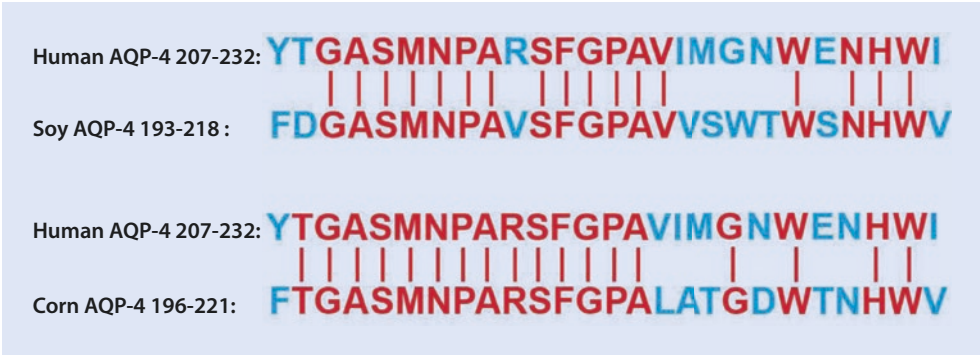
The connection between milk and MS appears to be due to molecular mimicry or cross-reactivity. The basic protein antibody to human myelin showed a calcium-mediated interaction between the recombinant protein and caseins in milk

Fig. 48.10 Amino acid sequence similarity between casein and islet cells. A structural similarity exists between β-casein protein in cow's milk and islet cell antigen. That fact supports the link between milk reactivity and diabetes



Human AQP-4 207-232: YTGASMNPARSFGPAVIMGNWENHWI
Soy AQP-4 193-218 : FDGASMNPAVSFGPAVVSWTWSNHWV
Human AQP-4 207-232: YTGASMNPARSFGPAVIMGNWENHWI
Corn AQP-4 196-221: FTGASMNPARSFGPALATGDWTNHWV

Fig. 48.11 Human AQP4 shares homology with plant aquaporin. Human aquaporin-4 (AQP4), found in astrocytic food processes within the brain and nervous system, has very significant similarities in amino acid sequence to four food aquaporins: soybean, corn, spinach, and tomato. Antibodies produced against these food aquaporins may result in autoimmune attacks on human AQP4, leading to neuroautoimmunity. Only the similarities with soy and corn are shown above

from transgenic (genetically modified) cows [80]; and milk butyrophilin, a milk-fat protein, has a structural similarity to myelin oligodendrocyte glycoprotein (MOG) [81, 82]. Guggenmos et al. [83] found that one-third of patients with MS had immune reactivity to both MOG and milk butyrophilin. For this reason we screened 400 so-called healthy subjects for the presence of antibodies against different wheat and milk components and neural antigens and found that approximately half of the sera with antibody elevation against gliadin reacted significantly with GAD-65 and cerebellar peptides. About half of the sera with elevated antibodies against α + β-casein and milk butyrophilin also showed antibody elevation against MBP and MOG. MBP and MOG are very commonly detected in the blood of patients with MS. Our inhibition studies showed that only two out of four of the samples with elevated cerebellar or MOG antibodies could be inhibited by gliadin or α + β-casein, confirming individual variation in epitope recognition.

From this study we concluded that in about 20% of the so-called healthy subjects, the oral tolerance mechanism was dysfunctional; about half of these individuals (about 10%) produced antibodies against MBP and MOG. Detection of high levels of antibodies against neural antigens may put these individuals at risk of developing neuroimmune disorders [84]. In addition to neural tissue antigens, casein from milk has been shown to be an essential co-factor in the induction of antibodies against C-terminal SmD1 peptide in systemic lupus erythematosus [85]. Based on these results, it is the recommendation of the senior author that food antibodies should be measured by a reliable methodology and that when they are detected in the blood, items such as gluten and dairy should be removed from the diet of individuals in the early stages of autoimmunity, as they could otherwise exacerbate or progress the autoimmune disorder. Reliable food panels can be obtained from only a few specialty labs offering this type of testing.

48.8.3 Cross-Reactivity of Aquaporin with Human Tissue

Neuromyelitis optica (NMO) is a neurologic disease greatly similar to MS and is characterized by simultaneous inflammation of the optic nerve and the spinal cord. Aquaporin-4 (AQP4) has been implicated as a triggering factor in the development of NMO. This water channel protein is expressed in the astrocytic foot processes that line the nervous system's side of the blood-brain barrier (BBB). AQP4 is also contained in some plants, including corn, soy, spinach, tomato, and even tobacco. Indeed, food-sourced AQP4 has amino acid sequences similar to human AQP4 (see Fig. 48.11), enough to cause significant cross-reactivity [86–89]. Highly stable in digestion, food aquaporins can survive as intact proteins. In cases of increased intestinal permeability, these intact aquaporins can infiltrate the body and become antigenic, and the immune reaction against them could

ignite antibody production. If those cross-reactive antibodies penetrate the BBB, they could attack aquaporin in the brain astrocytes, resulting in NMO [89]. In addition to aquaporin antibody elevation in NMO, we reported a significant elevation in IgG, IgM, and IgA antibodies against human AQPS in patients with relapsing-remitting MS (RRMS) [90]. Because of this mechanism of cross-reactivity between soy, corn, spinach, tomato, and human AQP4, it is suggested that patients with neuroimmune disorders eliminate these food items from their diet if antibodies against these foods are detected in their blood.

Because these cross-reactive antibodies cross the barrier in susceptible individuals, the immune response could result in NMO and/or MS. Indeed, when the sera of NMO patients were applied to both AQP4 and various plant peptides, a significant reactivity was observed against both human and plant AQP4 [90]. These results further delineate the role of the environment in NMO etiology. These naturally expressed proteins should be exploited in therapeutic interventions, such as the sublingual low-dose introduction of dietary antigens [91] and the development of guidelines for dietary modifications in NMO and other neuroimmune disorders. Figure 48.12 shows the association between various dietary proteins, peptides, and environmental AQP4 and the development of NMO and other neuroautoimmune disorders including MS.

48.8.4 Cross-Reactivity of Pectin with Human Tissue

Researchers have demonstrated that carbohydrate antigen-specific autoantibodies may play a role in rheumatoid arthritis. Using pectin, they found arthritogenic potential for α1, 4-polygalacturonic acid (PGA) moiety in many pectin-containing foods such as apples, quince, oranges, grapefruits, and berries. The researchers concluded that "the PGA cross-reactive moiety represents a major autoantigen in the joints and can be targeted by autoantibodies capable of triggering arthritogenic responses in vivo" [92]. A variety of food proteins can trigger autoimmunity. Whether by causing molecular mimicry or cross-reactivity, or by binding to tissues, the end result is autoimmune reactivity to human tissues. Clearly, dietary protocols based on targeted tissues can be implemented as a strategy to reduce tissue autoimmune reactivity and even to prevent the onset of disease when a patient has a known genetic susceptibility for autoimmunity.

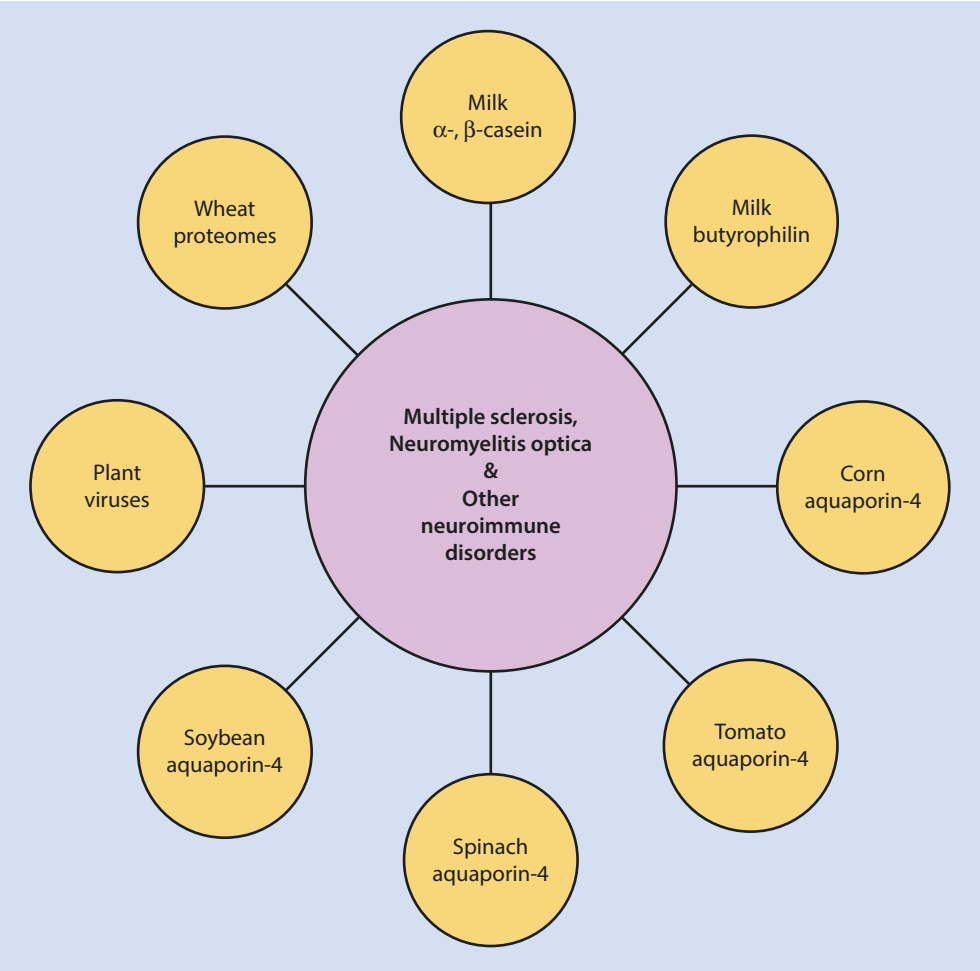


Fig. 48.12 Contribution of various dietary proteins/peptides/environmental AQP4 in the development of neuroautoimmune disorders

48.8.5 Cross-Reactivity of Food Antigens with Diabetes and Thyroid Antigens

In search of additional cross-reactivity between human tissue target antigens such as diabetes and thyroid, we purchased a series of monoclonal and affinity-purified polyclonal antibodies and reacted them with 204 different food antigens [93, 94].

For diabetes we measured the reactivity of antibodies to insulin, insulin receptor alpha (IR-A), insulin receptor beta, zinc transporter 8 (ZnT8), tyrosine phosphatase or islet antigen 2 (IA2), and glutamic acid decarboxylase (GAD) 65 and 67 against 204 dietary proteins that are commonly consumed. These included unmodified (raw) and modified (cooked and roasted) foods, herbs, spices, food gums, brewed beverages, and additives. We identified strong to moderate immunological reactivity with antibodies against insulin receptor alpha (IR-A), ZnT8, IA2, GAD-65, and GAD-67 with several dietary proteins. For IR-A the strongest reactions were with milk butyrophilin (5+), potato (3+), amaranth (3+), quinoa (2+), and potato (1+); for GAD-65 the most reactive were buckwheat (3+), amaranth (3+), rice (3+), corn (3+), yeast (3+), potato (2+), quinoa (2+), and oats (2+) (Table 48.2).

With IA2 antibody, the strongest reactions were with seaweed (5+), guar gum (5+), pea lectin (3+), cooked white and brown rice (3+), and fish (2+).

With ZnT8 antibody, the strongest reactions were with seaweed (5+), cooked lentil (5+), pea protein (5+), guar gum (4+), wheat (4+), cooked pea (4+), oleosin (3+), roasted peanut (3+), and fish (3+).

The results of our study identified immune reactivity between antibodies to insulin, insulin receptors, islet cell antigens, and food antigens. Potential tissue antibody binding with various food antigens or food antibody binding to specific pancreatic sites can lead to the possibility that some dietary proteins may play an antigenic role with autoimmune diabetes.

Even though many of the individual proteins in these groups may be considered safe or of low glycemic index, the consumption of these foods by a sensitive or predisposed individual may trigger immune reactions or autoimmunities.

Regarding the thyroid antigens, we identified immune reactivity between dietary proteins and target sites on the thyroid axis that included thyroid hormones, thyroid receptors, enzymes, transport proteins, thyroid-stimulating hormone (TSH) receptor, 5′deiodinase, thyroid peroxidase, thyroglobulin, thyroxine-binding globulin, thyroxine, and triiodothyronine against the same 204 purified dietary proteins commonly consumed in cooked and raw forms. Specific antigen-antibody immune reactivity was identified with several purified food proteins with triiodothyronine, thyroxine, thyroglobulin, and 5′deiodinase.

We selected sixteen foods to see if the same immune reactivity with a specific food – for instance, latex hevein, elicited by a monoclonal antibody made against T3 – would occur with a different monoclonal antibody. The data clearly shows that each monoclonal antibody presents different patterns of immune reactivity to the food antigens (see Table 48.3). In fact, TBG had no reactions to any food at all.

Table 48.2 Example of 17 selected foods and their degree of reactivity with antibo`dies made against diabetes target antigens

	Anti-insulin receptor-α	Anti-GAD-65	Anti-islet antigen 2	Anti-ZnT8
Buckwheat	+	+++	–	–
Potato	+++	++	–	–

Guar gum	–	–	+++++	++++
Wheat	–	–	–	++++
Pea lectin	–	–	+++	+
Pea protein	–	–	–	+++++
Lentil	–	–	–	+++++
Peanut	–	–	–	+++
Fish	–	–	++	+++

Our laboratory study found dietary proteins that share amino acid sequence homology with thyroid tissue antigen and have the potential to play a role in immune reactivity with thyroid target sites. The result was a significant list of many food proteins that demonstrated immune reactivity with thyroid antigens. This potential antigen-antibody against specific thyroid axis sites reacting with food antigens can lead to the possibility that some dietary proteins may play an antigenic role in autoimmune thyroid disease.

The results of our research provide a list of susceptible dietary proteins that may immunologically impact thyroid interactions and warrant further study. They also provide a first step in narrowing down a list of specific dietary proteins that, due to protein cross-reactivity, may potentially have an impact on autoimmune thyroid disease and diabetes [93, 94].

Table 48.3 Example of 16 selected foods and their degrees of reactivity with monoclonal antibodies against Tg, T3, T4, and TPO

	Tg	T_3	T_4	TPO		Tg	T_3	T_4	TPO
Latex hevein	+++	+++	–	–	Cashew, vicilin	–	+	+++	–

Cashew, roasted	–	++	+++	–	Pineapple bromeliad	–	–	–	++

The list of reactive and cross-reactive foods presented in this section is just the tip of an iceberg that should be explored further so as to shed light on an entire world of autoimmunities hidden below.

48.9 Conclusions: A Word to the Practitioners

The food and drink that we consume daily are constantly being affected and transformed by the food and beverage industries with ever-new advancements in food processing technology. Some of the reasons may be desirable, such as improving taste, nutritional value, or shelf life. Others are external or cosmetic sleight of hand aimed at our pockets or designed to persuade us to choose one brand over others. Whatever the purpose, the result of all this food tampering and manipulation is neo-linked neo-antigens, transformed molecules, and delivery systems, representing an intestinal mucosal load with altered physiochemical and immunogenic properties that challenge both mucosal and central immunity. The many layers of the immune system are masterpieces of signaling networks, molecules, and mediators. Beneath the mucosal layer lies the intestinal barrier. A breach in the intestinal barrier brings out the agents of the innate immune system and the patrolling immune cells of central tolerance. The authors have written that fact into each section of this chapter and, because it is so important to understand the concept, will repeat it one more time: When a failure in one of the layers occurs, it can cause a cascade of inflammation, opening protective barriers and exposing the body and the brain to environmental antigens that trigger autoimmune reactivity, tissue degradation, and disease. Normally the brain and the body's immune system work together in harmony, guiding each other, supporting each other, giving and taking in a healthy symbiotic relationship. In Fig. 48.13, Lymphia (representing lymphocytes) loves

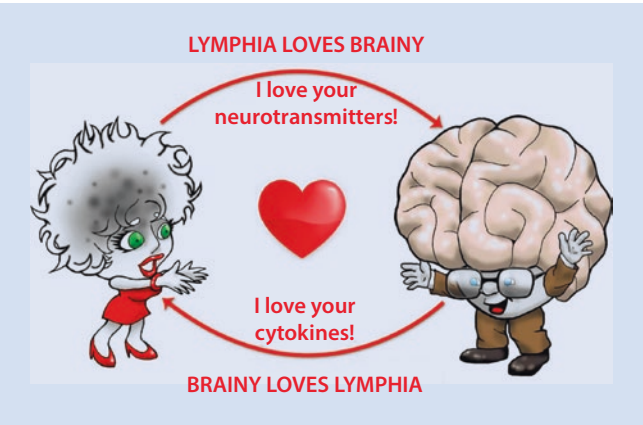

Fig. 48.13 Lymphia loves Brainy and vice versa. Yes, but will their mutually beneficial relationship be able to survive the assault and interference of the dreaded environmental triggers?

Brainy, and Brainy says, "Right back at you." However, when all these environmental triggers, all these infections and reactive foods and toxic chemicals, come down on poor Lymphia's and Brainy's heads like a sea of troubles, as Shakespeare said, how can this poor couple manage to fight the tide of this onslaught and still maintain a healthy, working relationship?

This is what can happen when the assault of environmental triggers comes in a massive horde that overwhelms the guardians of our immune system. Thus, intestinal and blood barrier permeability is increased through damage done to the tight junctions, resulting in the entry of foreign immunogenic antigens such as food, infections, and toxic chemicals into the circulation, where antibody production against the invaders activates the autoimmune cascade (see Fig. 48.14). Because autoantibody development predates clinical autoimmune diagnosis by several years [75], the measurement of antibodies against food antigens, toxic chemicals, infections, tight junction and BBB proteins, and various tissue antigens

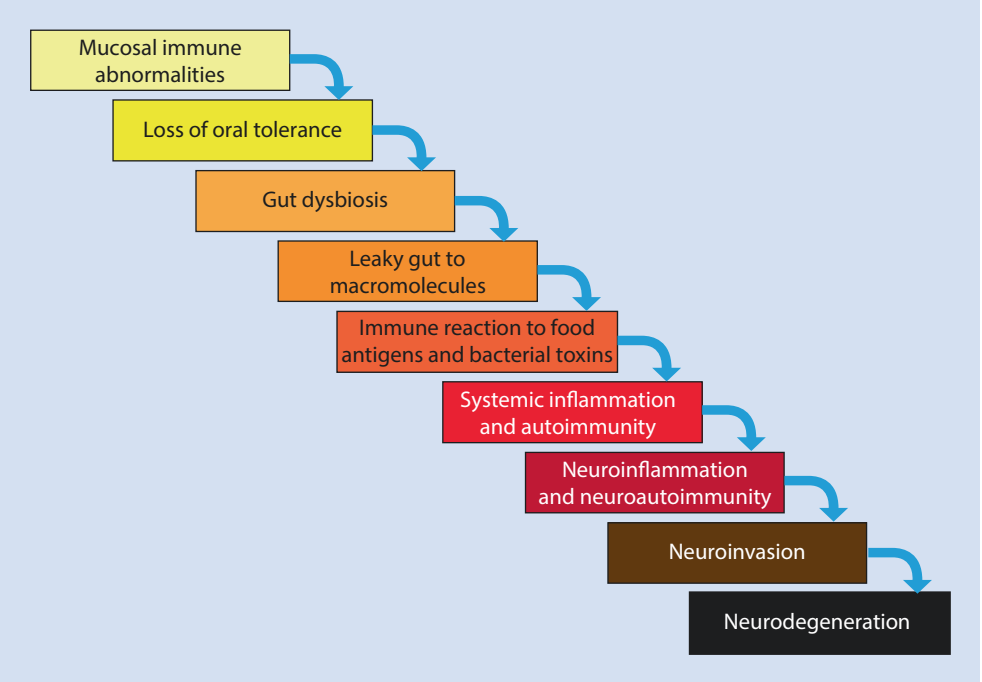

Fig. 48.14 Dysfunction from the gut to brain. The figure shows the downward, step-by-step process that takes an individual from loss of mucosal immune function to neurodegeneration. When the process is left unaddressed throughout the pathogenesis, the result is loss of neurological function

can help practitioners to modify or remove the triggers. The senior author of this chapter was one of the first functional immunologists to develop such tests. Panels are available for intestinal permeability, gluten reactivity, cross-reactivity and sensitivity, and chemical immune reactivity; tests for diabetes, neurological, joint, and other tissue autoantibodies; and multiple food immune reactivity panels. Tests such as these enable clinicians to help patients avoid years of suffering by detecting these predictive antibodies while there is still time. Simply by detecting first, removing the triggers, and then healing the intestinal barrier and optimizing the mucosal and innate immune system, we can reverse many disorders. If mucosal or intestinal barrier dysfunction is detected and addressed early, the onset of disease can be prevented.

49.1 Introduction

A diagnosis of ALS follows the descriptors of most diseases: cause(s), diagnostic criteria, symptoms, progression, management, treatments, and prognosis. The dilemma with ALS is that we don't know the cause(s), we have no effective treatments, but we do know the prognosis. Every ALS patient receiving a diagnosis hears the same script that the disease is usually fatal within 2–5 years, and there are no drugs or diets to avert the progressive deterioration. Less than 1% of patients with ALS will have significant improvement in function after 1 year, only 10% of patients will live past 10 years and 5% past 20 years. As stated on their website, "ALS is 100% fatal" [1], and the diagnosis of ALS is frequently described as a "death sentence" [2].

Nutrition counseling for persons with ALS (pALS) lags far behind other common neurodegenerative diseases such as Parkinson's disease, Alzheimer's disease, and Multiple Sclerosis, all conditions with a much better prognosis and life expectancy. One can easily surmise why most healthcare practitioners haven't had a role in working with pALS. They are dissuaded and intimidated by the futility of treatment and fatality of the diagnosis. Primary care physicians consign management of pALS to *neurologists who distances pALS* from other healthcare practitioners. The Ice Bucket Challenge in the summer of 2014 brought ALS out of relative obscurity and into the national spotlight [3], infusing funds into scientific research and empowering pALS to network across the globe for support. An increasing number of pALS and their caregivers explore the Internet, use social media, and seek a range of resources, healthcare professionals, and healers beyond the purview of the neurologist.

A holistic approach to ALS recognizes the multifactorial, metabolic, genetic, epigenetic, inflammatory, immune, environmental, excitotoxic, gastrointestinal, mitochondrial, substrate altered, nutritionally challenged, emotional, and spiritual crisis confronting the care of the patient. ALS presents the Integrative and Functional Medical Nutrition Therapy (IFMNT) practitioner the responsibility of leveraging metabolic pathways through diet and nutritional supplements to hopefully delay progression, improve symptoms, or even reverse disease.

49.2 pALS Advance Nutrition Research

Some pALS engage in their own ($n = 1$) case-controlled studies by researching and designing their own protocols, sharing experiences with other pALS, and hiring selected practitioners to support them. pALS and their loved ones are the stimulus driving nutritional practices and research for ALS. They refuse the death sentence and, out of necessity, become their own students, researchers, patients, and physicians. This phenomenon is seen in pALS like Dr. Craig Oster [4], Eric Edney [5], ALS Winners [6], pioneering advocates [7], blogs [8], and *The Deanna Protocol: Hope for ALS and Other Neurological Conditions* [9].

There are patients who have accomplished brief reversals [10] and others who have healed significantly [11]. The study of ALS reversals by neurologist Dr. Richard Bedlack at Duke University has included demographics, disease characteristics, treatments, and comorbidities to try to understand the mechanisms of disease resistance [12]. It is not false hope. It is hope that pALS draw from selected preclinical and clinical scientific research that they interpret and translate into their own self-styled treatment. Consider that 17 years is the typical lag time for translational research [13], and pALS know that only 5–10% of them might still be alive at that point. pALS are not weighing "alternative" treatments over conventional medical treatments. There is nothing to dispute, as there are no available medical treatments to halt or reverse ALS.

As IFMNT practitioners, we must serve as "carrier molecules" for a higher standard of dietary/nutritional care for pALS into our own practices and ultimately into the conventional healthcare system. We must advance education, mentorship, and training among our colleagues. IFMNT practitioners uphold these principles of practice: First, do no harm. Second, apply best available practice-based and evidence-based research to inform clinical decision-making. Third, respect the values and desires of every pALS. Fourth, practice with hope.

49.3 Hope, Nutrition, and ALS

What about the willingness to adopt a strict nutrient-dense diet? An online survey was conducted to study whether ALS patients would follow such a diet if it were to increase longevity. The survey found that dietary self-care choices appear to be related to hope issues [4]. Dr. Oster's work was referenced again in a study on illness trajectories in pALS as determined by illness perception, trust in medical care, self-construction, and the distribution of dependency [14].

Dr. Craig Oster, the lead author of the nutrient-dense diet survey, was diagnosed with ALS in 1994, yet he persevered to obtain his PhD in Psychology from the University of Michigan in 1996. By late 2008, he entered hospice care as he had lost over 45 pounds of muscle, refused a feeding tube, and needed a mechanical ventilator to get through the night [15]. In tremendous agony and deep prayer, he was released from hospice in 2009 and then came "back to the future" to continue his healing journey [16]. He regained weight, muscle, and stamina and reversed some of his ALS symptoms, as of 2017. He never used commercial oral formulas, tube feedings, or any medications for ALS. He follows an individualized diet plan with nutritional supplements, massage, spiritual practice, psychotherapy, yoga, advanced technologies for exercise and movement like pacer gait trainers, neurofeedback, and LED light therapy, among other therapeutic modalities [17].

pALS and their loved ones are the driving force behind research in nutritional interventions. They become their own students, researchers, patients, and physicians. Out of their discoveries, they are able to advise the research community about promising therapies.

49.4 What Is Amyotrophic Lateral Sclerosis (ALS)?

ALS, also named motor neuron disease or Lou Gehrig's disease, is a progressive and fatal neurodegenerative disease. ALS usually strikes between the ages of 40–70, with an average age of 55 years at diagnosis. Males comprise 60% of ALS cases and Caucasians make up 93% of the people in those cases. Today, more than 6000 Americans are diagnosed each year, and about 20,000 Americans have ALS at any given time. ALS afflicts an estimated 350,000 people around the world [18]. According to the World Health Organization, the World Bank, and Harvard School of Public Health, neurodegenerative diseases will become the 8th leading cause of death by mid-century [19], with a projected 69% global increase in ALS cases from 2015 to 2040 [20].

ALS was first identified in 1869 by French neurologist Jean-Martin Charcot. The official recognition of the disease began in 1939 when Lou Gehrig, one of the most famous baseball players of all time, was diagnosed with ALS at 36 years of age and died 2 years later. Readers of Mitch Albom's New York Times bestseller in 2000, "Tuesdays with Morrie," might recall that ALS drained his old professor's life in 1 year over the 14 visits the author made to his home [21]. Famous theoretical physicist Stephen Hawking lived with ALS for more than 50 years before his death in 2018 [22]. ALS is notoriously conspicuous in professional sports and the military, presumably from traumatic brain injuries (TBI) in athletes and both TBI and toxic exposures in the military [23].

ALS is a disease of motor neurons, the neurologic cells that initiate and control the movement of muscles. Motor neurons that originate in the brain are characterized as upper, and those originating in the spinal cord are characterized as lower. ALS affects both upper and lower motor neurons, although each person with ALS has varying amounts of upper and lower motor neuron involvement. Bulbar ALS, also called progressive bulbar palsy, prominently affects the muscles involved in speech, swallowing, and tongue movements. Upper motor neuron disease causes stiffness or spasticity. Lower motor neuron disease causes weakness, loss of muscle (atrophy), and muscle twitching (fasciculations). ALS may begin with abnormalities of upper or lower motor neurons.

As motor neurons gradually die, the brain is unable to initiate and control voluntary muscle movement. ALS does not affect the heart muscle or the smooth muscle of the digestive tract, bladder, and other internal organs. An exception is a secondary complication that involves the gradual weakening of the muscles of the lungs, leading to atelectasis or collapse [24]. A patient's cognition, sexual function, and eyesight, along with the senses of smell, taste, hearing, sight, and touch, remain intact.

Most ALS cases are sporadic (SALS), but 5–10% of the cases are familial (FALS) [1, 25]. However, the boundary between familial and sporadic ALS is somewhat blurred since up to 95% of "apparently" sporadic ALS cases have involvement of the same ALS-associated genes (SOD1, TARDP, FUS, C9orf72) as seen in familial ALS [26].

Copper-zinc superoxide dismutase (Cu-Zn SOD1) reduces superoxide (O2-) to yield hydrogen peroxide and oxygen (H2O2 and O2). H2O2 is less reactive than O2- but still highly reactive. O2 reacts with nitric oxide to yield peroxynitrites. In the case of SOD1 ALS, the mutation allows it to bind with copper but not with zinc, which causes the conversion of H2O2 back to O2- in a reversed enzymatic step. This gain-of-function mutation results in misfolded proteins that aggregate and become toxic [27]. Only 2% of all ALS patients have the SOD1 ALS mutation, while 20% of the familial cases have been found to carry this mutation [27–28]. Rotunno and colleagues [28] support the controversial hypothesis that misfolded forms of wild-type SOD1 contribute to sporadic ALS pathogenesis, whereas others have reported the opposite to be true [29]. Saccon and colleagues [30] bring together historical and experimental findings to suggest that SOD1 gain and loss of function could complement each other in both FALS and SALS. Cu-ZnSOD1 is differentiated from manganese superoxide dismutase (MnSOD2), which has no genetic association with ALS [31]. It is interesting to note that higher concentrations of Mn exists in spinal cords of ALS patients and is known to inhibit neuronal transmission [32].

There are five medical classifications of ALS as seen in Fig. 49.1 [1, 25, 33].

Riluzole, the only approved drug since 1995, may extend life by 3–5 months [34], and Radicava, just approved in 2017, may slow progression of ALS by 33% [35]. Riluzole decreases glutamate excitotoxicity and Radicava reduces oxidative stress, but outcomes are limited. Although the scientific research on ALS describes multisystem metabolic pathways, pharmaceutical research only approaches a pathway at a time. Important neurodegenerative pathways such as detoxification, inflammation, immunity, oxidative stress, nutritional deficiencies, gut-brain, mitochondrial, energy homeostasis, and others lack successful therapeutic applications. The majority of research has been done on the human mutant transgenic SOD-1 G93A mouse model developed in 1994 [36]; however, the metabolic and nutritional underpinnings of FALS and SALS share many common multifactorial pathways.

ALS can no longer be viewed as a single disease entity guided by reductionist single target pathways for medications. ALS involves biological heterogeneity and is a multisystem disorder [37]. It is also a complex clinical syndrome with a rapidly evolving understanding of biomarkers and potential therapeutic treatments [38]. Approaching an ALS patient from an individualized and multisystem metabolic framework aptly places ALS in the IFMNT model of therapeutic assessment and interventions.

49.5 Altered Metabolism and Hypermetabolism

Hypermetabolism in ALS patients is an early and persistent phenomenon with studies confirming approximately 50% of pALS are hypermetabolic and 80% of them remain hypermetabolic over time [39]. Hypermetabolism is largely a result

- **Classical ALS** - a progressive neurological disease characterized by a deterioration of upper and lower motor neurons (nerve cells). This type of ALS affects more than two-thirds of those with the disease.
- **Primary Lateral Sclerosis (PLS)** - a progressive neurological disease in which the upper motor neurons (nerve cells) deteriorate. If the lower motor neurons are not affected within two years, the disease usually remains a pure upper motor neuron disease. This is the rarest form of ALS.
- **Progressive Bulbar Palsy (PBP)** - a condition that starts with difficulties in speaking, chewing and swallowing due to lower motor neuron (nerve cell) deterioration. This disorder affects about 25% of those with ALS.
- **Progressive Muscular Atrophy (PMA)** - a progressive neurological disease in which the lower motor neurons (nerve cells) deteriorate. If the upper motor neurons are unaffected within two years, the disease usually remains a pure lower motor neuron disease.
- **Familial** - a progressive neurological disease that affects more than one member of the same family. This type of ALS accounts for a very small number of people with ALS in the United States (between five and ten percent).

Fig. 49.1 How is ALS classified? (Based on data from Johns Hopkins Medicine [33])

of mitochondrial dysfunction being fueled by oxidative stress in motor neurons and skeletal muscle with broader systemic effects [39]. pALS have altered expression of metabolic proteins and adipokines [40], which profoundly affect appetite and satiety. A decrease in ghrelin (appetite) with no change in leptin (satiety) levels causes reduced food intake due to low appetite along with increased satiety. Impaired insulin action is thought to contribute to reduced glucose tolerance and reduced ability to use glucose as energy [41]. Increased inflammatory cytokines (IL-6, IL-8) may contribute to insulin resistance, and increased TNF-alpha induces lipolysis, causing the breakdown of fat stores, weight loss, and lower BMI [41].

The brain has the highest energy requirements of all organs in the body, accounting for 2% of the total body mass and consuming 20% of the body's oxygen [41]. Within the brain, energy consumption is predominantly demanded by the neurons and less by the astrocytes. This results in a vicious cycle of bioenergetic deficits that exacerbate the pathogenesis of ALS as depicted in Fig. 49.2 [41]. The utilization of glucose by neurons and skeletal muscle is impaired in ALS, seemingly driven by insulin resistance and glucose intolerance. As a result, the increased reliance on fat as an energy substrate depletes endogenous energy storage, promotes weight loss, and perpetuates higher metabolic demands.

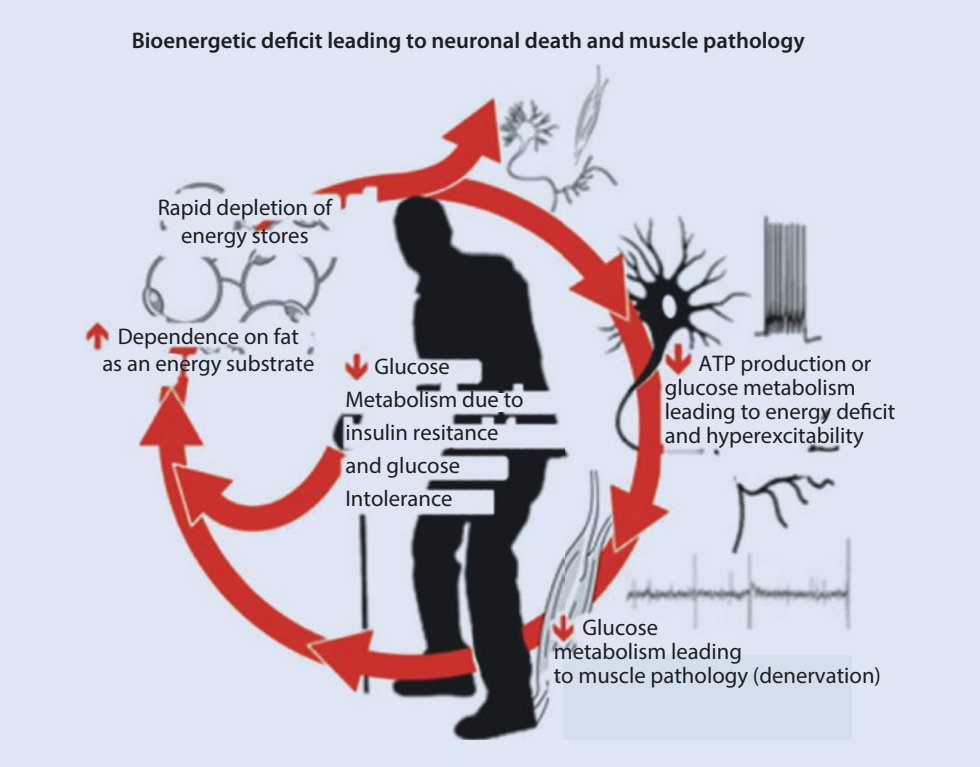
Decreased production of adenosine triphosphate (ATP) or decreased glucose metabolism in neurons and decreased glucose metabolism in the skeletal muscle may contribute to the hyperexcitability and selective degeneration of upper and lower motor neurons and muscle pathology/denervation in ALS, respectively [41]. Insulin resistance and glucose intolerance may underpin an inability to efficiently use glucose as an energy substrate. Overall, an inability to use glucose in the periphery, in neurons and in skeletal muscle, will result in an increased dependence on the use of fat as an energy substrate to offset energy deficit. With escalating metabolic pressure, the rapid depletion of endogenous energy stores will result in a catastrophic failure to meet increased metabolic demand. Thus, a vicious cycle of bioenergetic deficit may underpin or exacerbate disease pathogenesis in ALS [41].

49.6 Blood-Brain Barrier

The blood-brain barrier (BBB) is the main focus of nutritional research and potential therapeutic targets for ALS. The central nervous system is tightly sealed from the changeable milieu of blood by the BBB, the blood-cerebrospinal fluid barrier (BCSFB), and the blood-spinal cord barrier (BSCB) [42]. However, neurodegeneration creates vulnerability of the BBB, which disrupts the barrier function [43]. A short overview of the BBB is presented to better appreciate how macronutrients, micronutrients, and other nutritional interventions impact brain health, as the BBB will be frequently referred to throughout this chapter.

Picture the BBB as an organized structure of framing, trusses, insulation, ducts, locks, leaks, and weathering. Also, picture the BBB as an infrastructure of gatekeepers, guards, patrol officers, defenders, escorts, and conservators. Endogenously produced cholesterol and peripherally derived dietary fats comprise the main structure and function of the cell membrane, especially arachidonic acid (AA) and docosahexaenoic acid (DHA) [44]. Other fats that cross the BBB are oleic acid, palmitic acid, and alpha-linolenic acid [45]. It cannot be overstated how crucial lipids are to the health of cell membranes to provide structure, fluidity, transmission of electrical signals, movement of membrane proteins, stabilization of synapses, and protection [44].

The BBB provides protection from invading microbial pathogens, antigens, antibodies, inflammatory cytokines, and toxins and controls the microenvironment of the tissues by tightly regulating the movement of molecules and ions between the cellular spaces. The basic process of BBB break-



Bioenergetic deficit leading to neuronal death and muscle pathology
Rapid depletion of energy stores
Dependence on fat as an energy substrate
Glucose Metabolism due to insulin resitance and glucose Intolerance
ATP production or glucose metabolism leading to energy deficit and hyperexcitability
Glucose metabolism leading to muscle pathology (denervation)

down leading to neuronal dysfunction, neuronal inflammation, and neurodegeneration is depicted in Fig. 49.3 [43].

The brain barrier function has many similarities to the gut barrier function. Daneman and colleagues [46] describe how the gut immune barrier (GIB) protects the blood from entry of pathogens and toxins ingested in food and how the BBB protects the CNS from pathogens and toxins derived from blood. The GIB and BBB share several structural and functional features such as basement membranes, endothelial cells, tight junctions with their structural proteins, claudins, occludin, and junctional adhesion molecule [46]. Impaired permeability of gut and brain barriers share simi-

lar descriptive terminology in the medical and popular literature such as "leaky" and "leakage" or "leaky gut" and "leaky brain" [47].

The integrity of the gut and brain barriers is vulnerable to bacterial lipopolysaccharides, inflammatory cytokines, antigens, antibodies, and toxins causing permeability [48]. A molecule called microRNA-155 is responsible for cleaving epithelial cells to create microscopic gaps that allow toxins and other molecules access to the brain [49], hence the term leaky BBB. Further supportive evidence describes various mechanisms of BBB structural and molecular disruption occurring in CNS pathologies [50].

From an IFMNT perspective, the goal is to minimize allergens, toxins, microbes, and other inflammatory molecules from harming the BBB while optimizing nutrients that protect the BBB. The idiom "where the rubber meets the road" has many analogies to "where the brain meets the membrane." IFMNT is judiciously positioned to support this crucial interface at the BBB.

49.7 ALS Defined as Metaphor for Nourishment

As found on the ALSA website [51], the meaning of amyotrophic lateral sclerosis is derived from Greek roots: "A" means no, "myo" refers to muscle, and "trophic" means nourishment, so amyotrophic means "no muscle nourishment," referring to the loss of nerve cells that normally signal to muscle cells. This trophic definition of nourishment includes the provision of food and nutrients while encompassing sustenance and maintenance of function. When a muscle has no nourishment, it atrophies or wastes away and loses function. "Lateral" means "to the side" which refers to the location of damaged portions of these nerve cells. As the spinal cord degenerates, it leads to "sclerosis," which is scarring or hardening in the region. The word "diet" derives from the Greek word "diata," which means a way of life. The IFMNT practitioner recognizes that diet and nutritional management becomes a way of life for ALS patients who want to extend their life span and quality of life on the physical, emotional, and spiritual levels.

49.8 Current Limitations in Clinical Dietetics and Nutrition Care

As discussed above, it is not surprising that a dietitian, nutritionist, many physicians, and other healthcare providers may never experience directly caring for an ALS patient throughout their career. Patients with abnormal neurological symptoms are referred to and managed by neurologists; thus dietetic management typically focuses on high-calorie diets, chewing and swallowing issues, and tube feeding management under the auspices of the neurologist. Dietary goals are to support feeding and provide enough calories to prevent weight loss. Dietitians lack sufficient education and training in neurodegenerative diseases, and standardized protocols lack personalized application. Most dietitians are not trained in the therapeutic application of nutritional supplements. As reported in Today's Dietitian [52], "Dietitians play an important role in the care of ALS patients, yet there is little evidence on how we should be caring for these patients." This perspective is reiterated in the following statement: "Training and support in ALS/MND nutrition should be made available as part of post-dietetic registration."

Rio and colleagues [53] report further dietetic research is required to stimulate nutritional care. Fast-forward 10 years when data were analyzed from the data extraction tool (DET) provided by the Academy of Nutrition and Dietetics (AND). "This systematic review shows that there is a lack of high-quality evidence regarding the efficacy of any dietary interventions for promoting survival in ALS or slowing disease progression; therefore, more research is necessary related to effects of nutrition interventions" [54]. This conclusion leaves doctors, dietitians, other clinicians, families, and pALS feeling hopeless and under the mistaken impression that there is no specific nutrition information or intervention for pALS.

One review [55] offers the long-standing conventional recommendations for feeding support and adequate nutrition; however, another review has made an effort to improve the suggestions for high-calorie and easy-to-chew recipes [56]. Prior to these suggestions, the ALS Association (ALSA) website only offered "Maintaining Good Nutrition with ALS" [57] that included many detrimental foods made from processed and toxic ingredients (sugar, monosodium glutamate, preservatives, artificial flavors and dyes, GMO ingredients, etc.). There was no regard for the nutritional value of food beyond calories, texture, and convenience. This limited perspective on ALS and nutrition was established in 1998 by a physician expert on the American Academy of Neurology (Committee to Study and Develop Guidelines for the Role of Nutrition in ALS), who stated that "In ALS, it's not so much what you eat, but how much you eat" [58].

Advances in scientific research are showing that there are many metabolic targets for nutritional intervention in ALS. As practitioners, we must evaluate the practice-based and evidence-based research for insight into best practices and take a leadership role in providing individualized therapeutic plans for our patients. The validation of an individualized multisystem IFMNT approach to ALS is alluded to in this article [59], where the authors hypothesized that there may be subgroups of patients, eventually defined by a specific underlying etiology or clinical presentation, which selectively respond to a particular regimen, supporting the concept of a personalized nutritional approach.

Many of our patients and their loved ones scour the scientific literature on diet and nutrition and seek out integrative and functional practitioners. They are not willing to passively accept their death sentence diagnosis or be limited by antiquated dietetic recommendations. Drugs are not likely to effectively treat or cure this disease in the near future, as discussed in "ALS Clinical Trials Review: 20 Years of Failure. Are We Any Closer to Registering a New Treatment?" [60]. For pALS and their caregivers, while waiting for new drugs, the most hopeful and empowering therapeutic intervention is diet and nutrition.

Patients will experiment on themselves and design protocols, and some will successfully stall, reduce, or reverse symptoms of ALS. As IFMNT practitioners, we do not myopically fight ALS but holistically address metabolic imbalances throughout the body. We are obligated to support our patients on this healing journey by combining our hope with the best practice-based and evidence-based research and therapeutic plans in tandem with our patient's goals and value systems. The purpose of this chapter is to provide translation of scientific research into possible therapeutic applications for ALS.

49.9 Conventional Dietary and Nutritional Protocols

From the conventional perspective, ALS is deemed a fatal disease of progressive deterioration. The goal of food, oral formulas, or tube feeding is to maximize caloric intake to offset weight loss and malnutrition. There is scant research on nutritional status and ALS disease progression based on the macronutrient composition of calories and even less research on the micronutrient composition. The consumer and professional resources provided by the ALS Association (ALSA), Motor Neurone Disease Association (MNDA), American Academy of Neurology (AAN), and Academy of Nutrition and Dietetics (AND) are standardized and formulaic. They don't guide the practitioner to establish therapeutic goals much beyond feeding and swallowing assessments, estimating energy requirements, and anthropometrics. A 2009 Report of the Quality Standards Subcommittee of the AAN provides a nutrition management algorithm based on the assessment of choking, dysphagia, aspiration, weight loss, and dehydration to determine food consistency, oral liquid supplements, and alternative routes for delivering calories and nutrients [61]. This nutrition management algorithm is what the majority of ALS healthcare professionals still use to determine dietary and nutritional care of their patients.

49.10 Complementary and Alternative Medicine

A majority of pALS and/or their families search beyond the knowledge and practice-based limitations of conventional healthcare professionals and their corresponding professional organizations to find complementary and alternative (CAM) practitioners and resources to hopefully achieve symptom reduction and increased longevity. In an excellent review of CAM therapies, the prevalence of supplement users is even greater in the ALS community (75%) as compared to the American public (50%) [62]. Another study of 121 pALS [63] reports that 52% of those ALS patients who took supplements reported greater vitality, physical and social functioning, and an overall improved quality of life in the early and mid-stages of the disease.

The relationship between pALS and their conventional healthcare providers may deteriorate if CAM therapies are glibly dismissed as quackery, unscientific, useless, or, at worst, dangerous. Many patients have reported mockery and intimidation when discussing CAM therapies with their doctors or conventional dietitians, and these patients either seek new healthcare providers or simply decide to keep their CAM usage private. A relationship of trust and shared decision-making, along with the appreciation that patients often make independent choices for their health, will foster a supportive alliance between patient and healthcare provider. The patient might pursue a variety of CAM therapies and therapeutic technologies such as hyperbaric oxygen, neurofeedback, LED light therapy, sonic vibration therapy, infrared sauna, ultraviolet light therapy, and others. It is not expected that the primary care physician or dietetic-nutrition professional be knowledgeable in all CAM and technological therapies; however, a collaborative approach that honors the patient's desire to explore options will support a positive provider-patient relationship.

49.11 Integrative and Functional Medical Nutrition Therapy

Integrative and Functional Medical Nutrition Therapy (IFMNT) model of care emphasizes a more patient-centered approach and less of a diagnosis-centered approach in all aspects of assessment and treatment. The IFMNT practitioner searches to discover underlying causes and mechanisms that result in the signs and symptoms of a disease. Regarding ALS, the IFMNT practitioner evaluates the following factors as they contribute to neuroinflammation and neurodegeneration: chewing and swallowing, food allergies and intolerances, alterations in substrate utilization, genomics, inflammation, oxidative stress, immune function, hormonal balance, gastrointestinal function and microbiota, mitochondrial function, and detoxification.

The IFMNT approach supports optimizing function by addressing the previously mentioned contributing factors that drive progression of ALS. This must be further scrutinized based on the patients' pre-diagnostic history, looking at antecedents, triggers, and mediators. For example, an antecedent might be a family history of neurological disorders, a trigger could be a head injury or toxic exposure, and mediators could be common toxins, stress, dietary, and other factors. Each patient must be assessed based on evaluating biochemical individuality, physical function, and psychosocial variables in collaboration with the patient's goals and expectations. It is essential that the family and caregivers be on board with the patient's nutrition and health goals to uphold a patient-centered approach.

49.12 Weight as a Risk Factor

Malnutrition is an independent prognostic factor for survival in ALS with a 7.7-fold increase in risk of death and is estimated to develop in up to one-half of patients [59]. It is very

clear that weight loss and malnutrition are risk factors for disease progression. It was concluded that increased body fat prior to diagnosis is associated with a decreased risk of ALS mortality [64]. However, it is not known if maintaining weight (neutral balance) is more or less protective than gaining weight, regardless of start weight. A clinical trial [65] was commenced in 2008 to examine this question through the US National Institutes of Health titled "Quantitative Measurement for Nutritional Substrate Utilization in Patients with Amyotrophic Lateral Sclerosis (ALS)" but was terminated in 2015 due to lack of funding and support staff.

Factors that contribute to weight loss include impaired neuronal mechanisms, dysphagia, gastric discomfort and delayed emptying, fatigue and prolonged mealtimes, social isolation, upper extremity weakness, and impaired release of gut hormones that regulate appetite [66].

49.13 Calorie Requirements and Nutrition Assessment

The absence of specific methods for nutritional assessment of ALS patients shows the need to integrate clinical history, anthropometric measurement, dietary history, and laboratory tests for classification of nutritional status. Beyond this basic-level assessment, the IFMNT approach should consider how inflammation, hormonal status, oxidative stress, environmental factors, gastrointestinal function, food allergies, infections, and emotional health influence nutritional status.

There is a general agreement that energy expenditure is increased 10–20% in the majority of pALS, with estimated daily energy needs of 35 kcal/kg [67]. Coupled with these increased energy requirements is the finding that energy intakes are below recommended dietary allowances in at least 70% of ALS patients [68]. Several studies have found that standard equations used to calculate energy expenditure were not valid for pALS and indirect calorimetry has been suggested as an optimal measurement [69]. Yet indirect calorimetry is not practical in the outpatient or home setting. Another study [70] reported that clinicians should choose prediction equations that incorporate sex and age as predictor variables, such as the Harris Benedict and Mifflin-St Jeor equations that compare well with indirect calorimetry measurements. Multiple groups have reported an association between nutritional status determined by body mass index (BMI) and survival [41].

Loss of muscle is a more accurate prognostic factor in ALS than BMI [71]. Regression analysis demonstrated progressive decreases in body fat, lean body mass, muscle power, and nitrogen balance with an increase in resting energy expenditure as death approached [68]. The authors concluded that ALS patients require augmentation of energy intake rather than the consumption of high-protein nutritional supplements.

Bioelectrical impedance analysis (BIA) is a simple technique that is valid for use in ALS patients, both for single exam measurement and for longitudinal monitoring, with the use of an adapted equation and frequency of 50 KHz [72]. A more recent study [70] found that fat-free mass (FFM) by BIA was the strongest determinant of metabolic cart resting energy expenditure (mREE), along with sex and age variables. Another study [73] analyzed the relationship between phase angle (PA) obtained by BIA and found that patients with a PA <2.5 degrees had significantly poorer survival rates than patients with a PA >2.5 degrees. The study concluded that in ALS patients, PA is greatly decreased. It is related to the nutritional and cellular status of patients, and it is also an independent prognostic factor of survival.

While the nutritional status of pALS has been shown to be associated with mortality, fewer studies have evaluated the association of nutritional status and disease severity. The ALS Functional Rating Scale-Revised (ALSFRS-R) is a validated rating instrument for monitoring the progression of ALS in areas of speech, salivation, swallowing, handwriting, cutting food, dressing, hygiene, turning in bed, walking, climbing stairs, dyspnea, orthopnea, and respiratory insufficiency relative to years since onset of symptoms [74]. Park and colleagues [75] determined that nutritional status assessed by BMI and the geriatric nutritional risk index (GNRI) was negatively associated with disease severity using the ALSFRS-R and that intake of nutrients decreases with disease progression in ALS patients.

An ongoing challenge is determining the ideal balance between underfeeding and overfeeding. Underfeeding can cause diaphragm impairment, while overfeeding can increase the ventilatory load [69]. A review [76] of the therapeutic uses of the ketogenic diet (KD) reported benefits for patients with respiratory insufficiency, since the KD decreases carbon dioxide body stores and increases the efficiency of oxygen utilization. This is of particular importance in ALS patients with compromised respiratory function. Below there will be more discussion of the benefits of the KD.

49.14 Macronutrients: Carbohydrates, Protein, and Fats – What Do Dietary Studies Tell Us?

Caamaño [77] eloquently states, "nutrition is a non-genetic factor that has a transcendental influence on the prevention and treatment of neurodegenerative diseases." Yet, there is no consensus among researchers and clinicians on the best method of determining caloric requirements. A literature search reveals contradicting research on the optimal macronutrient composition of calories and scant attention on micronutrient and other nutritional requirements. Dietary studies on pALS are very difficult to obtain due to the logistics of reliable reporting and monitoring of food intake, so the majority of dietary studies rely on tube feedings for accurate measurements of quantity and composition of calories. In one recent study, investigators [78] compared three enteral diets (isocaloric, high-calorie/high-carbohydrate, and high-calorie/high-fat) and concluded that the high-calorie/high-carbohydrate diet (54% carbohydrate, 30% fat, 17% protein)

resulted in less weight loss and slowed progression of ALS. The authors reported that the higher-fat diet was poorly tolerated due to gastrointestinal side effects and surmised that the same concerns would exist for a ketogenic diet (KD). This study has been widely quoted in the literature and continues to promote the customary administration of high-calorie/high-carbohydrate diets that include highly processed ingredients. Another study [79] found the opposite results based on a self-administered food frequency questionnaire. Their findings suggest that diets consisting of high intakes of carbohydrate with low intakes of fat could increase the risk of ALS. A prospective interventional study [80] showed that a high-caloric food supplement with high fat is suitable to establish body weight compared to a high-carbohydrate formula. A mouse study found that a high-fat jelly diet reduced bioenergetic stress, attenuated excess AMPK activation, and extended survival of TDP-43-associated ALS, compared to a low-fat jelly diet or standard pellets [81].

The customary standard of practice dietary guidelines for pALS emphasizes high-calorie and high-carbohydrate foods and liquid oral or tube feeding formulas containing highly refined and processed ingredients. There is currently no scientific evidence-based research to support sugar and other processed ingredients as optimal sources of calories in treatment of ALS. Physicians and dietitians follow dietary and nutritional standards of practice to prevent weight loss and negative nitrogen balance and manage dysphagia through diet, enteral or parenteral feedings. The standard of care does not include a nutritional assessment that includes vitamin, mineral, antioxidant, genomic, or digestive analysis and how these factors impact nutritional status and health parameters. The IFMNT practitioner recognizes that nutritional status impacts mitochondrial function, oxidative stress, inflammation, excitotoxicity, immunity, and other systemic parameters of ALS.

49.15 Sugar

The accumulation of sugar in neurons may explain the origin of several neurodegenerative diseases [82]. Studies in mice indicate that changes in glucose and glycogen levels occurred in peripheral tissues before any overt signs of disease and that glycogen accumulation in spinal cord tissue is a common feature of ALS [83]. Approximately 30% of pALS will show signs of frontotemporal degeneration (FTD) [84], and FTD is linked to excessively high cravings and consumption of sugar [85]. Glucose intolerance, insulin resistance, and hyperlipidemia have all been reported in ALS, as previously noted. A high-sugar diet may add to an already dysregulated metabolism in pALS. Sugar and refined carbohydrates are ubiquitous in the typical diets of pALS, yet they do not report specific sugar cravings or increased appetite.

There might be one caveat to the case against sugar found in a very interesting study on pure maple syrup in a *C. elegans* model of ALS, demonstrating neuroprotective and antioxidant properties [86]. The concentration of phenolic compounds in maple syrup (catechol, gallic acid, 3,4-dihydroxybenzaldehyde, syringaldehyde) may protect against neurodegeneration. It was shown that the combination of sugars with polyphenols in the pure maple syrup was more powerful than larger doses tested individually. The sugars, antioxidants, and phenols may have a broader efficacy when combined [86].

This discussion around the impact of sugar for pALS will focus on direct and indirect factors that impact neurodegeneration and declining health: (a) neurotransmitter imbalances, (b) inflammation and autoimmunity, (c) hormonal imbalances, and (d) brain-derived neurotrophic factor (BDNF).

49.15.1 Sugar: Neurotransmitter Imbalances (Dopamine and Serotonin)

Dopamine is a key intercommunication regulator of the immune and nervous systems [87]. ALS patients show abnormalities in dopamine metabolism [88], and antibodies from ALS patients inhibit dopamine release [89]. Sugar stimulates the release of dopamine in the nucleus accumbens, an area associated with reward and pleasure, yet sugar can lead to tolerance with a decrease in reward [90].

It has been found that platelet serotonin levels are significantly decreased in ALS and that platelet serotonin level is a strong predictor of survival independent of age [91]. Low serotonin levels usually intensify sugar cravings, because sugar produces insulin which helps tryptophan (precursor to serotonin) enter the brain [92].

Since signs of serotonin deficiency include anxiety, panic, insomnia, and depression, could the typical ALS diet be, by default, promoting desensitization to serotonin and dopamine? Could dysregulated neurotransmitter status in ALS with blunted responses to dopamine (pleasure) and lowered levels of serotonin (happiness) be exacerbated by the typical Western diet? With these concerns raised, the IFMNT practitioner should recommend a diet for pALS without sugar and refined carbohydrates to avoid aggravating neurotransmitter imbalances.

49.15.2 Sugar: Inflammation and Autoimmunity

Dietary patterns associated with the Western diet include excess refined starches, sugar, and saturated and trans-fatty acids, as well as low levels of natural antioxidants and fiber from fruits, vegetables, nuts, whole grains, and omega-3 fatty acids. These dietary patterns may cause an activation of the innate immune system, most likely by an excessive production of pro-inflammatory cytokines associated with a reduced production of anti-inflammatory cytokines [93]. The Western diet is also associated with inflammatory autoimmune diseases, including neurodegeneration [94]. Evidence is presented that several preexisting autoimmune disorders are associated with a small increased risk of ALS [95] and that autoimmunity in the form of SALS potentially

underlies pathogenic mechanisms [96]. IFMNT practitioners should recommend a diet for pALS without sugar and refined carbohydrates to avoid autoimmunity, systemic inflammation, and neuroinflammation.

49.15.3 Sugar: Hormonal Imbalances (Glucose and Insulin)

The brain is highly dependent on glucose for fuel. The majority of glucose uptake by the brain is independent of insulin, with only 10–20% of uptake insulin-dependent. Insulin resistance will inhibit this glucose-stimulated uptake into the brain and may decrease neuronal energy availability [97]. Glucose intolerance and insulin resistance have been reported in a significant percentage of pALS, suggesting defective carbohydrate metabolism [98]. Subsequent studies have confirmed multiple pathways linking diabetes and ALS [99]. However, conflicting data associate diabetes with both increased risk for ALS [100] and reduced risk for ALS. Reduced risk was hypothesized to be through a compensating neuroprotective role that was also associated with reduced cardiovascular risk factors [101]. But it is certainly not recommended to promote diabetes or cardiovascular risk factors in patients with ALS by adopting unhealthy dietary patterns, since the downside is chronic systemic inflammation caused by excessive and inappropriate innate immune system activity.

49.15.4 Sugar: Brain-Derived Neurotrophic Factor (BDNF)

Brain-derived neurotrophic factor (BDNF) is a neurotrophic hormone that plays an important role in survival, maintenance, and growth of many types of neurons promoting function and plasticity of synapses. BDNF is expressed mostly in the hippocampus, hypothalamus, and cerebral cortex. High-sugar and high-fat diets and obesity reduce BDNF, leading to impaired memory and learning [102]. BDNF serum levels were significantly lower in ALS patients who had lower ALSFRS-R scores. BDNF serum levels might be a biomarker and possibly contribute in part to ALS phenotypic variability [103]. A high-sugar and refined carbohydrate diet results in neurodegeneration by lowering BDNF, leading to another compelling reason to eliminate sugar and simple carbohydrates for pALS.

49.16 Gluten

It is not surprising that the subject of gluten is somewhat controversial in ALS, as it is in the general medical profession. It is known that celiac disease can mimic ALS [104]. There were significantly more cases than expected of ALS associated with a prior diagnosis of celiac disease, raising the possibility of shared genetic or environmental risk factors [95]. White matter lesions suggestive of ALS have also been attributed to celiac disease [105].

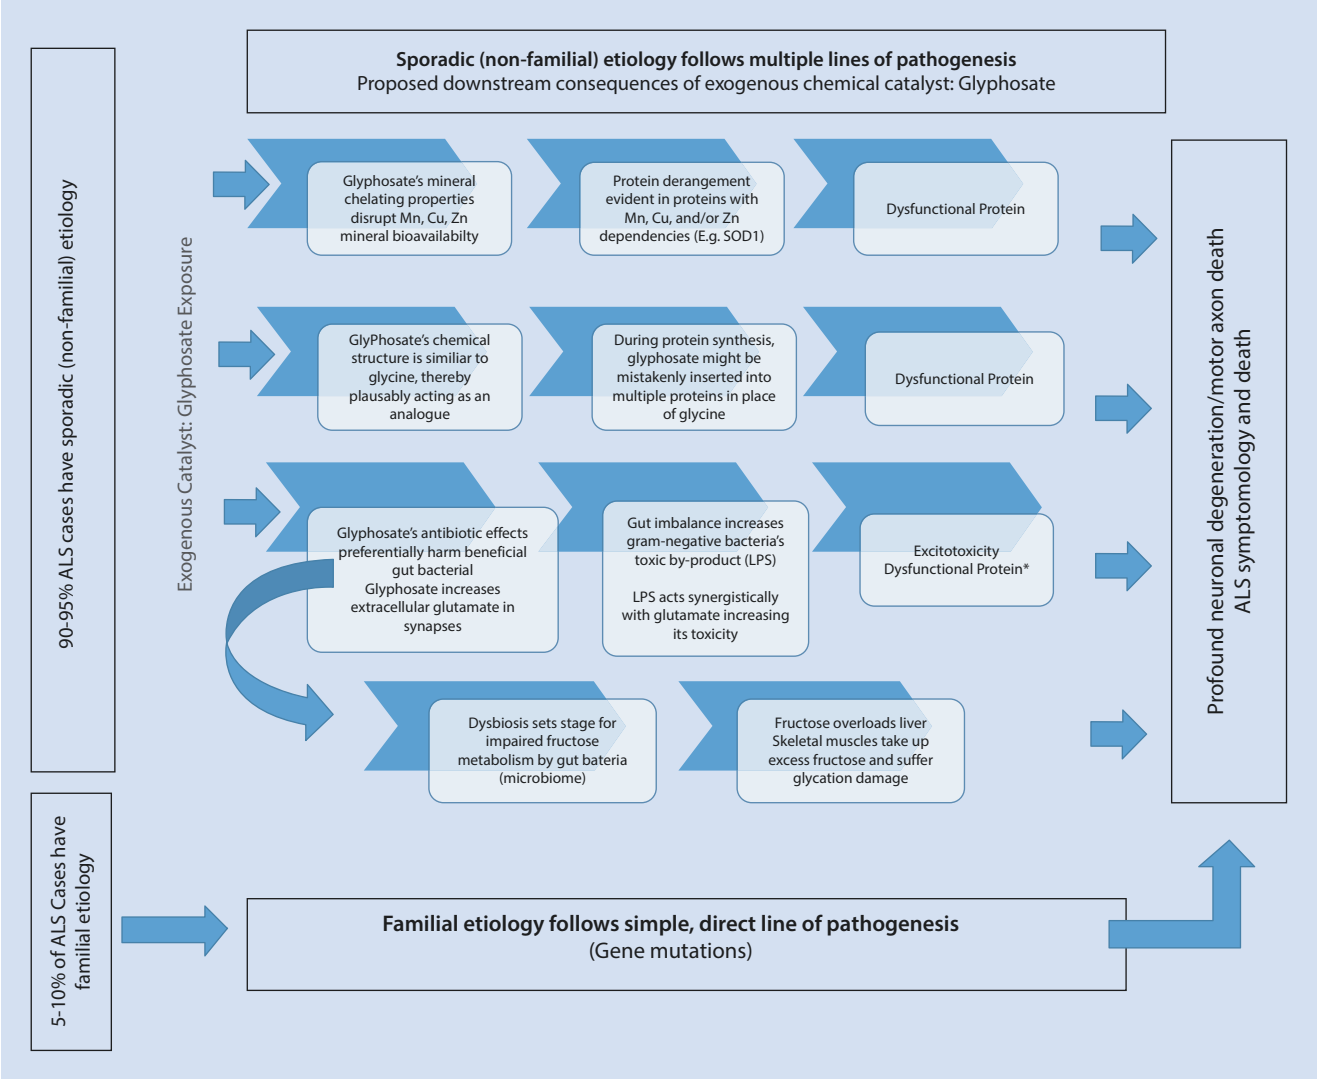
Gluten sensitivity may result in neurologic manifestations. One proposed mechanism is through stimulation and elevation of transglutaminase-6 antibodies (TG6), a neurological-specific marker, in the serum of patients with ALS [106]. Non-celiac gluten sensitivity refers to patients with gluten sensitivity in the absence of enteropathy but demonstrating neurological manifestations similar to patients with celiac disease [107]. It appears that TG6 mediates this response with or without HLA-DQ2 or HLA-DQ8 (Hadjivassiliou, 2016). Other studies report no association between gluten sensitivity, celiac disease, and ALS [108, 109].

Wheat should be avoided regardless of gluten content since residues of the organophosphate herbicide, glyphosate, have been found in wheat-containing products. Glyphosate is the active ingredient in Roundup™, which has been researched in isolation from the more toxic product actually used [110]. Glyphosate disrupts sulfate transport from the gut to the liver and may lead over time to severe sulfate deficiency throughout all the tissues, including the brain [111]. Sulfate deficiency in the brain has been associated with ALS. Glyphosate interacts synergistically with such factors as insufficient sun exposure, nutrient deficiencies of sulfur and zinc, and synergistic exposure to other xenobiotics whose detoxification is impaired by glyphosate [112].

A comprehensive article detailed the role of glyphosate as an amino acid analogue of glycine; the authors state that almost all cases of sporadic ALS share a common neuropathology characterized by transactive response DNA-binding protein 43 (TDP-43) protein inclusions [112]. Multiple missense mutations have been implicated in association with ALS regarding TDP-43 encoding of the C-terminal glycine-rich domain. Therefore it is likely glyphosate acts as an analogue to glycine, thus replacing glycine and exerting toxicity to increase the risk of ALS. Figure 49.4 shows the proposed downstream consequences of glyphosate exposure leading to the possible development of sporadic ALS [19].

Crop desiccation with glyphosate just prior to harvest may increase residues in foods prepared with wheat [113]. Glyphosate was declared a probable carcinogen by the International Agency for Research on Cancer for the World Health Organization (WHO). The WHO report and the associated researchers have suffered an intense backlash from Monsanto, which has accused them of "junk science" [114]. Glyphosate exposure is associated with oxidative damage and neurotoxicity in the hippocampus [115] and potentially disrupts the microbiome [116]. The IFMNT practitioner does not defend known toxins as part of anyone's diet, especially in neurodegenerative and high-risk patients.

Recommended alternative flours include organic quinoa, amaranth, buckwheat, legume-based flours, nut-based flours, millet, tapioca, coconut flour, oats (GF), flax meal, and other non-gluten products. Consuming organic potato, rice, and corn is allowed. Carbohydrate recommendations as part of



Sporadic (non-familial) etiology follows multiple lines of pathogenesis
Proposed downstream consequences of exogenous chemical catalyst: Glyphosate
90-95% ALS cases have sporadic (non-familial) etiology
Exogenous Catalyst: Glyphosate Exposure
Glyphosate's mineral chelating properties disrupt Mn, Cu, Zn mineral bioavailabilty
Protein derangement evident in proteins with Mn, Cu, and/or Zn dependencies (E.g. SOD1)
Dysfunctional Protein
GlyPhosate's chemical structure is similiar to glycine, thereby plausably acting as an analogue
During protein synthesis, glyphosate might be mistakenly inserted into multiple proteins in place of glycine
Dysfunctional Protein
Glyphosate's antibiotic effects preferentially harm beneficial gut bacterial
Glyphosate increases extracellular glutamate in synapses
Gut imbalance increases gram-negative bacteria's toxic by-product (LPS)
LPS acts synergistically with glutamate increasing its toxicity
Excitotoxicity
Dysfunctional Protein*
Dysbiosis sets stage for impaired fructose metabolism by gut bateria (microbiome)
Fructose overloads liver
Skeletal muscles take up excess fructose and suffer glycation damage
Profound neuronal degeneration/motor axon death
ALS symptomology and death
5-10% of ALS Cases have familial etiology
Familial etiology follows simple, direct line of pathogenesis
(Gene mutations)

Fig. 49.4 Downstream consequences of glyphosate exposure. * ALS hallmark sign of increased TDP-43 mislocation and aggregation. (Reprinted from Seneff et al. [19]. total calories will be discussed below. In summary, there is no evidence-based research to support the common inclusion of sugars, refined carbohydrates, or wheat in the diets of pALS. On the contrary, because of potential neurotoxic effects, metabolic dysregulation, gluten sensitivity, and glyphosate exposure, diets excluding sugars, refined carbohydrates, and gluten/gliadin would be the better option.

49.17 Protein

There is no consensus among researchers and healthcare professionals on protein requirements for pALS. ALS is a catabolic process of destructive metabolism that costs the body energy as molecules break down. The anabolic process cannot stay ahead of the net catabolic loss. Piquet and colleagues report in the absence of available data on protein requirements in ALS an intake ranging between 1 and 1.5 g/kg/day seems reasonable. This was with a caveat that there is a risk of deficiency when intake is less than 1 g/kg/day and that an increase to 1.5 g/kg/day, considered as harmless, could be useful in the event of hypercatabolism [67]. The calculation of protein requirements was based on the recommendations of the Brazilian Society for Food and Nutrition suggesting 1.0 g protein/kg/day with intakes ranging 1–1.2 g/kg/day. The authors go on to state food intake with a source of high biological value protein should be highlighted and comprise roughly 70% of the total protein intake per day [117].

It seems paradoxical that protein recommendations in terms of the amount, forms, and sources of protein cannot effectively address the critical reduction of skeletal protein muscle mass and function seen in ALS. As previously noted, the common approach of providing adequate calories to spare muscle mass is considered more effective than focusing on specific protein requirements.

49

49.18 Dairy and Soy as Protein Sources in Oral and Tube Feedings

Dairy or soy comprises up to approximately 50% of protein intake in the typical ALS patient on oral/enteral commercial formulas [118]. There is no scientific evidence that either of these protein sources are optimal for pALS, yet by default these protein sources are standard of practice for ALS.

49.18.1 Dairy

There is evidence that milk-derived foods appear to have a negative effect on ALS disease symptoms according to a study on 302 patients in the ALS Multicenter Cohort Study of Oxidative Stress, although the reasons are not understood (Anderson, 2016). Another study found that a diet enriched in casein may induce astrocyte activation through exaggerated blood-brain barrier (BBB) permeability [119].

Amen explains that casein is an excitotoxin that can lead to brain inflammation [120]. Blaylock further explains that sodium caseinate, calcium caseinate, whey protein, whey protein concentrate, and whey protein isolate are ingredients with hidden free glutamic acid excitotoxins [121].

An FDA report highlights findings that commercial milk contains permitted antibiotics, while some samples contain illegal antibiotics [122]. Antibiotic-induced neurotoxicity may affect at-risk patients causing neuropathy, neuromuscular blockade, nonspecific encephalopathy, and seizures [123]. Other contaminants in dairy products include exogenous estrogens [124], and detergents, sanitizers, disinfectants, and melamine, all of which pose a threat to human health [125].

Adding to the evidence presented above, the organophosphate herbicide glyphosate is the most widely used GMO herbicide in dairy cattle feed. In the first ever testing of glyphosate in feeding tube liquid, glyphosate may have untoward effects in ALS and several other neurodegenerative pathologies [112]. The FDA has suspended testing for glyphosate residues in food, including milk, pending further validation of testing methods [126]. ALS patients are prone to mucus plugs that occur when bronchial secretions accumulate and obstruct airflow [127]. If the cough is weak and the plug cannot be cleared, the situation can be deadly. Many pALS report that milk exacerbates phlegm; however, the scientific literature does not support the connection between milk and mucus or phlegm production. The IFMNT practitioner would assess milk sensitivity or allergy on an individualized basis.

There is no evidence-based research to support dairy products for pALS. In fact, there is evidence-based research to advise against dairy products in the diet for pALS [128]. This report showed unexplained negative effects of milk-derived products when included in ALS diets. Some substitutions for dairy protein to consider are vegetarian-derived proteins from pea, quinoa, almond, and hemp. An IFMNT perspective must consider the potential risk of dairy products due to associations with allergies, intolerances, excitotoxins, hormones, antibiotics, glyphosate, and other contaminants as we educate and nutritionally support the ALS patient.

49.18.2 Soy

pALS are frequently ingesting soy-derived products in processed foods and oral/tube feedings, especially as a protein source. Soy products are highly allergenic and genetically modified and contain glutamic acid which may potentiate excitotoxicity. Based on USDA survey data, the acres planted of herbicide-tolerant GMO soy has risen from 17% in 1997 to 94% in 2014 [129]. There is no evidence-based research to support the use of soy protein for pALS. However, inclusion of organic tofu and fermented soy (tempeh, miso, natto) might offer a healthy alternative for pALS without soy allergies.

Oral/tube feeding supplements frequently contain soy protein isolate, which has processed free glutamic acid [130]. Glutamate is a primary CNS excitatory neurotransmitter. In 1968, monosodium glutamate (MSG) was identified as the cause of "Chinese restaurant syndrome," also known as "MSG symptom complex," following numerous complaints made to the FDA of dizziness, headaches, flushing, chest pain, bronchospasms, numbness, and other symptoms [131]. There is an ongoing controversy about the impact of glutamic acid and MSG on human health. Many scientific articles report that neither dietary MSG as a food additive, free glutamic acid in processed foods, free glutamic acid in natural foods, or bound glutamic acid in whole protein foods affect brain function or neurotransmission [132]. However, MSG and glutamic acid produced for use in supplements and processed foods can cause neurodegenerative diseases in animals and humans, especially with long-term intake [133].

An excellent mechanistic review describes the luminal (blood facing) and abluminal (brain facing) membranes and their role in glutamate transport. The review describes how glutamate traverses the luminal membrane but cannot pass the abluminal membrane to enter the brain in any appreciable quantities except in the circumventricular organs [134]. This phrase "any appreciable quantities" acknowledges some vagueness that exists around the BBB. Could genetic alterations in glutamate metabolism [135], in addition to BBB susceptibility in neurodegeneration, predispose pALS to toxicity from dietary glutamates?

In summary, there is no evidence-based research to support the use of dietary soy-derived proteins for ALS. In fact, due to the high allergic potential, GMO contamination, and the presence of glutamates in soy products, it is advised that the IFMNT practitioner exclude processed soy for pALS.

49.19 Amino Acids

Studies have examined the role of individual amino acids and ALS to determine their role in muscle (maintenance, growth, and breakdown) and neurotransmitter balance. Several studies agree that ALS shows imbalances in plasma amino acids

compared to controls and imbalances in excitatory versus inhibitory neurotransmitters. The ability to personalize amino acid requirements is not easily determined by blood, urine, or CSF biomarkers of amino acids.

It is known that plasma amino acid composition of pALS differs from the general population. For example, there are significantly lower percentages of plasma tyrosine, valine, methionine, leucine, and isoleucine, as well as significantly higher percentages of glutamine and serine in ALS than in controls [136]. The clinical state significantly influenced the percentage of plasma phenylalanine and alanine [136]. Evidence of glutamate imbalances in ALS is associated with CNS alterations, and it was found that ALS patients had statistically significant elevations in plasma levels of aspartate, glutamate, and glycine [137]. Another study [138] found that higher levels of glutamate were correlated with early onset (<55 years.) compared to later onset (>74 years.) of ALS. Since plasma amino acids might show biological correlates of the age of onset in ALS, this could potentially provide insight into possibly aberrant biochemical pathways that might unlock key pathological pathways.

The biosynthesis of amino acids in the brain is regulated by the concentration of amino acids in plasma, although the levels of CSF and plasma amino acids are not directly correlated [139]. Essential amino acids cannot be synthesized by the brain and must be supplied from diet and protein breakdown. Other amino acids, including taurine, have various rates of movements into the brain, since many are synthesized endogenously which restricts peripheral entry into the brain [140].

Table 49.1 shows particular amino acids that have been the subject of interest in ALS: Branched Chain Amino Acids (BCAA), L-threonine, L-arginine, glutamine, serine, and taurine.

Table 49.1 Amino acids

	Proposed action	Evidence for or against	References
Branched-chain amino acids (BCAA), leucine, isoleucine, valine	Stimulate muscle growth and recovery after exercise; transported into the brain using the same pathway as serotonin and may compete for access to a limited number of transporters	BCAAs did not show clinical benefit and might worsen pulmonary symptoms; showed lack of benefit in improving survival time, muscle strength, or disability; altered immune profile of microglia as possible mechanism by which BCAAs might turn into toxicants and facilitate neurodegeneration; proposed decreases serotonin (*Not* recommended)	[91, 144–146, 147–149]
L-Threonine	Conversion of L-threonine to glycine, inhibitory amino acid blocking excitatory effect of aspartate	Conflicting evidence for improved vocal ability, swallowing, energy, and reduced drooling and spasticity; possible worsened pulmonary function (possibly ineffective)	[150–152]
L-Arginine	In vitro and in vivo demonstration of neuroprotective effects and prolonged life span; enters the Krebs cycle and may provide energy and promote muscle protein synthesis and strength	(No evidence for or against use)	[9, 142, 153]
L-Glutamine	In neurons, mitochondrial metabolism of exogenous glutamine is mainly responsible for the net synthesis glutamate; necessary for the synthesis of glutathione	Limited research; no clear guidelines; concerns for glutamate synthesis (caution)	[141, 154–155]
L-Serine	Low levels are associated with demyelination and neurological symptoms; endogenously produced by astrocytes and abundant in diet	In vitro and in vivo studies to be neuroprotective for ALS. In Phase I study, L-serine in doses up to 15 g twice daily appears to be safe in patients with ALS; possible dose-related slowing of disease progression; currently in Phase II trial (cautious recommended use in amounts used in Phase I study)	[156–158]
Taurine	Neuroprotective, prevents glutamate toxicity in cultured neurons, modulates intracellular calcium excess	May be a good candidate for therapeutic trials in ALS	[467]

Dietary protein should be from organic sources whenever available. The best animal protein sources are 100% pasture-raised beef and chicken, wild meats, wild-caught Alaskan salmon, herring, sardines, and eggs. Other good quality proteins are from nuts, nut butters, seeds, hemp, quinoa, organic soy, and lentils.

49

49.20 Fats

Lipids are a lifeline for the proper structure and function of cell membrane bilayers and as lipid rafts in subdomains of the plasma and mitochondrial membranes [159]. Abnormal lipid metabolism plays a central role in neurodegeneration. Figure 49.5 shows the various lipid systems in ALS, other CNS disorders, and brain injuries [160]. Every neurodegenerative disease has its own signature abnormalities in lipid metabolism [160]; therefore, a clinician cannot generalize a lipid-based treatment program to effectively address all neurodegenerative diseases.

Figure 49.6 lists some interesting brain and fat facts to "keep in mind" [161–172].

Figure 49.7 describes the important ways that lipids protect brain cell membranes [44].

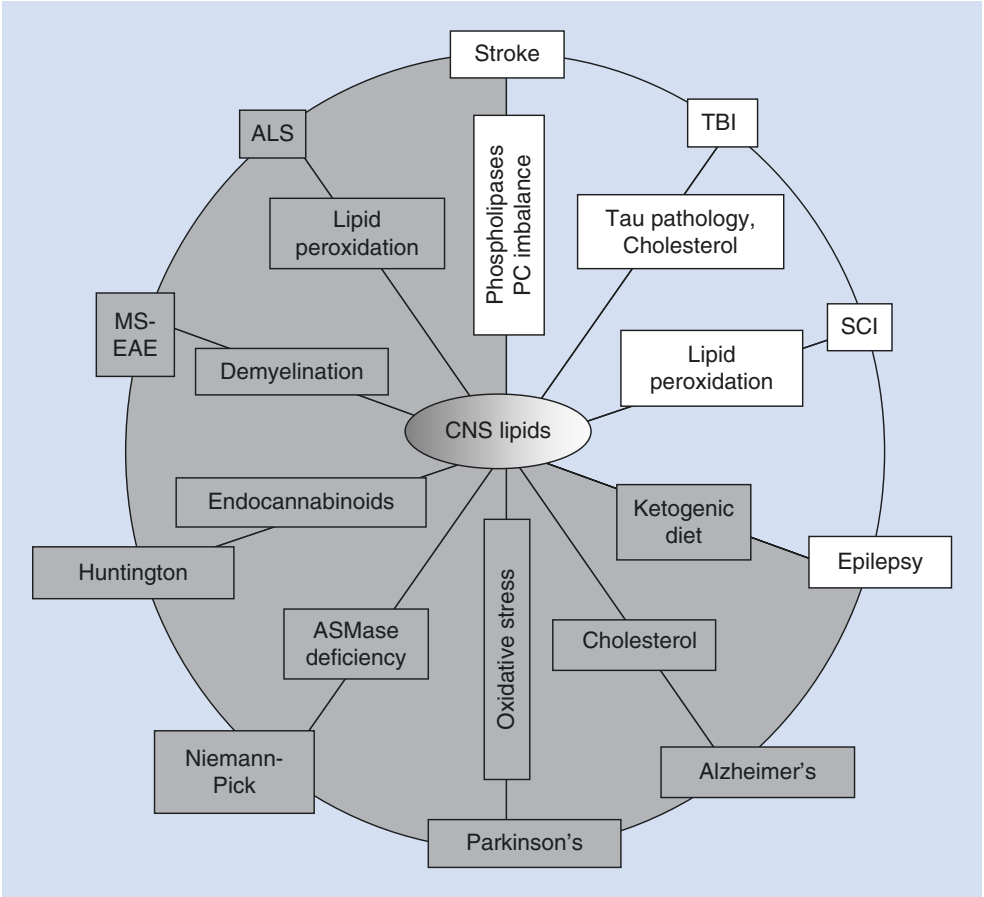

Fig. 49.5 Lipid wheel. (Reprinted from Adibhatla and Hatcher [160]. With permission from Springer Nature)

- 2% of total body weight
- 20% of total caloric expenditure
- 60% fat & fattiest organ
- 25% of total body cholesterol
- 70% of CNS cholesterol resides in myelin
- >95% of cholesterol synthesized in brain
- <5% of plasma cholesterol crosses BBB
- Brain contains 1:1 ratio AA:DHA
- DHA, AA, phosphatidylcholine and phosphatidylserine cross BBB
- BBB integrity is compromised in ALS
- Brain prefers glucose and ketone bodies for energy

Fig. 49.6 Interesting brain and fat facts

- SUPPORT cell membrane structure and function

49.21 Optimal Sources and Amounts of Dietary Fat

Most preclinical and clinical dietary research on lipid metabolism and ALS have not been translated into therapeutic interventions. Dietary fatty acids that freely cross the blood-brain barrier and contribute to the composition of brain fats are arachidonic acid, DHA, phosphatidylcholine, and phosphatidylserine [173], yet common practice does not manipulate these fats for therapeutic benefit. Dietary studies typically limit the role of fat as a macronutrient percentage of total calories, and fewer yet have examined the types and sources of fatty acids. The conventional standard of practice in ALS dietary treatment does not specify the balance, source, or composition of dietary fat via oral or tube feedings. We will discuss the potential benefits of the ketogenic diet (KD) for pALS and other chronic disorders here and elsewhere in this text.

A consistently ignored variable in most dietary studies is an analysis and description of the quality of the fat sources. We should be asking if lipid sources from organic cold-pressed oils behave differently in the body compared with industrially derived lipids that are oxidized, bleached, deodorized, solvent extracted, and genetically modified. How does the quality of the industrial-made lipid products influence immune and inflammatory responses, and how might these factors skew published literature outcomes regarding the anti-inflammatory and inflammatory balance? In other words, we need to understand the quantitative versus qualitative impact of lipids derived from various sources.

49.21.1 Omega-3 PUFAs (ALA, EPA, DHA)

Important omega-3 polyunsaturated fatty acids (PUFAs) include alpha-linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). The circulating levels of DHA and EPA available for uptake by the brain represent a combination of those derived from the diet and those biosynthesized in the liver from alpha-linolenic acid (ALA) [176]. Recent research highlights the critical role of omega-3 fatty acids in preserving the integrity of the BBB to protect the brain from blood-borne bacteria, toxins, and other pathogens [174].

Consumption of foods high in omega-3 PUFAs (alpha-linolenic and fish oils) may help prevent or delay the onset of ALS. Inflammatory processes that destroy motor neurons in the spinal cord, brain stem, and cortex during ALS could be reduced by DHA administration due to its potent anti-inflammatory properties [175]. It is known that DHA increases total glutathione levels in microglia cells, thus enhancing their antioxidant capabilities. In parallel, DHA causes a reduction of pro-inflammatory cytokines, such as IL-6 or TNF-α [175]. A prospective study evaluated five large cohort studies on a pooled analysis of 995 individuals with ALS, finding that overall total omega-3 intake was associated with a 34% reduced risk for ALS in the multivariable model comparing the highest with the lowest quintile [176]. The men in this study had a median dietary omega-3 intake of 1.40–1.85 g/day, and women had a mean dietary omega-3 intake of 1.14–1.43 g/day [176].

DHA does more than just protect the brain from neuroinflammation. It can also promote resolution of neuroinflammation. Neuroprotectin-D1 and Resolvin-D1 are specialized pro-resolving lipid mediators (SPMs) derived from DHA and dependent on sufficient DHA intake, conferring protection and resolution of inflammation [177]. Omega-3 PUFA may reduce neuroinflammation through prevention of microglial activation by pro-inflammatory cytokines and the production of anti-inflammatory and antioxidant Neuroprotectin-D1 [178]. The study findings on Resolvin-D1 may offer a new approach to attenuating the inflammation in ALS.

In the face of dietary (n-3) PUFA deprivation, homeostatic mechanisms slow brain DHA metabolism while increasing AA metabolism. These changes may exacerbate neuroinflammation and excitotoxicity [179]. Conversely, in the face of dietary (n-6) PUFA deprivation, homeostatic mechanisms increase brain DHA metabolism and their anti-inflammatory metabolites that likely promote neuroprotection [180]. The above examples illustrate how the body coordinates availability of dietary fatty acid intake with upregulation and downregulation of fatty acid metabolism in a dynamic balancing process within the brain.

In our enthusiasm about the therapeutic role of omega-3 PUFAs, it is important to caution against excessive or imbalanced dosages. All omega-3 PUFAs can be potentially oxidized by various environmental factors such as presence of microbes, UV light, heat, metals, and other factors [181]. One study found that EPA accelerated ALS progression in a mouse model of ALS, suggesting that prolonged high exposure of EPA should be contraindicated for ALS patients [182]. That same study did not evaluate DHA. The study used ethyl esters (70% EPA, 10% DHA), whereas eating fish generally provides higher levels of DHA [183].

The numerous publications supporting the neuroprotective effects of omega-3 PUFAs (especially DHA) warrant supplementation for most pALS. Keeping fish oil doses between 2 and 4 g/day might be therapeutic for pALS. pALS should be provided with the following resources on fish to avoid and fish that is safe [184–185]. A vegetarian or vegan diet is not recommended for pALS; however, healthy vegan choices of omega-3 PUFAs are derived from foods and oils containing alpha-linolenic acid (ALA) such as walnuts, flax seeds, pumpkin, chia seeds, hemp seeds, natto, cashews, Brazil nuts, Brussels sprouts, kale, spinach, watercress, mustard oil, hemp oil, and walnut oil [186]. There is only a 2–5% conversion rate of ALA to DHA [187], so the best direct vegan DHA source comes from marine-sourced algae and algal oil [188]. It is very challenging to achieve optimal omega-3 PUFA balance of EPA:DHA in vegan and vegetarian diets, especially considering the unique requirements for pALS. For more personalized recommendations on the

use of fish oil, the IFMNT practitioner can assess erythrocyte fatty acid status through laboratory testing for corresponding brain and erythrocyte levels of fatty acids (AA, EPA, DHA) and the total balance of cell membrane fatty acids.

49.21.2 Omega-6 PUFAs (LA, AA)

There is an ongoing international debate among the scientific and medical community regarding the inflammatory role of linoleic acid (LA). The intake of LA has increased 20-fold over the twentieth century to our current intake at approximately 6% of total calories [189]. The Academy of Nutrition and Dietetics (AND) advises LA dietary intake at 3–10% of total calories and concludes no risk of inflammation based on its analysis of 15 clinical trials [190–191]. Opposing scientific literature indicates that omega-6 PUFAs promote inflammation and augment many disease processes, whereas omega-3 PUFAs seem to counter these adverse effects [192]. The deleterious effects of LA-rich diets promote oxidized fatty acids, causing alterations in the gut microbiome that have potential to foster systemic inflammation [193]. The plethora of contradicting research on the anti- vs. pro-inflammatory roles of LA may reflect unaccounted for variables such as (a) substitution of LA for saturated, omega-3 or trans-fatty acids, (b) total ratio of omega-6/omega-3 dietary PUFAs, or (c) variations in desaturase and elongase enzyme functions in individuals, and genomic variability.

Most dietary studies in ALS patients use commercial oral and enteral formulas that contain processed omega-6 PUFAs containing mostly LA from soy, corn, and canola oil, with lesser amounts of omega-3 PUFAs from fish oil. Although they are called vegetable oils, they are actually derived from tough seeds and legumes. These types of lipids are unstable and susceptible to oxidation. They contain residues of pesticides and solvents and are genetically modified, which alter the microbiome and promote inflammation [194].

From an IFMNT perspective, pALS should optimize the quality of their dietary fat intake by avoiding oxidized, bleached, deodorized, solvent extracted, or genetically modified sources of fatty acids. pALS should choose organic, unrefined, cold-processed, and expeller-pressed oils, preferably in dark glass bottles. Assuming adequate intake of omega-6 fats to prevent deficiency (1–2% of calories), pALS should focus on healthy omega-3 fats (e.g., salmon, sardines, mackerel, herring, chia seeds, flax seeds, walnuts, hemp seeds), omega-7 fats (macadamia nut oil, sea buckthorn oil, avocado oil), omega-9 fats (e.g., olives, olive oil, grapeseed oil, avocado, avocado oil, almonds, macadamia nuts, eggs), and saturated fats (e.g., coconut, grass-fed butter, ghee, and grass-fed animal proteins). pALS can reduce inflammation by optimizing ratios of omega-6 PUFA to omega-3 PUFA from the typical Western diet of 25:1 toward optimal levels of 3–1:1 [195–196].

49.21.3 Medium-Chain Triglycerides

Medium-chain triglycerides are defined as triglycerides that contain two or three fatty acids on the glycerol backbone that are medium chained: C6, C8, C10, and C12 from palm or coconut oil [197]. Coconut oil is preferred because palm oil isn't considered socially or environmentally sustainable [198], and there is questionable reliability even when palm oil is verified through certification by the Roundtable on Sustainable Palm Oil [199].

Coconut oil, a medium-chain lipid, contains more than 50% lauric acid (C12) and equal parts caproic acid (C6), caprylic acid (C8), and capric acid (C10) [200]. Caprylic acid (C8) converts to ketones the most efficiently and may be easiest on digestion; thus it is preferable to use fractionated coconut oil as a combination of caproic and caprylic acids or caprylic acid alone [201]. Caprylic acid has been specifically studied in ALS mice showing reduced progression of weakness, protection of spinal cord motor neurons, and a lower mortality rate, which may translate to a high impact on quality of life for ALS patients [202]. A clinical trial was designed to determine safety and tolerability of caprylic acid in ALS patients, with the goal for subsequent studies to determine if caprylic acid slows or stops ALS disease progression [203]. A consequence of solely using caprylic acid is that it might decrease glycolysis and the levels of TCA intermediates in the brain [204].

MCTs do not require lipase for digestion or bile acids for emulsification [205]. They are rapidly absorbed into the portal circulation, rather than being transported through chylomicrons into the lymphatic system. They convert into ketones (beta-hydroxybutyrate, acetoacetate, acetone) in the liver, yet are never metabolized by the liver. These ketone bodies provide energy for the peripheral body and cross the BBB to provide energy to the brain [205].

Triheptanoin is synthesized from heptanoic acid (C7) as an alternative MCT fuel source, having the unique role of sparing glycolysis and refilling the TCA cycle (anaplerosis) by providing pyruvate for carboxylation into oxaloacetate, a key intermediate. Triheptanoin slows motor neuron loss, muscle wasting, and the onset of motor symptoms in ALS mice, which is likely mediated by reducing oxidative stress and preserving mitochondrial function [204]. ▶ Clinicaltrials.gov lists 28 trials for triheptanoin in various mitochondrial diseases, Huntington's disease, ALS, and other conditions [206].

49.21.4 Saturated Fatty Acids (SFAs)

The Western diet (high in saturated fat, trans fats, and omega-6 fatty acids) causes damage to the brain, including oxidative stress, insulin resistance, inflammation, and changes to vascularization and BBB integrity [207]. Saturated fatty acids (SFAs) are derived from (a) animal foods that contain cholesterol, (b) processed foods that also contain trans fats, and (c) vegetarian sources (coconut oil, palm oil). In this

analysis of dietary fat substitutions, replacing the equivalent calorie value of SFAs with PUFAs and monounsaturated fatty acids (MUFAs) was associated with a 27% combined reduction in mortality from neurodegenerative disease. This effect was not recognized when SFAs were substituted with carbohydrates [208].

Blood cell palmitoleic acid (MUFA16:1) to palmitic acid (SFA16:0) is an independent prognostic factor for ALS, with higher ratios extending life for 10 months independent of BMI [209]. The highest content of dietary palmitoleic acid is found in macadamia nut oil, sea buckthorn oil, and lesser amounts in avocado [197]. Palmitoleic acid has beneficial effects of lowering hsCRP and TNF-alpha and improving glucose and insulin regulation [210].

The balance of fatty acid intake is emphasized for optimal brain health, and though current dietary guidelines suggest SFA intake should comprise less than 10% total calories daily [211], individual assessment of fatty acid status is best for personalizing requirements during altered metabolic states such as ALS.

49.21.5 Cholesterol

The brain synthesizes its own cholesterol. About 25% of total body cholesterol resides in the brain, and the majority (70%) of brain cholesterol resides in myelin that surrounds axons and facilitates the transmission of electrical signals [212]. Other crucial functions of brain cholesterol are to build and maintain membranes, modulate membrane fluidity, and support synapse development, formation and function, dendrite differentiation, axonal elongation, and long-term potentiation [213]. Cholesterol has a remarkable dual effect on membranes by making them stiffer but retaining the fluidity required for membrane function, similar to an "antifreeze agent" [214]. The maintenance of cholesterol homeostasis is crucial for the metabolic and structural benefits in neuronal and glial plasma membranes and in the composition of myelin. The impact of modifying free cholesterol and cholesteryl ester levels in the brain to decrease neurodegeneration is an active area of scientific and pharmacologic research [215].

Cholesterol balance is dysregulated in several neurodegenerative diseases, yet the brain disease sites and mechanisms of cholesterol metabolism are variable, thereby lacking a common therapeutic approach [216]. A recent report measured the serum and CSF in 20 ALS patients to compare levels of cholesterol and cholesterol metabolites [217]. As neurons die in ALS, cholesterol is released into the CNS and becomes toxic to surrounding neuronal cells, while saturated metabolic pathways are insufficient at removal of excess cholesterol [217].

Demyelination, or the loss of "insulation" of oligodendrocytes, damages the ability and efficiency of nerve transmission. Demyelination is a primary symptom of Multiple Sclerosis (MS), and the brain shows disturbed lipid metabolism with serum lipid profiles in the normal range. In MS mouse models, increasing dietary cholesterol actually supports remyelination and reduced axonal injury [218]. Demyelination is considered a secondary symptom of ALS, which occurs after neuronal death has begun [219]. However, researchers at Johns Hopkins University found that significant changes also occur in oligodendrocytes prior to neuronal death; thus demyelination is both a cause and result of damage to motor neurons. It is important to appreciate that motor neurons are dependent on healthy oligodendrocytes and that oligodendrocytes are dependent on sufficient availability of cholesterol [220]. Therefore, adequate cholesterol in the diet and serum is important for healthy oligodendrocytes.

The generalized message throughout the literature is that the brain is highly dependent on dietary fatty acids but is quantitatively less dependent on dietary cholesterol since the brain (neurons and astrocytes) synthesizes cholesterol endogenously and is independent of the peripheral cholesterol levels [213]. However, we might question this rigid assumption of the blood-brain barrier (BBB), as it has been found through radiolabeled dietary cholesterol feedings that <5% does cross the BBB to comprise brain cholesterol [166]. Exogenous cholesterol enters the CNS through an impaired BBB, resulting in enhanced repair and amelioration of the neurological phenotype in two distinct models of remyelination [218]. The data suggest that dietary cholesterol directly facilitates repair of myelin by modulating the profile of growth factor expression and promoting oligodendrocyte precursor cell (OPC) proliferation [218]. These findings emphasize the safety of dietary cholesterol and its nutritional importance in both prevention and remediation of remyelination.

Does dyslipidemia improve or worsen ALS? One study found that dyslipidemia (elevated LDL:HDL) was possibly protective for ALS patients, associated with an extra 12 months of survival [221]. Another study found that dyslipidemia was associated with an extra 14 months of survival and that a diet rich in lipids and calories should be considered [222]. A subsequent study found that hypolipidemia was associated with ALS even when the diet was intact [223]. A review on 11 antecedent diseases in a large-scale human ALS study found that the prevalence of hyperlipidemia and all diseases was less in ALS compared to the age and gender ratio-matched control conditions [224]. Another study found that there were no significant differences between mean total cholesterol, LDL, LDL:HDL, or triglycerides between ALS patients and controls; however, ALS patients with higher triglycerides (>127.5 mg/dl) had increased life expectancy by 5.8 months [225]. Over the past decade, studies have found varying results and associations between serum lipid measurements, morbidity, mortality, and ALS, resulting in no evidence-based consensus regarding lipid measurements as biomarkers for ALS.

Weighing the risk/benefit of dietary cholesterol in the presence or absence of elevated lipid markers, the ALS patient will likely benefit from more dietary cholesterol. Eggs from organic pasture-raised hens would be the healthiest and easiest way to raise serum cholesterol in pALS.

49.21.6 Phospholipids (PLs)

Neurodegenerative diseases incur extensive oxidative damage to mitochondrial cell membranes. Mitochondrial dysfunction, a hallmark of ALS, is highly influenced by derangements in lipid structures and metabolism, especially involving glycerophospholipids such as phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI,) phosphatidic acid (PA), and phosphatidylglycerol (PG) [159]. PC accounts for approximately 50% of the phospholipids that make up cell membranes [141]. These phospholipids are essential components of the inner and outer mitochondrial cell membranes, governing membrane integrity, fluidity, fission, fusion, and cell-to-cell signaling [226].

Phospholipids are fundamental building blocks of all cell membranes, forming stable bilayers, with their polar head groups exposed to water and their hydrophobic tails buried in the interior of the membrane [227]. The fluid-mosaic model of membrane structure describes the structure of the plasma membrane as a mosaic of components, which includes the phospholipids, cholesterol, proteins, and carbohydrates and provides the structure to give the membrane a fluid character [228–229].

Beneficial effects of dietary PLs have been known since the early 1900s as they relate to different illnesses and symptoms [230]. Dietary PLs are found in egg yolk, soy, milk, and marine sources, and the average diet contains 2–8 grams [230]. Phosphatidylcholine is sometimes used interchangeably with lecithin, although the two are different. Choline is a component of PC, which is also a component of lecithin, but lecithin is also a mixture of several lipids and phospholipids [231]. Various phospholipid products are used to replace damaged lipids in cellular membranes and organelles and are commercially available. These include intravenous preparations available pharmaceutically and over-the-counter oral preparations.

Veterans of the 1991 Gulf War had an "outbreak" of ALS for 10 years presumably due to exposure to toxins [232]. Phospholipid profiling of plasma from Gulf War illness showed dysfunction within DHA and AA-containing phospholipids and inflammatory imbalances [233]. There exist numerous peer-reviewed publications on membrane lipid replacement for cancer and other fatigue-causing illnesses; however, no specific studies on ALS. A Phase I clinical trial that was underway at the time of this writing might advance our understanding of dietary phospholipids in ALS: "The Combination of Phospholipids and Medical Herbs for the Treatment of Patients with Amyotrophic Lateral Sclerosis (ALS): A Pilot Study" [234].

Most clinical studies have used 1.5–3 g daily of dietary phospholipids or 0.5–2 g daily of IV administration [229]. Commercially available dietary supplements contain approximately 1.5 g per dose, and therapeutic doses are upward of 4 g daily without any side effects [235]. It is more expensive and invasive to receive IV phospholipids, and less accessible due to travel for appointments and a paucity of physicians competent to administer this therapy. Dietary phospholipids are affordable and convenient and can be given orally or in tube feedings. To date, peer-reviewed scientific studies on phospholipid therapy for mitochondrial membrane support have focused on dietary but not IV phospholipids. Many IFMNT physicians use intravenous or dietary phospholipids as a therapeutic intervention for pALS and other neurodegenerative disorders. This is a good example of applying evidence-based research to treat mitochondrial damage, a hallmark of ALS, for a potentially therapeutic and personalized intervention.

49.22 Ketogenic Diet (KD) and Medium-Chain Triglycerides (MCTs)

The diagnosis of ALS is concomitant with a race against malnutrition mediated by metabolic derangements in aerobic and anaerobic metabolism, substrate utilization, impaired mobility, chewing and swallowing, frequent gastrointestinal disturbances, inflammation, breathing abnormalities, sleep disturbance, and mental and emotional factors. The ketogenic diet (KD) optimizes energetic efficiency and beneficially modulates various metabolic pathways to help protect against neurodegeneration. Despite the relative lack of clinical data, there is an emerging scientific literature supporting the broad use of the KD (and its variants) against a variety of neurological conditions. Regarding the KD, the authors ask, "How can a simple dietary change lead to improvement in disorders with such a huge span of pathophysiological mechanisms?" [236].

The KD is the intentional or therapeutic provision of ketones for energy as part of a calorie-sufficient diet consisting primarily of fatty acids, limited protein, and very low carbohydrate intake. The KD and the following variants may be neuroprotective as seen in ◘ Fig. 49.8 [237]. For further information regarding the KD, please see ▶ Chap. 22.

In conclusion, there is very little clinical research on the KD in ALS patients, so ultimately the therapeutic understanding and application of the KD diet for ALS will require large randomized, placebo-controlled clinical trials [238]. An unknown consideration is the timing of implementation of the KD relative to the advancement of ALS disease progression [236]. From the IFMNT perspective, using each of our ALS patients as their own case controls, we can individually determine if the KD or a variation of the KD is helping to improve signs and symptoms. For pALS to follow the KD, it is most practical to aim somewhere between an MCT or low glycemic index meal plan.

49.23 The Deanna Protocol (DP)

The Deanna Protocol (DP) was developed by Dr. Vincent Tedone to treat his daughter with ALS [239]. Winning the Fight, Inc. helps pALS implement the DP and is a collaborative effort of Dr. Tedone, researchers, and advisors. The primary ingredients in the DP are a TCA cycle intermediate

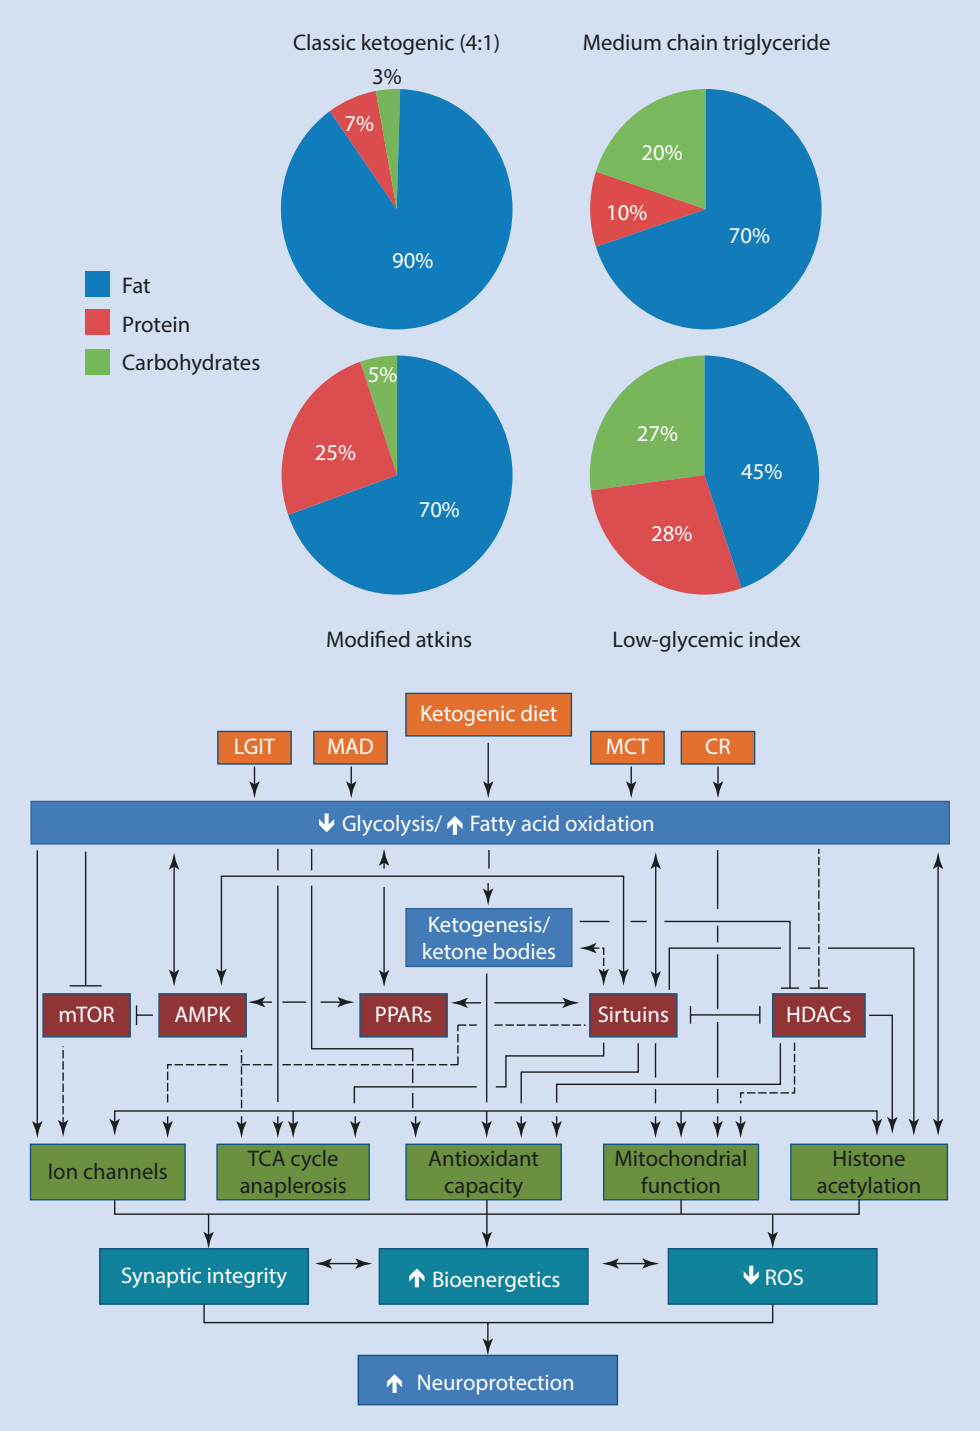

Fig. 49.8 The KD and the following variants may be neuroprotective: low glycemic index treatment (LGIT), modified Atkins diet (MAD), medium-chain triglycerides (MCT), and calorie restriction (CR) [241]. (Reprinted from Gano et al. [237]. With permission from the American Society for Biochemistry and Molecular Biology)

(arginine alpha-ketoglutarate (AAKG)), the ketogenic diet with 10% MCT oil, gamma-aminobutyric acid (GABA), and ubiquinol. There were positive results in a preclinical study [240]. The true effects of the DP in pALS are worth studying in a Phase I clinical trial; however, this will be very difficult, because most patients are taking other dietary supplements and vitamins [241].

49.24 Commercial Enteral Formulas

The enteral formulas [242] used in the comparison study of isocaloric, high-calorie/high-carbohydrate, and high-calorie/high-fat formulas [78] contain a combination of highly processed, genetically modified, and artificial ingredients, such as soy, milk, corn, sugar, corn syrup solids, maltodextrin, artifi-

cial flavors, and glutamates. The fats in the high-calorie, high-carbohydrate formula are from corn, canola, and medium-chain triglyceride (MCT) oils. The fats in the high-calorie, high-fat formula are from omega-3 fatty acids (anchovy, cod, menhaden, pollock, sardine, and tuna) and omega-6 (borage oil), omega-9 (canola oil), and MCT oil. The fish sources typically contain contaminants [243] from GMO ingredients, pesticides such as DDT and dieldrin, heavy metals such as mercury, and PCBs. Canola oil is refined, bleached, deodorized, genetically modified, and processed with hexane, an industrial solvent [244]. Borage oil may contain hepatotoxic and carcinogenic pyrrolizidine alkaloid constituents [245]. Furthermore, this study on hypercaloric enteral nutrition in patients with ALS [78] didn't consider the classification of fatty acids; the ratio of omega-3-6-9 fatty acids; the specific composition of MCT oil, such as amount of C6, C8, C10, or C12 fatty acids; the quality of the fatty acids in terms of oxidation or contamination; or the ketogenic diet.

Other commercially available widely used enteral formulas contain refined carbohydrates, sugars, damaged and toxic fats, processed free glutamates, and allergenic proteins. They are chemically adulterated and contain genetically modified ingredients. They are not tailored to the unique metabolic demands of pALS and may be contributing to worsening inflammation and metabolic derangements. Dietary studies on tube feedings only evaluate macronutrients while disregarding the immune and inflammation-modulating variables of the total formula. The Academy of Nutrition and Dietetics has concluded the lack of any efficacious diets for ALS [54]. Could this conclusion result from a generic approach to nutrition intervention that uses oral/enteral formulas with imbalanced substrates and toxic ingredients?

49.25 Healthy Enteral Feedings

There are convenient whole food-based oral/enteral products. These are unique formulations, but all share the same commitment to nutritional quality.

Homemade oral/enteral formulas are another favorable option. Steve Smith, an ex-NFL player, was on commercial tube feedings for 6 years before changing to a whole foods homemade tube feeding. Enough formula is made to last for 2 weeks, frozen, and then used as needed [246]. From the author's communication with his wife, Chie Smith, while Steve was on commercial feedings, he was diabetic and prescribed metformin twice daily, constipated, bloated and had fingernail fungus. After he switched to whole foods homemade feedings, his diabetes was reversed and all other symptoms cleared up. Chie Smith granted permission to include this information in this reading.

49.26 Foods Containing Phytonutrients

A recent *JAMA Network* report described a cohort of 302 ALS patients studied for 5 years and found there was higher function at the time of diagnosis when antioxidants, carotenes, fruits, and vegetables were in the diet [247]. Many phytonutrients can cross the BBB to increase the endogenous antioxidant capacity of the brain to protect against oxidative stress in neurodegenerative disorders [248]. Because ALS is a multifactorial disease, bioactive compounds like flavonoids that target more than one aspect are needed to fight this devastating disease [249] (Table 49.2).

49.27 Environmental Toxins

There is a broad scientific consensus that sporadic ALS is caused by gene-environment interactions. In fact, given that only about 10% of ALS diagnosis has a genetic basis, gene-environment interactions may account for the remaining sporadic cases of ALS. Unfortunately, there's been relatively little attention paid to environmental toxins and lifestyle factors that may trigger the cascade of motor neuron degeneration leading to ALS [270]. Ultimately, the relationship between genetic background and xenobiotics may be the avenue to pursue in order to clarify the influence of environmental factors in ALS [271]. Accumulating data indicate that environmental exposure may influence the development of the ALS phenotype, suggesting that specific populations of neurons may be more sensitive to specific toxins; however, specific exposures have not yet been linked to precipitating ALS [272].

Several occupations are linked to an increased risk of ALS such as welders, electrical workers, athletes from head injuries and chemicals used on athletic fields, carpenters, cockpit workers, construction workers, farm workers, hairdressers, house painters, laboratory technicians, leather workers, machinists, medical service workers, military personnel, power production plant workers, tobacco workers, precision metal workers, rubber workers, veterinarians, nurses, funeral directors, truck drivers, flight attendants, firefighters, and miners [23, 273–277].

The following environmental exposures have been identified as potential risk factors for ALS, such as electromagnetic fields, heavy metals, pesticides, beta-methylamino-L-alanine and cyanobacteria, head trauma, metabolic diseases, cancer, viral infections, formaldehyde, diesel exhaust, polychlorinated biphenyls (PCB), polycyclic aromatic hydrocarbons (PAH) and dioxin, selenium, zinc, copper, smoking, and aromatic solvents in residential ambient air [23, 270, 273–274, 278–279]. Many studies have shown elevated glutamate levels in different brain areas due to electromagnetic radiation, aluminum, cyanide, aspartame, and MSG. In addition to glutamate neurotoxicity, glutamate has been found to mediate the hazardous effects of some environmental pollutants [280].

US statewide mortality for motor neuron diseases are significantly correlated with the percentage of the state's population that uses well water, a known reservoir for *Legionella* infections that may cause some cases of ALS. For example, Vermont has the highest age-adjusted motor neuron disease

Table 49.2 Phytonutrients

Phytonutrient	Proposed activity	Reference
Pomegranate juice	Contains many polyphenols; inhibits excitotoxicity and calcium influx in human neurons	[251]
Avocados	Contains glutathione, phytosterols, carotenoids, flavonoids, omega-3 and oleic fatty acids; protects against oxidative stress, mitochondrial dysfunction, and neurodegeneration	[252]
Walnut, date, and fig extracts	Protects against quinolinic acid (QUIN) and 1-methyl-4-Phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced excitotoxicity in human neurons	[253]
Cruciferous vegetables	Contains sulforaphane, activates Nrf2 and antioxidant response element (ARE), protects against oxidative stress, regulates several genes (Keap1/Nrf2) that protect against neurodegeneration, and penetrates the BBB to deliver neuroprotective effects in the CNS	[254]
Blueberries, grapes	Contains resveratrol, improves mitochondrial bioenergetics, improves autophagy in ALS, activates survival pathways (sirtuin-1, AMP-kinase), delays ALS disease onset, and extends survival	[255]
Asparagus	Contains sarsasapogenin, increases proteins called neurotrophic factors, and mimics their effects in the CNS, and orphan designation of sarsasapogenin was granted in the United States for the treatment of ALS	[256]
Green tea	Contains epigallocatechin gallate (EGCG) – protects motor neurons from stress, significantly prolonged symptom onset, and increased life span; neutralizes ferric iron to form redox-inactive iron in neuronal cells	[250, 257]
Cherries	Contains anthocyanins – protect neurons from oxidative stress, especially tart cherries	[258]
Pecans	Delayed ALS progression, increased survival of motor neurons	[259]
Saffron	Contains crocin, protects neurons from demyelination, and suppresses inflammation	[260]
Cocoa	Contains polyphenols (catechin and epicatechin), downregulates excitotoxicity, protects neurons from neurotoxins, reduces neuroinflammation, promotes neuronal survival and synaptic plasticity	[261]
Artichoke, parsley, celery, peppers, olive oil, rosemary, lemons, peppermint, sage, thyme	Contains luteolin and apigenin, prevents neurotoxic inflammatory mediators, reduces stimulation of microglial cells, neutralizes free radicals, promotes nerve and muscle function, reduces microglial CD40 expression	[262–263]
Lemon peel essential oil	Contains limonene and other flavonoids, inhibits lipid peroxidation by inhibiting quinolinic acid-induced malondialdehyde production, scavenges free radicals, and chelates ferrous iron	[264]
Turmeric	Contains curcumin, inhibits cytotoxicity, modulates microglial gene expression and migration, inhibits lipopolysaccharide neurotoxicity, ameliorates cellular damage by heavy metals, attenuates reactive oxygen species COX-2 expression in ALS	[265–266]
Coffee	Contains chlorogenic acid, protects degenerating motor neurons, reduces upper and lower motor neuron excitability, increases antioxidant enzyme capacity; not associated with increased ALS risk in humans	[267–268]
Cannabis sativa	Contains cannabinoids, provides antioxidant, anti-inflammatory, and neuroprotective effects in the CNS, and humans studies indicate cannabinoids may ameliorate spasticity, appetite loss, depression, pain, and drooling	[269]

mortality rate and historically has had a high prevalence of legionellosis [281]. Bisphenol A (BPA) and phthalates pose a theoretical risk of ALS, and 6–10% of ALS is apparently caused by any of the following toxins: DDT, lead, mercury, and organophosphate pesticides [110].

Many heavy metals are potential risk factors for ALS. Lead, manganese, iron, selenium, copper, aluminum, arsenic, cadmium, cobalt, zinc, uranium, and vanadium have been found in higher levels in the CSF of ALS patients when compared with healthy controls [23]. Single metal evalua-

Table 49.3 Heavy metals

Heavy metal	Adverse effects	References
Mercury	Mercury toxicity listed in differential diagnosis of ALS; vapor from mercury amalgams absorbed by motor neurons leads to increased oxidative stress and enhanced glutamate toxicity Accidental mercury exposure may be associated with ALS Retrospective study reported a statistically significant association between an increased number of amalgam fillings and the risk of motor neuron diseases pALS should have mercury amalgam fillings removed under the care of a biological dentist accredited through the International Academy of Oral Medicine and Toxicology Exposure to mercury from amalgams removed incorrectly may hasten onset or worsen ALS Methylmercury from fish may hasten the onset of ALS and worsened outcomes for pALS eating fish high in methylmercury	[87, 270, 284–289]
Aluminum	Aluminum adjuvants in vaccines are neurotoxic and change DNA expression Animal models after injections of aluminum adjuvants are associated with neurological deficits and lead to an ALS phenotype Link in aluminum miners and development of ALS Avoid aluminum in food products such as baking powder and processed foods, food additives with the word aluminum, and aluminum cookware Aluminum can be found in toothpastes, antiperspirants, dental amalgams, nasal sprays, antacids, and popular prescription and OTC medicines	[290–293]
Cadmium	Impairs the BBB Reduces brain Cu-Zn SOD Enhances excitotoxicity of glutamate Suggested as a cause-effect relationship in a worker at a battery factory diagnosed with ALS Elevated levels are found in cigarette smoke, electronics, seafood and organ meats, and plant foods grown in contaminated soils Cocoa powder generally contains four times amount Cadmium and lead have been found in 45 out of 70 popular chocolate products	[294–297]

tions may underestimate their relevance for health risks compared to the additive synergistic effects of various metal interactions, and more studies are needed to investigate the role of environmental factors on the development of ALS [282] (Table 49.3).

A study involving 156 ALS patients and 128 healthy controls evaluated for occupational and residential exposure by obtaining surveys of exposure and blood levels of 122 persistent neurotoxic organic pollutants [298]. Seven pollutants were significantly associated with ALS, including three organochlorine pesticides (OCPs), two polychlorinated biphenyls (PCBs), and two brominated flame retardants (BFRs). Although there was weak concordance of survey data and blood measurements, there were strong associations of specific environmental toxins and ALS, which may represent modifiable risk factors [298]. A large population case-control study found that long-term exposure to traffic-related air pollution increases susceptibility to ALS [299].

Although the literature overwhelmingly implicates environmental toxins with risk of ALS, a contradictory CDC study found that "white-collar" jobs are linked to a 55–67% increase in ALS deaths, compared to a 31% decrease in ALS deaths in occupations more likely exposed to environmental toxins [300]. These statistics are confounding and counterintuitive yet implore us to continue examining the interrelationships of toxins, both separately and cumulative, toward the risk of ALS.

It is important to remember that the IFMNT approach does not require unequivocal proof that specific toxins cause ALS, as neurotoxins and all toxins are harmful for pALS. Most pALS that we see in the clinic are being cared for at home. It is our responsibility to help our patients remove existing unintended exposures in their homes while reducing their toxic load through responsible detoxification support and elimination.

49.28 Detoxification of Heavy Metals

The use of chelating agents to treat acute metal poisoning is now well established; however, adaptation of chelation therapy to neurodegenerative diseases is directed toward brain metal redistribution rather than brain metal scavenging and removal [301]. This review found that chelation therapy has not been reported to help ALS patients and may cause harm in some cases [62]. Chelation therapy should be undertaken by a professional trained in the use of chelating agents in neurodegenerative disorders, both over-the-counter and pharmaceutical.

49.29 Natural Chelators

Some examples of natural chelators are curcuminoids and catechins (green tea, berries, cocoa, onions) which permeate the BBB and combat neurotoxicity [250]. Modified citrus pectin as well as dietary fibers from grains and fruit may interrupt entero-

hepatic circulation of metals, with findings of reduced levels of mercury in the brain and blood [302]. Sulfur-containing foods, such as allium from garlic, and brassicas, such as broccoli, support glutathione [302].

Beyond the effort to chelate specific heavy metals, we must try to support the liver's detoxification pathways for pALS. Diet should focus on optimizing the body's metabolic Phase I and Phase II detoxification pathways and metallothionein, through a variety of foods and food-based nutrients known to contain bioactive compounds with demonstrated or potential clinical impact on detoxification systems [303]. The authors report clinical evidence of effects from cruciferous vegetables, allium vegetables, apiaceous vegetables, grapefruit, resveratrol, fish oil, quercetin, daidzein, and lycopene [303].

49.30 Essential Metals

49.30.1 Iron

Iron dyshomeostasis is linked to ALS with brain iron accumulation in the motor cortex, and the SOD-1 mutation has been shown to cause damage via iron-induced oxidative stress [304]. Also, there appears to be a link between mutations in the hemochromatosis gene (HFE; principally the H63D polymorphism) and SALS [305]. Iron accumulation in the motor cortex corresponds to the hand knob region, presumably causing small hand muscle weakness seen in these patients [23]. Higher concentrations of serum ferritin correlate to poor prognosis in ALS patients [305].

If a pALS has elevated ferritin, then it is recommended to avoid high-iron foods [306]. Curcumin, green tea, and blueberries provide direct binding and complex formation with toxic metals such as iron, with enhanced free radical scavenging effects protecting the neurons from toxicity and inflammation [301].

49.30.2 Copper

Copper and iron are described as "peas in a pod" since they are both highly reactive redox metals, where a deficiency or excess of either one can damage mature neurons and neuronal activities [307]. Both excessive [308] and deficient [309] copper have been associated with ALS. Copper is a regulator of the contents of iron in the CNS [310]. The balance of metals is regulated by the integrity of the BBB and Blood-CSF Barrier (BCB), which are damaged in neurodegenerative diseases and from environmental interferences [307].

A patient-driven ALS free copper pilot study showed that free copper was elevated in ALS, postulating that low ceruloplasmin was connected to initiation of the disease process; thus high free copper would correlate with neuronal damage [311]. Free copper initiates free radicals which is potentially harmful for brain circuits, whereas ceruloplasmin scavenges free radicals and participates in many important enzyme systems [310].

Dr. George Brewer, an expert in copper metabolism, describes two forms of copper: Copper 1 (Cu+) cuprous which is organic and found in nature and Copper 2 (Cu++) cupric which is inorganic and found in supplements [312]. Cu++ is also found in drinking water exposed to copper pipes (Oskarsson, 2011). To lower overall copper load and especially free copper, it is advised to reduce intake of red meat, monitor copper in one's water supply, and avoid copper in supplements. Also, N-acetylcysteine has been proposed as a copper chelator in ALS treatment [270].

In the potential case of copper insufficiency or deficiency, dietary copper in the organic Copper 1 cuprous (Cu+) form can be found in foods such as sesame seeds, cashews, soybeans, sunflower seeds, shitake mushrooms, tempeh, garbanzo beans, lentils, lima beans, and walnuts [313].

49.31 BMAA

Beta-methylamino-L-alanine (BMAA) is a cyanobacterial neurotoxin that has been found on autopsy of SALS patients, suggesting a gene-environment interaction triggering ALS [314]. It was first identified 50 years ago in Guam where one in three adults died of ALS. In short, they determined that the cyanobacteria biomagnified from cycad tree seeds eaten by fruit bats that subsequently were eaten by natives [315]. Cyanobacteria are some of the oldest organisms on the planet and can occur wherever there is moisture. Blooms are fed largely by nutrients in agricultural and urban runoff, and fish and shellfish from contaminated waters may be another way that people ingest BMAA [316]. The body may mistake BMAA for the amino acid L-serine, which is mistakenly inserted into proteins that become misfolded [316]. Chronic dietary exposure to BMAA is a cause of neurodegenerative illness; therefore a clinical trial will determine if L-serine is a safe and efficacious treatment to reduce disease progression in ALS [317].

49.32 Gastrointestinal System

ALS and the gastrointestinal (GI) system have some mutual patterns of pathological expression, and the care of ALS patients should include evaluation and treatment of the GI system. The bidirectional gut-brain axis consists of the entirety of the intestinal microbiota, enteral nervous system (ENS), parasympathetic and sympathetic nervous systems, CNS, neuroendocrine connections, humoral pathways, cytokines, neuropeptides, and signaling molecules [318]. ENS deficits are reported to accompany an increasing number of CNS disorders, from neurodevelopmental to neurodegenerative, and dysfunctional GI manifestations might occur even before CNS symptoms become evident [319]. Neuronal connections and the immune system might provide conduits that allow diseases acquired in the gut to spread to the brain, such as ALS, a disorder with both gastrointestinal and neurological consequences [319]. The gut is both a pathological marker of neurodegeneration and a site for studying the pathology of neurodegeneration [320] (Table 49.4).

Table 49.4 Gut-brain pathologies in neurodegeneration

Interactions		References
Misfolded proteins	SOD1 and TDP43 occur in both the ENS and CNS reflecting common neurodegenerative mechanisms	[320]
GI phenotype of ALS G93A mice	Show abnormal tight junctions, increased mucosal permeability, decreased Paneth cell expression of the antibacterial peptide defensin-5	[319]
Microbiome abnormality of ALS G93A mice	Show abnormal intestinal microbiome and decreased butyrate-producing bacteria associated with increased inflammatory cytokines (IL-17) and intestinal permeability before ALS onset and during ALS progression; cyanobacteria from the GI tract may produce elevated levels of ß-N-methylamino-L-alanine (BMAA) in the brain, an excitatory neurotoxin which depletes glutathione and induces protein misfolding	[321, 323–324]
Lipopolysaccharides from gut-associated microbial translocation	LPS are elevated in the plasma of sporadic ALS patients; LPS are inversely correlated with anti-inflammatory monocyte IL-10 expression in sporadic ALS patients which may be associated with disease progression	[325]
Neurotoxins	Produced in the gut, such as clostridial species; might cause sporadic ALS	[322]
Xenobiotics	Can disturb microbial balance; become more toxic to the brain if microbial demethylation is suppressed or the absence of necessary GI microbiota reduces fecal excretion; mercury is a neurotoxin that may increase the risk of ALS	[287, 326–327]

49.33 Microbiome

Gut microbiota influence neurodegenerative diseases through such pathways as the vagal nerve, cytokines, neurotransmitters, bacterial metabolites, and the HPA axis [328]. Figure 49.9 depicts how changes in the gut microbiota impact neuropathology and neurodegenerative diseases through neurological, endocrine, and immune pathways [318].

It is rare for individual researchers to conduct both animal and human ALS studies of the microbiome. The collaboration between preclinical and clinical researchers strengthens the quest for scientific understanding of gut-brain pathologies and potential therapeutic treatments of dysbiosis in pALS, which may affect onset and progression of ALS. The University of Illinois at Chicago, in collaboration with Wellness and Integrative Neurology in Westchester, Illinois, published the first comprehensive examination of the gut microbiome in pALS [329]. They compared five ALS patients with a large database of healthy cohorts to evaluate bacterial diversity and abundance, infection, short-chain fatty acids, inflammation, and immunology through stool testing [329]. The most notable results included low microbial diversity in all ALS patients, low *Firmicutes*/*Bacteroidetes* ratio and elevated gut inflammatory markers (calprotectin, secretory IgA, and/or eosinophilic protein X) in most patients, celiac disease in one patient, and candida infection in another patient [329]. All patients had preexisting GI symptoms prior to their ALS diagnosis. The authors encouraged further research using comprehensive stool analysis to evaluate microbiome and other gut health indices in ALS, in addition to studying how other inflammatory markers commonly reported in ALS patients (serum LPS and CSF cytokines IL-17 and IL-23) might correlate to gut inflammation in pALS [329].

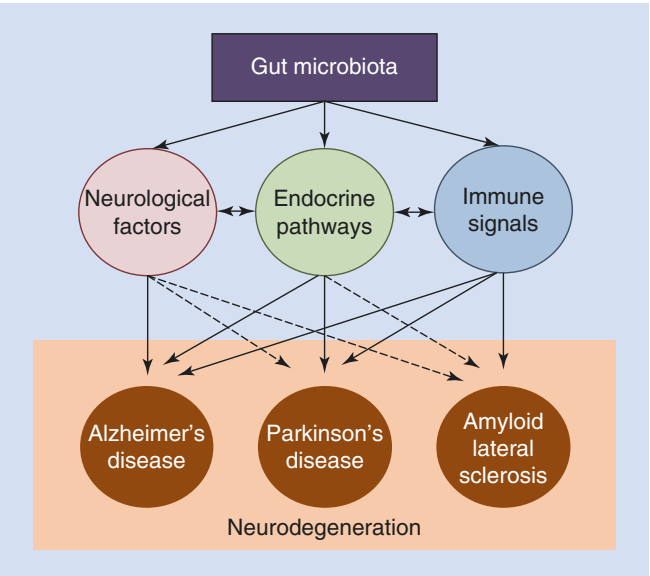

Fig. 49.9 Gut microbiome [322]. (Reprinted from Westfall et al. [318]. With permission from Springer Nature)

There are other active investigations into the microbiome of ALS patients. The Microbiome Assessment in People with ALS (MAP ALS) at the time of this writing is seeking 100 pALS and 100 healthy volunteers for a one-time stool collection for microbiome assessment [330–331]. In contradiction to the findings that the microbiome could be involved in ALS, a study of 25 ALS patients and 32 controls found that microbial diversity is not altered in ALS and argues against a primary role of the gut microbiota in it [332].

Given that several ALS G93 mouse studies indicate an associated role of the gut microbiota and inflammatory

markers with onset and progression of ALS [329] and that pALS often report gut symptoms before and after diagnosis of ALS, it is timely and vital for continued research in the gut-brain relationship in ALS. It may be important to study the microbiome as it relates to gut-associated inflammatory and immune markers, short-chain fatty acids, and intestinal permeability to better understand the gut-brain connection in ALS.

Box 49.1 Suggestions to Assess and Support the Gut-Brain Connection in pALS

- *Obtain comprehensive stool testing* to assess microbiome diversity, beneficial, pathogenic, potentially pathogenic and commensal bacteria, yeast, viruses and parasites, digestive enzymes, inflammatory and immune markers, malabsorption, intestinal permeability, short-chain fatty acids and other factors.
- *Individualize probiotic recommendations* based on results of stool testing.
- *Individualize antimicrobial recommendations* based on specimen sensitivity testing.
- *Evaluate for small intestinal bacterial overgrowth (SIBO)* through breath tests to detect hydrogen and methane gas-producing bacteria.
- *Remove allergenic foods and xenobiotics* to reduce gut and systemic immune activation resulting in neuroinflammation.
- *Add digestive enzymes and HCL* if required.
- *Add supplemental nutrients and herbs* to heal mucosa, reduce gas and bloating, and decrease abdominal pain.
- *Eat organic, low glycemic index, or ketogenic diet with high levels of phytonutrients* to heal the gut and protect the brain.

49.34 Probiotics

One study found that archaebiotics, which are probiotics derived from prokaryotic single-cell bacteria, could reduce mutant SOD1 misfolded proteins and cellular toxicity in ALS cell cultures [333]. Since then, research in animals has evaluated specific probiotic strains in neuroprotection, MS, Alzheimer's disease, Parkinson's disease, and neurodegenerative disorders in general, though less specifically in ALS [318]. Positive effects, such as improved antioxidant capacity, reduced inflammation, reduced microglial activation, increased GABA, downregulating genes involved in neurodegeneration and reducing neuronal apoptosis, are associated with specific probiotic strains [318], which hopefully will lead to researching specific effects of probiotic strains that might be therapeutic in ALS.

49.35 Butyrate

Diet influences intestinal microflora composition, which has an important role in the fermentation of dietary fibers leading to the production of short-chain fatty acids (SCFAs) such as butyrate [334]. Butyrate is primarily used as an energy source for colonocytes, and some butyrate exits the portal vein to the liver, but it is the remaining butyrate at the distal end of the colon that enters the systemic circulation and reaches the BBB [335]. Butyrate exerts multiple beneficial effects at intestinal and extraintestinal levels, including neuroprotection, related at least in part to the epigenetic regulation of gene expression [334]. Phenylbutyrate (PB) acts as a prodrug to easily penetrate the BBB [336].

In ALS mice with abnormal microbiomes, damaged junctions, and leaky guts, supplementation with butyrate restored the microbiome, improved neuromuscular function, delayed onset of ALS symptoms, and extended life span compared to untreated ALS control mice [321]. Additionally, sodium butyrate was associated with protection of the endothelial cells of the BBB through increased expression of tight junctions [337]. This role of butyrate working to protect both the gut and brain endothelial barriers nicely illustrates a congruent linkage between the gut and the brain.

A Phase II clinical study of sodium phenylbutyrate (NAPB) in ALS significantly increased histone acetylation, and the majority of patients tolerated very high doses, yet it was found that the lowest dose of 9 grams daily was therapeutically beneficial [338]. Another Phase II clinical trial is underway at the time of this writing and will evaluate a combination compound of PB and tauroursodeoxycholic acid (TUDCA) for the treatment of ALS [339]. TUDCA is a bile acid that may have cytoprotective and anti-apoptotic action with potential neuroprotective activity, having shown significantly higher ALSFRS-R scores in pALS who received TUDCA in a proof of principle study [340]. PB and TUDCA combination therapy is designed to reduce neuronal death through blockade of key cellular death pathways originating in the mitochondria and endoplasmic reticulum while measuring the rate of decline from the ALSFRS-R and monitoring biomarkers of neuronal death and neuroinflammation [339].

The following foods will promote butyrate production: whole grains; fiber-rich fruits and vegetables such as green beans, legumes, leafy greens, apples, kiwi, and oranges; milk fats (butter, ghee); and prebiotics such as raw jicama, underripe bananas, Jerusalem artichokes, and raw dandelion greens [341]. Over-the-counter products are available in time-release formulations that maximize absorption and have better taste and smell compared to the common mineral salt butyrate products using sodium, potassium, calcium, or magnesium.

49.36 Small Intestinal Bacterial Overgrowth (SIBO)

The involuntary muscles such as those that control the GI tract are not directly affected in ALS. However, prolonged immobility can lead to indirect GI issues in ALS [342]. Gastrointestinal motor dysfunction or motility disorders, such as delayed gastric emptying and delayed colonic transit times, can occur in ALS, even if patients do not complain of GI symptoms [343], and motility disorders are a risk factor for SIBO [344].

Clinical manifestations of SIBO seriously impact nutritional status via weight loss; steatorrhea; deficiency of fat-soluble vitamins, vitamin B12, and iron; excess folate; low total protein and albumin; and decreased xylose absorption when evaluating carbohydrate malabsorption [344]. Further discussion of SIBO can be found in ▶ Chaps. 23 and 24.

49.37 Laboratory Biomarkers

Laboratory biomarkers have been a missing piece in the diagnosis and monitoring of ALS. At present, the diagnosis of ALS is based on a differential clinical diagnosis and may include electromyography, nerve conduction studies, muscle biopsy, MRI, and genetic testing [283]. The key monitoring measures are the ALSFRS-R, clinical examination, and spirometry [25], with outcomes determined by survival rates [345]. From standard laboratory measurements to in-depth metabolomics, biomarkers have become the focus of intense research in the field of ALS, with the hope for therapeutic development [346].

Few studies have evaluated deficiency or overload of essential elements in ALS using blood, urine, and hair. A study of 34 ALS patients and cohorts evaluated calcium, zinc, magnesium, iron, copper, magnesium, and selenium to determine if different concentrations were related to a higher frequency of ALS. Levels of Ca and Cu in blood and Se and Zn in hair were significantly higher in pALS than controls, while urinary excretion of Mg and Se was significantly lower in pALS [347]. The authors suggest that multiple metals involved in multiple mechanisms have a role in ALS degeneration and might serve as good biomarkers [347] (◘ Table 49.5).

◘ **Table 49.5** ALS serum biomarkers that increase risk

Laboratory assessment	Elevated levels	Lowered levels	References
Inflammation and immunity	Copper Sedimentation rate Fibrinogen hs/wr C-reactive protein TNF-alpha IL-2, IL-6, IL-8, IL-10, IL-18 Interferon-gamma CD4+ T lymphocytes CD16+ leukocytes Natural killer cell T lymphs Neutrophils/monocytes C16:1/C16:0 ratio Arachidonic acid	Albumin CD14+ monocytes CD8+ T lymphocytes IL-2	[209, 345, 354–361, 376]
Excitotoxicity and neurodegeneration	Ammonia Quinolinate Glutamate	Kynurenate Glutamine Vitamin D	[143, 348, 360]
Glycolysis and oxidative phosphorylation	Pyruvate Carnitine Phosphate		[349]
Lipids and liver function	LDL/HDL Triglycerides SGOT, SGPT		[222, 225, 352]
Collagen degradation		Hydroxyproline Type 1V collagen	[348]
Oxidative stress	Ferritin Homocysteine 8-OH-2′-Deoxyguanosine 4-OH-2,3-Nonenal (HNE) GSSG/GSH Prostaglandin (PgE2)	Folate Vitamin E Uric acid GSH GPx Transferrin	[345, 350, 359, 362]
Detoxification		7-Methylxanthine	[359]
Muscle mass	Creatine	Creatinine Creatine kinase	[348, 363]

Pathologically elevated and lowered serum biomarkers reflect ALS disease and progression. Many values may change from early to late progression of ALS. Some biomarkers appear paradoxical, such as the suggested protective effect of raised LDL/HDL and triglycerides; however, in this table elevated lipids are listed as detrimental biomarkers of ALS.

The following discussion will cover metabolomics, blood biomarkers, and the potential relevance of urinary organic acid (OAA) laboratory testing to extend understanding the metabolic and nutritional imbalances in ALS. It should be noted that the CSF represents a very valuable source of biomarkers, which contain proteins and metabolites at relatively higher concentrations than other fluids [345], but the invasive nature of CSF assessment makes it largely unavailable for IFMNT practitioners.

49.38 Metabolomics

Metabolomics is the study of small molecules in biological systems such as cells, tissues, blood, urine, and CSF. Metabolomic biomarkers reflect the overall metabolic status of an individual as the result of highly complex metabolic exchanges between diverse biological compartments, including organs, biofluids, and microbial symbionts [348]. Applied to a biofluid such as plasma, metabolomics could provide an understanding of biochemical changes in ALS and identify a panel of biomarkers for diagnosis and disease progression [349]. At present, we lack consensus and independent validation of metabolomics biomarkers for ALS [350]. Appropriate application of multimodal approaches, international collaboration, presymptomatic studies, and biomarker integration into future therapeutic trials are among the essential priorities going forward [364].

49.39 Urinary Organic Acid Analysis (OAA)

Does the urinary organic acid analysis (OAA) have clinical relevance for the IFMNT practitioner when caring for pALS? Urine is not subject to homeostatic mechanisms as much as the blood and CSF in neurodegenerative diseases; however, every neurodegenerative disease carries its own metabolic signature which is a potential biomarker [365]. There are limited studies using urine from pALS, since biomarker research has primarily focused on blood and CSF. A recent review on ALS-associated urinary biomarkers could only positively validate collagen degradation biomarkers and 8-OH2'dG [366]. The OAA reflects metabolic pathways that can't move forward due to inadequate nutrients, toxins, genomic influences, or disease states, causing buildup of pathway intermediates to overflow from the blood into the urine. It is challenging to discern OAA markers of nutritional imbalances from inherent ALS metabolic defects; however, a better understanding of ALS metabolism will help the clinician determine nutritional requirements. The urinary OAA analysis is helpful to evaluate requirements for Coenzyme Q10, B vitamins, and other nutrients in energy metabolism and assessment of metabolic contributions of environmental toxins, methylation, dysbiosis, oxidative stress, and other parameters. Interpretation and therapeutic intervention must be carefully considered in light of the signature metabolic abnormalities of ALS.

Box 49.2 The Above-Described Defects in Energy Metabolism May Be Reflected in the Urinary OAA

- *Pyruvate* may be increased during impaired metabolism to acetyl-CoA.
- *Lactate* may be increased since more pyruvate goes to lactic acid, and there is failure of the ATP-dependent muscle-neuronal-lactate shuttle to regulate the flow of lactate from muscle to neurons and vice versa. This leads to lactate toxicity and degeneration of nerve endings at the neuromuscular junction [367].
- *Citrate* may be lowered during impaired metabolism of oxaloacetate convergence with acetyl-CoA to form citrate.
- *Beta-hydroxybutyrate* may be increased during ketosis.
- *Alpha-ketoglutarate* may be increased during fatty acid metabolism and ketosis or may be decreased due to both impaired glycolysis, fatty acid oxidation, and deficient glutamate transamination.
- *Adipate and suberate* may be increased during impaired fatty acid oxidation and carnitine deficiency. The demand for carnitine is increased to shuttle long-chain fatty acids from the cytosol to mitochondria for beta-oxidation [349].

Box 49.3 Impaired Urinary Neurotransmitters and Excitotoxicity

- *Quinolinic acid* may be increased
- *Kynurenic/quinolinic ratio* may be decreased, reflecting excitotoxicity and neurodegeneration. The kynurenine pathway, the major biochemical pathway for tryptophan metabolism, is dysregulated in ALS. Accumulation of the neuroactive and cytotoxic intermediate, quinolinic acid, contributes to the pathology of ALS [143].
- *Ammonia* may be increased. Neurotoxic ammonia accumulates in ALS during impaired glycolysis, along with reduced ammonia removal and hepatic urea cycle dysfunction [353], and during excessive protein intake.
- *Glutamate* may be increased [368].
- *Proline* may be increased due to weakened collagen tissues, especially noticeable in the skin. The increased urinary excretion of collagen metabolites is highly associated with ALS [348].

49.40 Impaired Glycolysis, TCA Cycle, and Oxidative Phosphorylation

A combination of defective energy metabolism, decreased glucose use in the cortex and spinal cord, reduced expression of TCA cycle intermediates in the brain and spinal cord, damaged neuronal mitochondria, and mitochondrial Electron Transport Chain (ETC) dysfunction suggest a bioenergetic limitation of ATP generation [41]. This is due to reduced phosphofructokinase, pyruvate dehydrogenase [241], citrate synthase, succinate dehydrogenase [369, 370], and impaired oxidative phosphorylation ETC complexes I, II, III, and IV [371]. These defective metabolic pathways shift energy utilization through lipolysis, beta-oxidation of fatty acids, and ketosis [44, 372, 373].

49.41 Methylation and ALS

It is necessary to understand the causal relationship between DNA methylation and ALS and how environmental factors trigger the DNA modifications. For example, hypomethylation of promoter regions of SOD1 and VEGF causes no transcriptional silencing in ALS, whereas hypermethylation of the promoter regions of EAAT2 and ATXN2 causes functional loss of excitatory amino acid transporters and pathogenic CAG expansions [351]. MTHFR C677T and A1298C polymorphisms are reported as genetic risk factors for SALS women [374]. Homocysteine exerts multiple neurotoxic mechanisms relevant to ALS pathogenesis [375], and elevated plasma homocysteine is a biomarker of ALS [376]. The pathway from homocysteine to S-adenosylmethionine (SAMe) may be blocked by deficiencies in folate, B6, and B12 [351]; therefore the IFMNT practitioner should assess vitamin status and supplement accordingly.

49.42 Additional Considerations for Laboratory Testing

49.42.1 Erythrocyte Fatty Acid Analysis

The IFMNT practitioner might obtain the ALS patient's fatty acid status through an essential fatty acid analysis based on red cell biopsy to help guide therapeutic interventions. On ▶ ClinicalTrials.gov, a study was commenced in 2015 titled "Evaluating the Potential of the Diet as Disease Modifier in Amyotrophic Lateral Sclerosis" to study dietary intake and erythrocyte fatty acid composition as it relates to disease progress or survival [377]. The study aims to develop beneficial interventions and therapy options for ALS patients based on the understanding that PUFAs, especially DHA, are an important structural components in neuronal membranes, support neurogenesis and neuroprotection, and exert potent anti-inflammatory effects in the brain [377].

The erythrocyte fatty acid analysis could inform the practitioner of existing omega-6 to omega-3 ratios as well as levels of other parent fatty acids that contribute to these ratios. The omega-6 to omega-3 ratio of the average Western diet is 20:1, whereas the diet of our paleolithic ancestors contained a 1:1 ratio, the same level that is found in balanced neuronal lipids. This ratio (between 2:1 and 1:1) should be the target for human nutrition [378]. Also, the increased ratio of palmitoleic acid (C16:1) to palmitic acid (C16:0) increases ALS risk associated with misfolded proteins [209]. The IFMNT practitioner can assess erythrocytes fatty acids and adjust diet or supplements to optimize fatty acid ratios for pALS.

49.42.2 Liver Function and ALS

A high incidence of mild liver dysfunction and ultrastructural changes in hepatocytes has been found in ALS patients [379]. Elevated lipids and hepatic steatosis are frequent and unique phenomena of ALS [352]. These abnormalities are concomitant with elevated homocysteine, ammonia levels, and a faulty urea cycle [353]. Although it has been suggested that impaired liver function serves a protective effect, we should caution against inadvertent clinical dismissal of this phenomenon. The typical ALS diet contains very high levels of refined carbohydrates and sugars, especially in the form of fructose, which may contribute to impaired liver function, along with inherent lipid metabolism abnormalities in ALS. A low glycemic load or ketogenic diet would be advised to help protect the liver.

49.42.3 Thyroid and ALS

Repeated studies have shown that thyroid function in ALS patients does not differ from controls, and clinical parameters of the disease do not influence the measured hormones [380]. However, two large retrospective studies observed that approximately one-fifth of pALS reported a personal or family history of thyroid disease or had biochemical evidence of thyroid disease [95]. Each patient should be assessed with a complete thyroid panel, including autoantibodies to determine thyroid involvement.

49.42.4 Adrenal and ALS

ALS is associated with significant distress linked to changes in hypothalamic-pituitary-adrenal axis activity, possibly due to a loss of cortisol circadian rhythmicity. Increased morning plasma cortisol levels have been associated with spinal-onset ALS and in those with intermediate to rapidly progressing disease [381]. The researchers determined that the changes were too small to make it a sensitive biochemical biomarker [381]. Alternatively, researchers have found a blunted cortisol awakening response in pALS that correlated with disease and depression severity [382]. The adrenal status of each patient should be assessed through dried urine or salivary hormone testing measuring different time points during the day for cortisol levels.

49.42.5 Autoantibodies, Antibodies, and ALS

ALS lacks the prominent infiltrates of blood-derived mononuclear cells that characterize primary autoimmune diseases [383]. A panel of highly expressed serum IgG antibodies served as very sensitive and specific biomarkers to differentiate pALS from controls and monitor disease severity [386]. It is important to learn where, in the course of ALS disease progression, inflammation and immune responses are conferring protection or damage [384].

49.42.6 Infectious Diseases and ALS

Infections may play a role in the etiology or constitute a risk factor for ALS. A main cause of death in ALS is bronchial pneumonia and pneumonia [385]. The diagnosis of Lyme

disease can mimic other neurological disorders such as ALS [386]. Some pALS who have Lyme with coinfections can improve with antibiotics and nutritional and herbal support (such as the Cowden Protocol), especially when Lyme, Babesia, and mycoplasma are present [387]. Hepatitis B virus antibodies [388] and hepatitis C virus antibodies [389] have been suggested to be involved in the pathogenesis of ALS. ALS is highly associated with human endogenous retroviral (HERV) sequences, notably HERV-K compared to controls [390]. There has been increasing evidence for disseminated fungal infection in CSF and brain tissue from pALS [391], and 11 ALS patients revealed numerous varieties of intracellular and intranuclear yeast in neural tissue [392]. The common parasite, *Toxoplasma gondii* (toxoplasmosis), disrupts glutamate function, potentially leading to ALS in predisposed individuals [393]. It has been hypothesized that ALS can be caused by motor neuron toxins from a gut clostridial species [322]. Infections may be antecedents, triggers, or mediators of ALS; thus IFMNT practitioners must assess the potential role of viral, bacterial, fungal, and parasitic infections in pALS.

49.43 Supplements

49.43.1 Reductionist Versus Systems Biology Approach

The ALS research on specific vitamins, minerals, metabolic intermediates, cofactors, neurotransmitters, and other nutraceuticals are presented in ◘ Table 49.6. It is beyond the scope of this chapter to include all supplements that have been referenced in research, clinical practice, or public popularity. It is not surprising that no single nutraceutical has been proven efficacious for ALS treatment in humans. With the exception of the preclinical Deanna Protocol study [142] and the clini-

◘ **Table 49.6** Supplements

Supplement/diet	Research status	Rationale	Use in pALS	References
Deanna protocol	Preclinical	The metabolic therapy with DP supplementation delays disease progression and extends survival in ALS mouse model. The premise of the DP is to provide targeted metabolic therapies that address mitochondrial deficits and excitotoxicity, to increase survival and quality of life	Anecdotal reports (26 testimonials) from ALS patients describe symptomatic improvement in motor control following DP, and the ingredients (arginine-alpha-ketoglutarate, GABA, CoQ10, MCT oil) have a good safety profile without negative side effects being reported	[9, 142]
Arginine-alpha-ketoglutarate (AAKG) and alpha-ketoglutarate (AKG)	Preclinical	A study showed that AAKG and AKG, key ingredients of the Deanna Protocol (DP), are TCA cycle intermediates that stall ALS progression, improve motor performance and survival time, conceivably through protection of mitochondria in muscle fibers, motor neurons, and astroglial cells. Alpha-ketoglutarate can refill deficient C4 carbon TCA cycle intermediates (anaplerosis), which thereby will improve oxidative phosphorylation of any fuel in addition to providing alternative fuel.	Since AAKG and AKG have a good safety profile and are available OTC, pALS can consider this supplement individually or as part of the DP, recognizing that dosages may vary per individual. AAKG at 16–18 g in divided doses is required to have an effect, beginning at a lower dose to offset possible bloating and diarrhea	[142, 241]
Glutamate oxaloacetate-transaminase (GOT) and oxaloacetate (OAA)	Preclinical	OAA is a TCA cycle intermediate and glutamate scavenger in blood, reduces CSF glutamate by concentration gradient, and requires very high-dose injections to achieve this effect. OAA is pro-mitochondrial, yet researchers need to address the unknown brain and blood levels of OAA that cause this effect before clinical trials can be planned. The combined treatment of GOT and OAA provides significant neuroprotection through glutamate scavenging without needing to cross the BBB and may have high clinical significance for the future treatment of chronic neurodegenerative disease	A safe source of GOT and OAA for human consumption is not yet available for pALS; however, OAA is available for human use, and the authors cautiously advise prescribing OAA for ALS patients, until clinical trials show it is safe and effective	[9, 396, 397]

(continued)

49

Table 49.6 (continued)

Supplement/ diet	Research status	Rationale	Use in pALS	References
Acetyl-L-carnitine (ALC)	Clinical	ALC increases intracellular levels of carnitine and serves as a major transporter of fatty acids into the mitochondria and animal studies found that ALC counteracts motor neuron death. This study compared Riluzole alone to riluzole plus ALC, finding that patients on the combination treatment had significantly better results on the ALSFRS-R and forced vital capacity (FVC), and there were no differences in adverse events between the groups. There have not been any trials using ALC alone. The acetyl group allows it to cross the BBB which does not occur with L-carnitine	The study used ALC powder which was safe at 1000 mg TID, and 4000–8000 mg in divided doses is recommended on the ALS Worldwide website	[398–400]
Gamma-aminobutyric acid (GABA)	None	GABA is the major inhibitory neurotransmitter, and supplements that block glutamate release, enhance reuptake, or protect cells against the damaging effects of excessive glutamate may aid in the medicinal management of ALS. There is conflicting evidence with regard to GABA's BBB permeability and if GABA exerts any biologically relevant effect, even though there are hundreds of consumers who report a calming effect of GABA	OTC 250 mg BID of a sustained-release GABA. GABA is likely safe. Liposomal drug delivery in neurodegenerative diseases are potentially more effective at crossing the BBB and possibly a liposomal form of GABA would be more effective	[400–403]
Coenzyme Q10 (CoQ10) and MitoQ	Clinical (CoQ10) and preclinical (MitoQ)	CoQ10 is essential for ETC oxidative phosphorylation, an antioxidant, and is anti-inflammatory, apoptotic, and neuroprotective. An ALS Phase II clinical trial of CoQ10 as ubiquinone (1800 mg daily or 2700 mg daily) versus placebo found insufficient evidence to support a pPhase III trial. It should be noted that ubiquinone (oxidized state) formulations are significantly less bioavailable than ubiquinol (reduced state) formulations due to poor intestinal absorption. MitoQ differs structurally from CoQ10 by the addition of a fat soluble, positively charged molecule, facilitating ubiquinone to pass through the BBB and negatively charged mitochondrial membrane for conversion to the active form, ubiquinol. Preclinical ALS research on MitoQ demonstrated reduced oxidative stress, improved generation of ATP, preservation of the neuromuscular junction, and significantly extended life span, yet there are no human studies	CoQ10 has not shown efficacy in human ALS; however, daily doses can be as high as 3000 mg for pALS. Only one preclinical ALS study has shown that MitoQ readily crossed the BBB, entering deep inside mitochondria to quench free radicals and reduce oxidative stress, but human studies are lacking. CoQ10 and MitoQ are safe, well tolerated, and available OTC. MitoQ shows potential for pALS. Clinical trials of MitoQ in other conditions have used 40 mg and 80 mg doses of MitoQ	[404–409]

Table 49.6 (continued)

Supplement/ diet	Research status	Rationale	Use in pALS	References
Glutathione (GSH)	Clinical	ALS patients have lower brain GSH concentrations which suggest ongoing oxidative stress and compromised endogenous antioxidant defenses, thus promoting neuronal injury and functional decline in ALS. Clinically, GSH levels and the activities of glutathione reductase (GR) are reduced in ALS patients which correlate with disease progression. In addition to antioxidant defense, GSH is critical for detoxification of environmental toxins, which pose added risk to pALS. ALS patients received reduced GSH IM at 600 mg daily for 12 weeks, and results found no significant effect of GSH in modifying ALS progression. The evidence for GSH is mostly indirect in ALS, but hypothetically very promising.	Although there are no clinical trials proving the efficacy of GSH for ALS, there is potential therapeutic utility based on known metabolic roles of GSH in neurodegeneration. The best delivery system of GSH is IV 3000 mg once weekly, according to what is currently being used by neurologists and wellness clinics, and oral liposomal or sustained-release GSH is another option. Approximately 430 mg daily oral GSH would equal 3000 mg weekly, considering variations in GI absorption and mitochondrial availability. Although it is commonly assumed that supplemental GSH is degraded in the gut by gamma-glutamyl transpeptidase (GGT), a substantial amount of evidence shows that it is bioavailable and absorbed into the plasma. GSH has been extensively studied as a feasible and promising approach for targeted drug delivery across the BBB, especially effective with GSH attached to liposomes. A logical but unproven inference is that OTC liposomal GSH formulations would enhance the oral delivery of GSH	[410–418]
N-acetylcysteine (NAC)	Clinical	NAC boosts GSH production by providing cysteine, the rate-limiting amino acid in GSH production. Other mechanisms of NAC include modulation of oxidative stress, mitochondrial dysfunction, detoxification, neuroinflammation, and dysregulation of glutamate. Preclinical studies of NAC on ALS mice showed significantly delayed impairment and extended life span. The ability of NAC to cross the BBB is still disputed in the literature. A systematic review of NAC found that the largest study failed to show any benefit of subcutaneous 50 mg/kg/day of NAC in survival or disease progression when compared to pALS getting the placebo, and 3 other studies showed either no benefit or mixed results	NAC has not been proven efficacious in ALS yet is possibly supportive. 2–2.4 g oral NAC total daily dosing was safe and well tolerated, except mild GI symptoms were reported in some pALS	[419–421]
Alpha-lipoic acid (ALA)	Preclinical	ALA is an antioxidant and cofactor for several mitochondrial enzymes, and an animal study showed a significant delay in onset of ALS, increased survival, and attenuated weight loss compared to controls	ALA is well tolerated and safe and can be given orally or IV. Dosages range from 300 mg to 1200 mg daily in divided doses	[422–423]
Creatine monohydrate	Clinical	Creatine has demonstrated beneficial effects in AD, PD, and HD. Creatine is phosphorylated by ATP to the high-energy phosphocreatine which prevents energy depletion and stabilizes mitochondrial membranes by binding to phospholipids. Many preclinical studies were promising, though several clinical trials failed to show significant beneficial effects in ALS progression or survival. There are multiple anecdotal reports of beneficial effects and some positive results from a phase II trial	Creatine monohydrate might be helpful	[241]

(continued)

Table 49.6 (continued)

Supplement/ diet	Research status	Rationale	Use in pALS	References
Vitamin D	Clinical	Vitamin D has genomic and non-genomic effects on ALS: cell signaling, glutamate, matrix metalloproteinases, mitogen-activated protein kinase (MAPK) pathways, prostaglandins, oxidative stress, and other mechanisms. Severe vitamin D deficiency in pALS reduces life expectancy and accelerates the rate of decline by 4X, serving as a reliable prognostic factor of ALS. Low vitamin D levels were associated with the clinical severity of ALS. A study found that ALS patients receiving 2000 IU daily had a slower decline in ALSFRS-R at 3, 6, and 9 months after treatment initiation compared to untreated ALS patients even after data were adjusted for age and baseline vitamin D levels. Low vitamin D levels were associated with lower gross motor scores, but low vitamin D didn't predict disease progression over 12 months. Another study found a negative effect of higher vitamin D levels on prognosis in pALS. A recent study found that pALS receiving supplemental cholecalciferol 100,000 IU weekly did not result in any clinical differences or improve prognosis compared to untreated patients. It has been verified that vitamin D receptor gene polymorphisms are linked to ALS	Although studies on vitamin D are conflicting, and most don't consider genomic variables or diet, pALS might benefit with vitamin D as part of the total nutritional approach. Since pALS have reduced or no mobility and spend less time in the sun, the need for vitamin D and other synergistic nutrients (calcium, magnesium, vitamin K2, boron, etc.) is important for bone health too. A minimum of vitamin D3 2000–3000 IU daily is recommended on the ALS Worldwide website	[360–361, 424–429]
Vitamin E	Clinical	Vitamin E (alpha-tocopherol) protects cell membranes from lipid peroxidation, by decreasing pro-inflammatory cytokines such as IL-1ß and TNF-alpha. The year after Lou Gehrig was diagnosed with ALS in 1939, a preliminary report on vitamin E was published in the *Journal of the American Medical Association*, claiming that early treatment of ALS animals with alpha-tocopherol yielded "spectacular" results with the "possibility of not only arresting the process but of reversing it.". Numerous preclinical and clinical studies since then, and a pooled analysis of 5 prospective cohort studies, found that vitamin E supplementation was associated with lower ALS rates and that higher serum alpha-tocopherol was associated with lower risk of ALS	Although vitamin E is promising as an antioxidant, we still lack clinical trials that demonstrate benefits for survival outcomes, functional status, or quality of life. Only alpha-tocopherol has been used in human ALS studies, and 500 mg (1100 IU) twice daily is suggested on the ALS Worldwide website. It should be noted that alpha-tocopherol combined with mixed tocopherols (alpha, gamma, delta) protects cells from lipid peroxidation, more than alpha-tocopherol alone	[38, 61, 362, 430–433]
Vitamin B12	Clinical	Cell culture studies have shown that methylcobalamin can ameliorate oxidative stress, glutamate toxicity, and apoptosis that might be useful for ALS. High doses of B12 can inhibit DNA methylation which is known to be increased in the spinal cords of pALS and is potentially responsible for harmful transcriptional dysregulation. B12 lowers plasma homocysteine levels which are characteristically elevated in pALS and can be toxic to motor neurons in culture. B12 is a cofactor in the conversion of methylmalonyl-CoA (MMA) to succinyl-CoA, and elevated MMA is an indication of impaired myelin synthesis that affects neuronal function. Researchers from Japan presented results of a phase III clinical trial where early administration of ultrahigh-dose methylcobalamin (50 mg IM twice weekly) could reduce progression and increase survival by a median of 600 days compared with placebo; however, the latest new drug application for B12 as a treatment for ALS was withdrawn	B12 status should be assessed in each patient with a serum B12 and MMA. B12 IM shots allow for better bioavailability than oral, but oral may be satisfactory. Genomic variations might determine if methyl, hydroxyl, or adenosyl forms of B12 are preferred	[434–437]

Table 49.6 (continued)

Supplement/ diet	Research status	Rationale	Use in pALS	References
Niacin (B3) as nicotinamide riboside (NR)	None	A protein, SARM1, underlies axonal degeneration both through intrinsic removal of damaged axons and in neurodegenerative diseases such as ALS through rapid breakdown and depletion of NAD+. This causes a massive loss of energy supply within axons. This detrimental effect was reversed by supplementing with nicotinamide riboside (NR), a precursor of NAD, which maintained the energy status in axons. NR is a naturally occurring form of vitamin B3 present in trace amounts in some foods, and studies in AD models indicate bioavailability and protection to brain. Several clinical trials have assessed safety, tolerability, and efficacy of NR to raise NAD levels, yet there haven't been any clinical trials completed on neurodegeneration	NAD depletion is implicated in the pathogenesis of ALS, and supplying NR as a precursor to NAD has been shown to increase NAD levels in humans. Dosages of 250 mg to 1 g will be used in a clinical trial studying brain function and cognition with an estimated completion date of December 2018	[438–444]
Magnesium (Mg)	None	Mg is an essential mineral and cofactor for over 300 biochemical reactions, including energy metabolism, detoxification, nucleic acid and protein synthesis, ion transport, muscle function, bone health, and cell signaling. Inhibition of vital enzymatic activities in the CNS due to Mg deficiency was suggested as a causative factor in CNS degeneration, and patients with ALS had significantly lower levels of Mg in the CNS compared to controls. A synthetically developed compound, magnesium-L-threonate (MgT), shows enhanced brain bioavailability in preclinical studies. According to 5 large prospective cohort studies, the relation between Mg intake from diet and supplements was not associated with either ALS risk or protection, although Mg deficiency is a possible risk factor for ALS in individuals who are genetically vulnerable or exposed to heavy metals. This study did not evaluate Mg status through serum, RBC, or CNS Mg levels	It is suggested to obtain an RBC Mg to determine Mg status, but this does not necessarily reflect CNS Mg. There are many forms of Mg available orally and transdermally. MgT is the most bioavailable form for the brain. Products include Mg chelates, MgT, bath salts, lotions, sprays OTC	[445–448]
Hydrogen (H2)	None	Molecular hydrogen may be neuroprotective against ALS, possibly through abating oxidative and nitrosative stress and preserving mitochondrial. H2 has been studied in numerous diseases with multiple therapeutic targets, including a clinical trial in PD, showing significant symptomatic differences between the treatment and placebo groups. H2 is safe at high concentrations, modulates gene expression, penetrates biological membranes including the BBB, and is easy to administer dissolved in water	Although there are no clinical studies of H2 and ALS, it is safe, provides superior antioxidant bioavailability, and has shown beneficial effects in PD. Numerous studies suggest that H2 may be useful for prevention, treatment, and mitigation of neurological disorders	[449–452]
Lunasin	Clinical	Lunasin is a peptide found in soy and some cereal grains that can reduce oxidative stress and inflammation and alter histone acetylation and gene expression. There are no preclinical studies using lunasin in ALS; however mice studies indicate that lunasin crosses the BBB. The success story of an individual pALS using lunasin showed significant improvement in the ALSFRS. A clinical trial including 50 pALS, "ALS Reversals – Lunasin Regimen" was recently completed with results showing that Lunasin doesn't slow progression	Lunasin is non-GMO and considered safe	[394, 453]

(continued)

Table 49.6 (continued)

Supplement/ diet	Research status	Rationale	Use in pALS	References
Multivitamin mineral			It is recommended that pALS take a multivitamin mineral supplement free of copper and iron and with bioavailable forms of B vitamins and other nutrients	
Other nutraceuticals		*Bee venom* has a neuroprotective effect against motor neuron cell death and suppresses neuroinflammation-induced disease progression in symptomatic ALS mice *Berberine* was able to reverse TDP-43 aggregates and neuropathology through autophagy clearance in mice *Vitamin K2* occurs predominantly in all brain regions as menaquinone-4 (MK-4), influencing cell growth, survival, and apoptosis. Vitamin K also participates in the synthesis of sphingolipids for brain cell membrane structure, proliferation, differentiation, senescence, and cell-cell interactions. Vitamin K2 may protect against oxidative stress and inflammation *Vitamin C* is highly concentrated in the brain and is dysregulated in neurodegenerative disorders. A damaged BBB may lead to diffusion of ascorbic acid from the CNS and impair the brain's ability to maintain a high CSF/plasma ascorbic acid ratio. Vit C reduces abnormal proteins in human astrocyte glial cells; participates in antioxidant defense, biosynthesis of collagen, carnitine, tyrosine, peptide hormones, and myelin; supports neurotransmission; and protects against neurotoxicity and excitotoxicity. Vit C might paradoxically act as a prooxidant to produce hydroxyl radicals in the CSF of SALS patients while potentially reducing SOD activity. 5 pooled prospective clinical studies showed that neither a high Vit C diet nor long-term Vit C supplementation affected risk of ALS. Assessing Vit C status in pALS is challenging, as plasma levels only reflect recent dietary intake. Leukocyte levels more closely reflect tissue stores, but do not accurately reflect muscle and brain tissue stores. It would seem prudent to make sure that pALS are replete in Vit C and take enough supplemental Vit C to saturate tissue levels, approximately 200–400 mg daily *Vitamin A* supplementation is not therapeutically understood in ALS. Motor neurons in ALS patients have altered retinoid signaling genes and receptors which promote oxidative-induced cell death *Inosine* raises endogenous urate, a promising therapeutic target for antioxidant and neuroprotection, with expected completion of a phase II trial in 2020 *Lithium* may have neuroprotective properties as a pilot trial reported remarkable improvements; then subsequent clinical trials have failed to replicate the positive results. Trace elements: zinc and selenium in blood were inversely correlated with ALS in patients with worse function, whereas copper was positively associated with ALS. Over exposure to selenium in the inorganic forms has been hypothesized as a risk factor for ALS [462]. In another study, selenium showed a protective role through antioxidant mechanism		[60, 377, 454–463]

cal Lunasin Regimen study [394], other studies evaluate a single nutrient at a time, similar to the reductionist pharmaceutical model of studying a single compound at a time. The Deanna Protocol used a more holistic approach, which studied four supplements and a controlled diet to evaluate the synergistic effects in ALS mice [142]. It is necessary to recognize the importance of an integrated research approach to ALS by emphasizing the multifactorial pathological pathways of ALS and the need for developing therapeutic strategies based on a systems biology approach [395].

49.44 Conclusion

The role of nutrition science with translation into ALS treatment is slowly evolving. As stated 30 years ago, "Nutritional etiology of amyotrophic lateral sclerosis (ALS), and other motor neuron disorders, cannot be ignored even though many trials of nutritional therapy have not, thus far, yielded any benefit to the sufferers. Possibly the nutrients available, or the dosages used, have not been adequate to the circumstances; perhaps an as-yet-unknown nutrient is deficient, poorly absorbed or under-utilized" [464]. Similar hurdles are expressed in recent testimony from Dr. D'Agostino in *The Deanna Protocol*: "Ordinarily, there is no significant depth of exposure to nutritional biochemistry and metabolomics in a general medical school curriculum. So, it is not surprising that doctors don't understand metabolomics, unless they choose to specialize in this area. I don't think that neurologists are ready to accept that a patient with ALS can manage this disease by diet. So, there is going to be a natural resistance to any claims that metabolomics delays the progression of ALS" [465].

pALS experiment with diet and nutrition in their fight against ALS, sometimes with profound beneficial outcomes. As IFMNT practitioners, we must obligate ourselves to champion nutrition research and practice to its fullest therapeutic potential for pALS. In "Non-Familial ALS: A tangled web," the authors state "when insights from genetics, cell biology, and epidemiology can be brought together, this disease will give up its secrets" [466]. Nutrition underlies genetic expression, cell biology, and epidemiology, and nutrition may be one of the most important keys to unlocking the secrets of ALS.

50.1 Gastrointestinal Disorders: Clinical Features and Prevalence

50.1.1 Introduction

The role of the integrative nutritionist in maintaining and optimizing gastrointestinal health is paramount, especially given the expanding body of scientific research elucidating the influence of digestive function on systemic health. Nutritional status is associated with risk for digestive disease, while, in return, gastrointestinal conditions affect food tolerability and nutrient requirement.

Diet is inextricably linked to health outcomes and optimal digestive function. Epidemiological data demonstrate the association between inadequate dietary intake, low in fruit and vegetable consumption, and increased risk of stomach and colorectal cancer [1]. Concurrently, the presence of existing gastrointestinal dysfunction impacts nutrient demand and the potential for frank deficiency or subclinical insufficiency. This direct influence on nutrient uptake may ultimately manifest in myriad symptoms and potential sequelae in the GI patient. For example, in Crohn's disease patients, where surgical resections, fibrotic tissue, villous atrophy, excess fluid loss from diarrhea, and anorexia may occur, both macro- and micronutrient deficiencies are prevalent. (◘ Table 50.1).

The digestion and absorption of nutrients, regulation of motility, potential impact of food-mediated disease, and structural abnormalities that influence dietary intake are all critical considerations for the integrative nutritionist supporting patients with a diagnosed digestive disorder, as well as those exhibiting symptoms of gastrointestinal disturbance.

50.1.2 Digestion and Absorption of Nutrients

Due to the direct interface between consumed nutrients and gastrointestinal structures, clinical nutritionists serve as essential care providers for patients experiencing digestive symptoms and chronic GI conditions. The transport, breakdown, and absorption of macromolecules rely on appropriate physiological conditions. Many digestive diseases result in impaired digestion and absorption of nutrients, creating a cascading effect on other systems of the body and overall function. Overt nutrient deficiencies and subclinical insufficiencies are the resulting outcome of this impairment and are prevalent in gastrointestinal patients [4]. Addressing and mitigating the effects of maldigestion and malabsorption is vital for optimizing patient outcomes. Without such intervention, patients may develop sequelae that increase the complexity of their condition and require additional treatments and providers. As such, integrative nutritionists serve as provider for the GI patient and a linchpin to prevent downstream pathophysiology.

50.1.3 Regulation of Motility

Regulation of motility is an essential consideration influencing dietary consumption and the resulting prospect for GI symptoms. Transit time, while variable in the individual, generally falls within assessable parameters absent any pathophysiological factors. Under appropriate physiological conditions, motility through the intestinal tract adheres to a pattern as outlined in ◘ Table 50.2.

◘ **Table 50.1** Common nutrient deficiencies associated with Crohn's disease

Nutritional deficiency	Pathological basis	Sequelae
Calories	Anorexia, bile acid malabsorption	Cachexia, poor growth (pediatric)
Protein	Enteropathy, impaired gastric acid and pancreatic enzyme secretion, proinflammatory cytokine activity, increased energy expenditure	Cachexia, poor growth (pediatric)
Vitamin D, calcium	Long-term and systematic steroid use, malabsorption	Osteopenia/osteoporosis, increased risk for GI cancer (vitamin D)
Vitamin K	Modulation of gastrointestinal microflora	Poor coagulation
Zinc	Intestinal losses, malabsorption	Poor wound healing
B12	Ileal resection	Anemia, hyperhomocysteinemia
Folate	Medication	Anemia, hyperhomocysteinemia
Magnesium	Chronic diarrhea	Arrhythmia, muscle spasm, anxiety, seizure
Iron	Blood loss, exudative enteropathy	Anemia
Selenium	Malabsorption	Oxidative stress, poor thyroid function

Based on data from Massironi et al. [2] and Wędrychowicz et al. [3]

Table 50.2 Gastrointestinal transit times under normal physiological conditions

Gastric emptying	2–4 hours
Small bowel transit	4–6 hours
Colonic transit	24–72 hours

Based on data from Maurer [5, 6]

Motility disorders involve alteration in the transit of nutrients, as well as secretions into the digestive tract. Transit time impacts nutrient delivery and can manifest in a variety of symptoms:

- Abdominal distension
- Severe abdominal colicky pain
- Visceral hypersensitivity
- Constipation
- Diarrhea
- Gastroesophageal reflux disease
- Intractable, recurrent vomiting

Source (► http://emedicine.medscape.com/article/179937-overview).

Examples of relevant dietary modifications in such cases may include considerations around the intake of fiber, fermentable carbohydrates, lipid load, alcohol, caffeine, and electrolyte balance.

50.1.4 Food-Mediated Disease

In addition to optimizing nutrient absorption, integrative nutritionists help identify and manage food-mediated disease in the digestive patient. A growing body of evidence supports the role of food antigens as mediators of chronic disease in susceptible patients [7–9]. Consequently, clinicians may seek to modify dietary intake to remove food compounds that irritate the GI tract, exacerbate symptoms, and cause reactivity in the patient experiencing immune imbalance. Lack of development in oral tolerance during early childhood, mediated by factors such as neonatal feeding, method of delivery, and inoculation of commensal gut bacteria, may determine eventual immune regulation and susceptibility to food-mediated disease [10]. This predisposition may carry over to adulthood and manifest in the appearance of symptoms when specific triggers result in perturbation of immune function. Antibiotic intervention, pathogenic infection, biopsychosocial stress, or a combination of these factors may serve as initiators of food-mediated dysfunction and symptom presentation. The proximity and activity of gut immunological structures, namely, the gut-associated lymphoid tissue (GALT), under modulation by the local commensal microbial population, play a crucial role and may, in part, dictate dietary modification.

50.1.5 Structural Abnormalities

Structural and mechanical abnormalities in the digestive patient are additional considerations for the integrative nutritionist. Each structure along the alimentary canal and in accessory digestive organs must work in concert to transform foodstuffs into a food bolus, chyme, and waste matter for eventual elimination. Structure dictates function; therefore, abnormalities in the tissues, glands, and cells integral to digestion can derail optimal gastrointestinal function and lead to symptoms. A comprehensive understanding of the complexity of GI anatomy and physiology is fundamental to developing appropriate treatment plans.

50.1.6 Prevalence of Gastrointestinal Disease and Global Impact on Health

In the USA alone, digestive disease accounts for nearly $142 billion in healthcare costs annually and affects upward of 60–70 million individuals [11]. Patients suffering from GI diseases encounter not only the physical burden of their symptoms but significant impairment in productivity, social interaction, and quality of life.

The data located in Fig. 50.1 highlight the significance of digestive disease in the USA and support the need for clinical dietetic intervention in this population:

Gastrointestinal disease can be divided into three primary clinical domains:

1. Organic or structural disease
2. Motility disorders
3. Functional disorders

- Prevalence: 60 to 70 million people affected by all digestive diseases
- Ambulatory care visits: 48.3 million (2010)
- Hospitalizations: 21.7 million (2010)
- Mortality: 245,921 deaths (2009)
- Diagnostic and therapeutic inpatient procedures: 5.4 million—12 percent of all inpatient procedures (2007)
- Ambulatory surgical procedures: 20.4 million—20 percent of all "write-in" surgical procedures (2010)
- Costs: $141.8 billion (2004)
- $97.8 billion, direct medical costs (2004)
- $44 billion, indirect costs—for example, disability and mortality (2004)
- Primary diagnosis at office visits: 36.6 million (2010)
- Primary diagnosis at emergency department visits: 7.9 million (2010)
- Primary diagnosis at outpatient department visits: 3.8 million (2010)

Fig. 50.1 Digestive disease statistics. (Based on data from The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) [11].)

50.1.7 Organic Gastrointestinal Disease

Organic gastrointestinal disease is classified based on histology and organ morphology [12]. Pathology in gastrointestinal tissue with observable damage to its form and structure marks this category of disease. Diagnosis of disease presence and measurement of its severity are identified via analysis of the affected tissues. Examples of organic gastrointestinal diseases include inflammatory bowel disorder (IBD) and esophagitis. In the presence of organic gastrointestinal disease, dietary restrictions may be necessary to alleviate irritation to the affected tissues. In specific scenarios, such as IBD, damage to absorptive sites warrants enhanced nutritional intake and may require supplementation where appropriate.

50.1.8 Motility Disorders

Motility disorders are defined in terms of organ function – specifically altered propulsion and movement of contents along the gastrointestinal tract. Abnormal visceral muscle activity results in dysregulated peristalsis or segmentation of the digestive tract, altering appropriate transit time of gastrointestinal contents. Assessment of motility disorders is conducted via the use of physiological testing, where transit time can be measured. Small bowel manometry, gastric emptying study, and whole-gut transit scintigraphy are diagnostic procedures available to analyze motility in the presenting patient. Gastroparesis and colonic inertia are two conditions classified within the clinical domain of motility disorders. Based upon the precise mechanism and location of motility disturbance, modification of dietary intake may be prudent to alleviate symptoms. For example, in the case of gastroparesis, which involves delayed gastric emptying and slowed movement of food from the stomach to the small intestine, intervention may require an initial reliance on a liquid diet, graduation to a small particle diet, and eventual progression to small frequent meals that are lower in fat and fiber content [13].

50.1.9 Functional Disorders

Whereas organic and motility disorders are diagnosed by clinical procedure, the patient's subjective illness experience distinguishes functional GI disorders (FGIDs). FGIDs are the most common GI disorders among the general population [14]. Estimates vary, but approximately 1 in 4 people or more in the USA have one of these disorders [15]. In the evaluation of functional GI disorders, the clinician relies on the patient-reported symptoms for classification. According to Drossman et al. "A symptom is a noticeable experiential change in the body or its parts that is reported by the patient as being different from normal and may or may not be interpreted as meaningful" [12]. This interpretation is a critical clinical distinction, as many patients become accustomed to familiar patterns of digestion and elimination, skewing their perspective and subjective experience. The task of the astute clinical nutritionist is to differentiate between what a patient deems as their "normal" state and ideal physiological function. This distinction often requires examination of health history and the use of the functional medicine timeline to identify initiating events where physiological function may have first shifted (Fig. 50.2).

A functional GI disorder is characterized as a syndrome based on a constellation of symptoms and is diagnosed by Rome criteria. Rome IV defines FGIDs as follows:

> » Functional GI disorders are disorders of gut–brain interaction. It is a group of disorders classified by GI symptoms related to any combination of the following: motility disturbance, visceral hypersensitivity, altered mucosal and immune function, altered gut microbiota, and altered central nervous system (CNS) processing. [12]

This definition highlights the variety of mechanisms at play within FGIDs, including both physiological components and biopsychosocial elements. In addition, the array of symptoms relates to the primary considerations for nutritionists discussed earlier (digestion and absorption of nutrients, regulation of motility, potential impact of food-mediated disease, and structural abnormalities).

Due to its prevalence, varied etiological factors, pathophysiological considerations, and influence on nutritional intake, this Grand Rounds in Gastroenterology will examine the case of a patient presenting with one of the most common, and often complex, functional gastrointestinal disorders: irritable bowel syndrome.

50.1.10 Prevalence of Irritable Bowel Syndrome

Irritable bowel syndrome affects between 7% and 21% of the population globally, and approximately 30% of people experiencing their IBS symptoms will consult physicians for medical intervention [16, 17]. Patients who seek medical attention do not necessarily have significantly different or more severe abdominal symptoms, but often report high levels of anxiety and greater impact of their symptoms on overall quality of life. Patients often do not pursue physician intervention at the onset of IBS symptoms and may wait months, if not years, before soliciting medical care. This hesitation to seek care may stem in part from the variable nature of IBS symptoms, which may wax and wane over time. Additionally, patient knowledge gap surrounding appropriate patterns of digestion and elimination may result in patients mistaking or attributing IBS symptoms to more general experiences of GI upset. Initial symptoms may at first be attributed to variation in food intake or acquisition of a transient stomach virus, and not necessarily be associated with an actual pathological condition. Finally, patients may forego medical intervention during initial prodrome with IBS, opting to manage the symptoms through self-medicating efforts using over-the-counter digestive aids or dietary modifica-

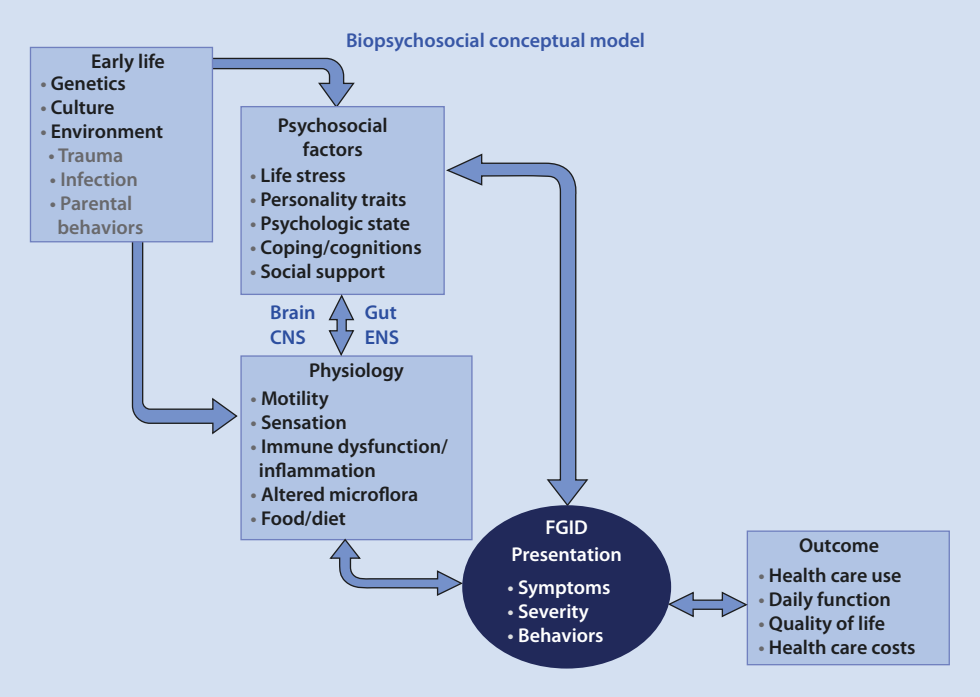

Fig. 50.2 Biopsychosocial conceptual model. A biopsychosocial conceptualization of the pathogenesis, clinical experience, and effects of functional GI disorders. There is a relationship between early life factors that can influence the psychosocial milieu of the individual, their physiological functioning, as well as their mutual interaction (brain-gut axis). These factors influence the clinical presentation of the disorder and the clinical outcome. Modified from Rome III. (Reprinted from Drossman [12]. With permission from Elsevier.)

tions. Inevitably when these measures fall short of remedying the situation, and symptoms increase in frequency and severity, impacting quality of life, individuals pursue medical care.

50.2 Pathophysiology Review and Conventional Approaches to Irritable Bowel Syndrome

50.2.1 Irritable Bowel Syndrome Pathophysiology

As a syndrome, IBS involves a constellation of signs, symptoms, and deranged physiology along the GI tract. Although symptoms can vary among patients, hallmarks of IBS include the following:

- Abdominal cramping
- Abdominal distension, bloating
- Change in bowel habits
- Exaggerated gastrocolonic response
- Visceral hypersensitivity and pain

Stratification and categorization of patients are based on predominant stool pattern (Fig. 50.3):

- IBS with predominant constipation (IBS-C)
- IBS with predominant diarrhea (IBS-D)
- IBS with mixed bowel habits (IBS-M)
- IBS unclassified (IBS-U)

Rome IV diagnostic criteria for irritable bowel syndrome:

Recurrent abdominal pain[1] at least 1 day per week for the past 3 months associated with two or more of the following (Fig. 50.4):

1. Associated with defecation
2. Associated with a change in frequency of stool
3. Associated with a change in form (appearance) of stool

In pathophysiology research and clinical trials, a pain frequency of at least two days a week during screening evaluation is recommended for subject eligibility.

The diagnosis of IBS should be made based on the following four key features: clinical history, physical examination, minimal laboratory tests, and, when clinically indicated, colonoscopy, or other appropriate tests.

Evaluation of symptom severity and quality of life for the presenting patient can be ascertained through the use of validated assessment tools, such as the Irritable Bowel Syndrome Severity Scoring System (IBS-SSS) [19] and the Irritable Bowel Syndrome Quality of Life (IBS-QOL) questionnaire [20]. IBS-SSS primarily evaluates the intensity of IBS symptoms during a 10-day period: abdominal pain, distension, stool frequency and consistency, and interference with life in general. The IBS-SSS calculates the sum of these five items; each scored on a visual analog scale from 0 to 100 [19]. The IBS-QOL questionnaire is a 34-item instrument designed from a needs-based conceptual paradigm, and scoring is

1 Criterion fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

50

Diagnostic criteria for IBS subtypes

Predominant bowel habits are based on stool form on days with at least one abnormal bowel movement.

IBS with predominant constipation: More than one-fourth (25%) of bowel movements with Bristol stool form types 1 or 2 and less than one-fourth (25%) of bowel movements with Bristol stool form types 6 or 7. Alternative for epidemiology or clinical practice: Patient reports that abnormal bowel movements are usually constipation (like type I or 2 in the picture of Bristol Stool Form Scale (BSFS), see Figure 2A).

IBS with predominant diarrhea (IBS-D): more than one-fourth (25%) of bowel movements with Bristol stool form types 6 or 7 and less than one-fourth (25%) of bowel movements with Bristol stool form types 1 or 2. Alternative for epidemiology or clinical practice: Patient reports that abnormal bowel movements are usually diarrhea (like type 6 or 7 in the picture of BSFS, see Figure 2A).

IBS with mixed bowel habits (IBS-M): more than one-fourth (25%) of bowel movements with Bristol stool form types I or 2 and more than one-fourth (25%) of bowel movements with Bristol stool form types 6 or 7. Alternative for epidemiology or clinical practice: Patient reports that abnormal bowel movements are usually both constipation and diarrhea (more than one-fourth of all the abnormal bowel movements were constipation and more than one-fourth were diarrhea, using picture of BSFS, see Figure 2A).

IBS unclassified (IBS-U): Patients who meet diagnostic criteria for IBS but whose bowel habits cannot be accurately categorized into 1 of the 3 groups above should be categorized as having IBS unclassified.

Fig. 50.3 Diagnostic criteria for IBS subtypes. (Reprinted from Lacy et al. [18]. With permission from Elsevier.)

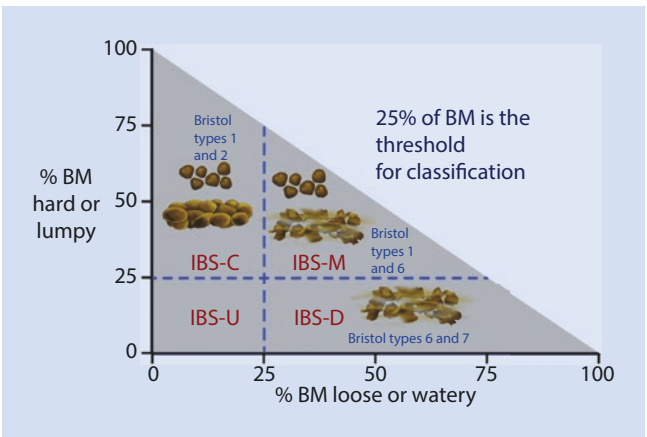

Fig. 50.4 IBS subtyping based upon Bristol Stool Form Scale (BSFS). IBS subtypes should be established according to stool consistency, using the BSFS. Accuracy in IBS subtyping is more readily achieved when patients have at least four days of abnormal bowel habits per month. Bowel habit subtypes should be based on BSFS for days with irregular bowel habits. (Reprinted from Lacy et al. [18]. With permission from Elsevier.)

composed of a total score and eight subscale scores that have been validated for a general IBS patient population [20].

The pathophysiology associated with IBS is multifactorial and often variable – presenting a challenge in both assessment and intervention. Identifying the relevant underlying and potentially unique factors in the presenting patient is necessary to determine the most appropriate course(s) of treatment. Deducing the critical drivers unique to an individual's presentation is particularly significant for the integrative nutritionist as the heterogenic nature of irritable bowel syndrome means that no single physiological anomaly accounts for symptoms in all patients.

Historically, the pathogenesis of IBS has focused on abnormalities in motility, visceral sensation, brain-gut interaction, and psychosocial distress [16]. More recently, altered gut immune activation, intestinal permeability, and intestinal and colonic microbiome have been identified in some IBS patients [21, 22]. Several other etiological factors may drive the IBS phenotype adding to the complexity of the condition:

- Celiac disease
- Non-celiac gluten sensitivity
- Food intolerance (e.g. lactose, fructose)
- Small intestinal bacterial overgrowth (SIBO)

Reportedly 20–23.3% of treated CD patients fulfill the symptom-based Rome criteria for IBS [23]. This may be due to an incomplete resolution of the inflammatory response, even upon intervention with a gluten-free diet. This chronic, low-grade inflammatory state may mediate elevated immunological status and visceral hypersensitivity that results in IBS symptoms.

The debate over the role of gluten and wheat-based products among those who present with gastrointestinal symptoms but test negative for celiac disease continues in the clinic setting. Non-celiac gluten sensitivity (NCGS) is often a self-administered diagnosis by the patient, who, after adopting a gluten-free diet, experiences full or partial symptom resolution. However, not all patients respond as such, highlighting the possibility that other dietary factors may be at play in patients experiencing the gastrointestinal and extragastrointestinal symptoms common to both NCGS and IBS. Aside from gluten, other constituents found in wheat-based foods, such as amylase-trypsin inhibitors and fructans, could contribute to IBS symptoms [24]. A low FODMAP (fermentable

oligosaccharides, disaccharides, and monosaccharides, and polyols) dietary intervention has demonstrated efficacy in IBS, supporting the associated intolerance and malabsorption of these short-chain carbohydrates as a causative factor in patients [25].

In addition to digestive difficulty with gluten and wheat derivatives, intolerance to other substrates has been implicated in IBS symptomology. Both lactose and fructose intolerance are cited as potential drivers in IBS pathophysiology, falling under the broader umbrella of FODMAPs as disaccharides and monosaccharides, respectively [26]. Researchers posit that intolerance develops by one of three potential pathways: food hypersensitivity (immune-mediated), food chemicals (bioactive molecules), and luminal distension [27].

Various studies evaluating the frequency of SIBO among patients with IBS as compared with controls have been conducted, elucidating the prevalence of small intestinal bacterial overgrowth among patients with irritable bowel syndrome. The majority of case-control studies reveal that SIBO was more common among IBS than controls, suggesting a significant association between SIBO and IBS.

Additional meta-analyses further support an association between SIBO pathogenicity in IBS clinical presentation. In a meta-analysis by Ford et al., of the 12 studies including 1921 patients with IBS, pooled prevalence of a positive lactulose-hydrogen breath test (LHBT) and glucose-hydrogen breath test (GHBT) was 54% [28]. In another meta-analysis that included 11 studies, breath testing was found to be abnormal among patients with IBS over that of controls [29].

Characteristically, SIBO disrupts normal gastrointestinal physiology, resulting in pathophysiological features present in IBS, including increased intestinal permeability, immune activation, carbohydrate malabsorption, visceral hypersensitivity, and GI dysmotility.

50.2.2 Altered Motility

Debate exists in the scientific community as to whether abnormal motility is a cause or a resulting effect of other pathogenic factors in irritable bowel syndrome. Mechanistically, peripheral abnormalities in enteric nervous signaling may lead to altered small bowel or colonic motility or both. The resulting motor dysfunction contributes to some symptoms of IBS, such as abdominal pain, defecatory urgency, and postprandial bowel movements. In addition to irregular motility patterns during the fed state, abnormal periods of migrating motility complex (MMC) contractions during the fasting/interdigestive phase have been observed in IBS patients [30]. Researchers have noted that the MMC of IBS-C and IBS-D patients can be changed, as compared with that in healthy people, and that abnormal stage III contractions in the jejunum may be a dominant change in IBS gastroenteric motility [30]. These irregular contractions result not only in impaired movement of matter through the GI tract but also in the accompanying sensations of cramping and visceral pain symptomatology in IBS patients.

50.2.3 Visceral Sensation

Visceral hypersensitivity of the peripheral and central nervous system is a principal etiological driver of symptoms in irritable bowel syndrome. Alteration of neurological signaling results in persistent visceral hyperalgesia and allodynia – elevated nociceptive sensation in response to normal stimuli. Changes in contents of the alimentary canal vary the pressure and volume within tissues, resulting in mechanical stimuli. Under normal physiological conditions, these changes would occur without any perception of pain. IBS patients experience enhanced perception of mechanical triggers from distensions and contractions of GI structures. The severity of visceral pain symptoms may be mediated, in part, by intake of certain dietary substrates as well as biopsychosocial stress. While the underlying cause of visceral hypersensitivity has yet to be fully elucidated, several factors, including microbial infections, intestinal dysbiosis, psychological factors, inflammation and immunological factors, brain-gut communication, diet, as well as genes, appear to be involved in the manifestation elevated pain perception [31].

50.2.4 Brain-Gut Interaction

Neurogastroenterology is a burgeoning area of clinical investigation, with clear associations elucidated between GI disease and behavioral disorders. The study of neurogastroenterology examines the physiological features of the brain-gut axis and clinical treatment targets for functional GI disorders. The connectedness between gastrointestinal health and neurological function is particularly relevant. At the foundation of this relationship is the enteric nervous system – replete with vast innervated tissues. The enteric nervous system and central nervous system communicate along vagal and autonomic pathways to modulate many gastrointestinal (GI) functions.

Stemming between the brain and these tissues runs the vagus nerve, a conduit of signaling that can serve to enhance or disrupt physiological function. Exogenous stress can activate the sympathetic nervous system and hypothalamic-pituitary-adrenal (HPA) axis, resulting in a release of glucocorticoids and catecholamines that have a downstream effect on the enteric nerves and digestive function.

In addition to these signaling molecules from primary neurological and endocrine tissues, several crucial neurotransmitters are synthesized locally within the GI tract, including serotonin (5-HT) – 90% of which is manufactured in the gut. In the GI tract, serotonin activates as many as 14 different 5-HT receptor subtypes [32] located on enterocytes [33], enteric neurons [34], and immune cells [35]. Serotonin influences small intestinal motility, a feature illustrated by the fact that the administration of serotonin agonists and antagonists alters intestinal function. Neuromodulators, such as selective serotonin reuptake inhibitors, are regularly administered in IBS patients to both modulate peristalsis and treat common comorbidities in

mood and behavior. In clinical trials, patients with IBS have exhibited significantly higher levels of anxiety and depression than healthy controls [36]. In addition, common clinical, psychosocial manifestations in patients presenting with IBS include the following:

1. IBS patients are more likely to have anxiety, depression, and somatization disorders.
2. They are more likely to have been physically or sexually abused in childhood.
3. Both factors can influence care-seeking.
4. Psychiatric disturbance and abuse history can influence the severity of symptoms and level of disability [37].

Expanding on the concept of the gut-brain connection, and overlapping with the clinical significance of gut commensal microbes in IBS, is the construct of the microbiota-gut-brain axis. Preclinical data have exhibited that changes in the microbiome can influence aspects of behavior and brain function [38]. Some of this influence may be a result of specific bacterial species that promote 5-HT biosynthesis from colonic enterochromaffin cells (ECs), which supply 5-HT to the mucosa and gastrointestinal lumen [39]. Serotonin synthesis may act locally to influence motility as well as distally to modulate pain perception and mood (Fig. 50.5).

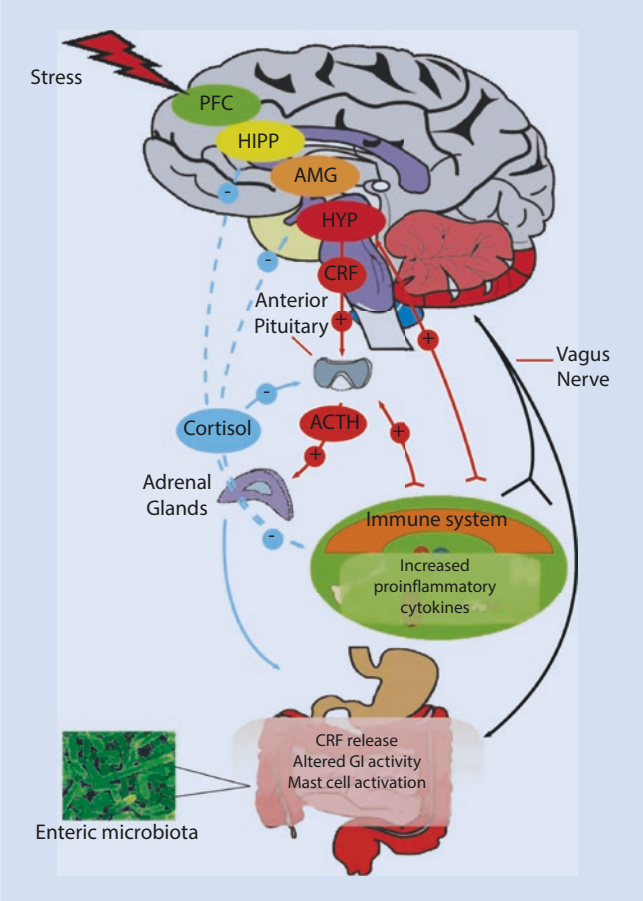

Fig. 50.5 Microbiome-gut-brain axis. The central nervous system (CNS) and enteric nervous system (ENS) communicate along vagal and autonomic pathways to modulate many gastrointestinal (GI) functions. The enteric microbiota influence the development and function of the ENS and immune system which affects CNS function. The hypothalamic-pituitary-adrenal (HPA) axis forms a key component of brain-gut signaling, responding to stress or heightened immune activity. Mood and various cognitive processes can mediate top-down bottom/bottom-up signaling. The HPA axis can be activated in response to environmental stress or by elevated systemic proinflammatory cytokines. Cortisol released from the adrenal glands feeds back to the pituitary, hypothalamus (HYP), amygdala (AMG), hippocampus (HIPP), and prefrontal cortex (PFC) to shut off the HPA axis. Cortisol released from the adrenals has a predominantly anti-inflammatory role on the systemic and GI immune system. In response to stress, GI activity can be altered, and corticotropin releasing factor (CRF) increased. Stress can increase systemic proinflammatory cytokines which can act at the pituitary to activate the HPA axis and can signal to the central nervous system via the vagus nerve, which also transmits changes due to mast cell activation in the GI tract. (Reprinted from Kennedy et al. [40]. With permission from Baishideng Publishing Group Inc.)

50.3 Integrative and Functional Medical Approach Beyond Conventional Protocols

Standard treatment of care for irritable bowel syndrome includes a variety of potential interventions, based mainly on the wide range of clinical manifestations and variable nature of etiological factors. Customizing treatment ensures greater effectiveness in addressing the symptoms in a presenting patient and their specific subtype.

Pharmacological interventions include medications to treat diarrhea, constipation, cramping/spasm, dysmotility, pain, and aspects of psychological distress. Table 50.3 lists examples of pharmaceuticals used in the treatment of IBS.

50.3.1 Integrative and Functional Medicine Approach

Integrative and functional medicine practitioners may rely on some initial pharmacological interventions in cases where severity of symptoms and long-standing pathophysiology warrant some degree of symptom relief for the patient, but ultimately seek to resolve the causative factors in the IBS patient. During treatment, integrative providers often initiate combination protocols utilizing dietary and nutritional/herbal supplement interventions that support appropriate mucosal barrier function, eradicate any infectious pathogens, ameliorate inflammatory activity, modulate immune function, and rebalance gastrointestinal microbial composition.

50.3.2 Dietary Intervention

From a dietary perspective, a low FODMAP diet has proven to be most efficacious among potential nutritional therapies and, in many parts of the world, is now considered a frontline therapy for IBS. FODMAPs (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) are categorized as short-chain carbohydrates that are either slowly absorbed

Table 50.3 Pharmaceutical applications utilized in the treatment of irritable bowel syndrome

Medication category	Treatment target
Antidiarrheal agents	Diarrhea
Laxatives	Constipation
Bulking agents (psyllium)	Constipation
Antispasmodic	Pain, cramping
Anticholinergics	Pain, cramping
Tricyclic antidepressants	Pain, visceral hypersensitivity, comorbid psychological symptoms
Selective serotonin reuptake inhibitors	Pain, visceral hypersensitivity, comorbid psychological symptoms

or incompletely digested in the small intestine. Evidence has accumulated over several years, supporting the effectiveness of a low FODMAP diet in patients with IBS. Historically, individual short-chain carbohydrates were identified as inducing or exacerbating abdominal symptoms. Eventually, these various substrates were combined in trials where their elimination as part of the composite low FODMAP protocol produced the most significant symptom resolution. A review of research shows that up to 86% of patients with IBS find improvement in overall gastrointestinal symptoms as well as such individual symptoms as abdominal pain, bloating, constipation, diarrhea, abdominal distension, and flatulence following the diet [25]. According to Nanayakkara et al., FODMAP restriction reduces the osmotic load and gas production in the distal small bowel and the proximal colon, providing symptomatic relief in patients with IBS [25]. Clinical trials testing the efficacy of low FODMAP dietary intervention demonstrate two vital for successful outcomes: (1) patient education and (2) dietitian-led intervention [41].

Despite substantial evidence of its efficacy in IBS patients, concerns over long-term implications exist, primarily related to the diet's effects on the gut microbiota and synthesis of anti-inflammatory short-chain fatty acids (butyrate, propionate, acetate) – both of which are influenced by the consumption of fermentable carbohydrates. The role of the integrative nutritionist applying a low FODMAP diet with IBS patients is to help address other pathophysiological underpinnings and carefully reintroduce these beneficial carbohydrates to the patient based on tolerability and optimization of overall digestive function.

50.3.3 Herbal and Nutritional Supplement Interventions

In the treatment of irritable bowel syndrome, integrative and functional medical providers often leverage various novel compounds to alleviate symptoms and address underlying pathophysiology. Compounds that display significant evidence in the scientific literature of ameliorating some of the physiological abnormalities associated with IBS include the amino acid l-glutamine, serotonin precursor 5-hydroxytryptophan, and a variety of herbal antimicrobials that have shown efficacy in the eradication of pathogenic and overabundant microbial species. Researchers at Johns Hopkins conducted a comparative trial placing a multi-ingredient herbal compound against standard course of treatment in IBS mediated by small intestinal bowel overgrowth (SIBO) and reported that the herbal antimicrobials were of similar efficacy to rifaximin for the resolution of SIBO, and were also as effective as triple antibiotic therapy for SIBO rescue therapy for rifaximin non-responders [42].

50.4 Nutritional and Lifestyle Clinical Application Principles

Whether driven by immunological imbalance or impaired digestive function, it is evident that IBS patients benefit from dietary modifications. The challenge for the integrative nutritionist is to strategically implement the appropriate evidence-based intervention, assess its efficacy in their individual patient, and progress the patient through phases of dietary adjustment as symptoms resolve and underlying pathophysiology is attenuated. A few dietary considerations to try for patients experiencing irritable bowel syndrome based on the influence of substrates and the presence of impaired digestive capacity:

- Avoidance of large meals – spread food intake throughout day
- Reduction or elimination/challenge of lactose
- Reduction or elimination/challenge of sorbitol, mannitol, xylitol
- Reduction or elimination/challenge of fructose especially high-concentration fruits, HFCS, honey
- Reduction in raffinose intake
- Maintenance of food journal citing intake and response (GI symptoms, bowel movements, etc.)
- Introduction to food preparation techniques that aid digestibility, e.g. soaking, and inclusion of fermented foods upon exclusion of bacterial overgrowth

Integrative nutritionists should also consider patient stress levels in the context of patient treatment. Essential in this component of care is the recognition that stress should be defined in the broader context of the biopsychosocial model, where stress includes not only mental-emotional duress but also endogenous and exogenous exposures.

Endogenous influences may arise from metabolic dysfunction – the by-products of which can increase oxidative stress and inflammatory cytokine activity that may contribute to IBS pathophysiology. Endogenous stress on the system may also arise from qualitative and quantitative gut microbial divergence, as well as endotoxins released from bacterial cells upon cell degradation.

Myriad exogenous factors impart stress on the body, and collectively these factors constitute part of the exposome. Per the Centers for Disease Control and Prevention, the exposome has been defined as "the measure of all the exposures of an individual in a lifetime and how those exposures relate to health [43]". These exposures begin before birth and include insults from environmental sources. In the case of the patient with IBS, influential factors may consist of peri-/postnatal exposure to antibiotics, microbial interaction during delivery method, food introduction, trauma/early adverse life events, and pathogenic infection. Post-infectious IBS, which develops in 4–32% of patients with bacterial gastroenteritis [44], appears to be a nonspecific response to infection caused by a variety of enteric pathogens and has been documented after illness due to *Campylobacter* species, *Salmonella* species, diarrheagenic strains of *Escherichia coli*, and *Shigella* species [45].

Psychological stress, either in conjunction with the appearance of symptoms or in subsequent years after initial diagnosis, is associated with patient-reported increases in symptom severity. Comorbidity of IBS and psychological distress is common, and prevalence of psychiatric disorders alongside IBS is evident. Research examining the psychosocial determinants of IBS has been explored, with studies reporting a significant increase in stress score just before progression from IBS non-patient to IBS patient [46]. Major life traumas (e.g. disruption of a close relationship, a marital separation, a family member leaving home, or termination of romantic relationship) were frequently reported 38 weeks prior to onset of IBS symptoms [46]. Techniques to mitigate mental-emotional stress such as cognitive-behavioral therapy and meditation are a vital component of care for IBS patients.

50.5 Grand Rounds Case Presentation

50.5.1 Assessment

50.5.1.1 Patient Profile: History and Subjective Information

A 53-year-old female engaged in care, presenting with significant abdominal bloating, distension, belching, and irregular bowel movements. The patient tended toward constipation, but would periodically (approximately every 7–10 days) have a large bowel movement she deemed as a "massive evacuation" with considerable fecal mass. Using the Bristol Stool Chart, the patient identified bowel movement as type 5/6 in consistency – oriented toward loose stool. Between these periodic eliminations, patient reported that bowel movements may not occur for 3–5 days at a time. Her chief complaint was bloating and abdominal distension, followed by the variability and discomfort associated with her bowel habits. IBS-SSS questionnaire was administered to gauge symptom severity and as a metric for reassessment and protocol efficacy. Patient IBS-SSS score was 360 out of 500 – designating her as a "severe case" per survey criteria.

Patient provided subjective history stating symptoms had initiated 24 years ago concurrent with the birth of her first daughter. Predominant symptoms at the time were severe abdominal cramping and diarrhea. After four years of self-management, patient sought medical care and was prescribed selective serotonin reuptake inhibitor (sertraline Hcl), along with meditation techniques to treat depression and manage the stress that seemed to precipitate an increase in gastrointestinal symptoms. The prescription and meditation seemed to alleviate symptoms for a period, but eventually, symptoms returned, and new symptoms of bloating and belching appeared.

50.5.1.2 Pertinent Medication History

Patient-reported medication list is included in ◘ Table 50.4.

50.5.1.3 Medical Assessment and Treatment

Patient had sought medical intervention with a gastroenterologist for the first time two years prior to initial nutrition consultation. The treating physician ran standard blood chemistries, including 25(OH)D, comprehensive metabolic panel, complete blood count, and lipid panel. Lipid panel indicated potential familial hypercholesterolemia due to total cholesterol at 299 mg/dL and LDL-C of 211.00 mg/dL. Familial hypercholesterolemia is suspected when fasting LDL cholesterol is above 189 mg/dL or non-HDL cholesterol is above 219 mg/dL. Collection of family history indicating high cholesterol and heart disease in first-degree relatives can support presence of FH, which was confirmed by patient. Status of serum 25(OH)D was deemed insufficient at 21 ng/mL. All other blood chemistries analyzed were within reference range. The patient's gastroenterologist also conducted a gastric emptying study, which returned unremarkable, with a conclusion of normal gastric emptying and absence of gastroesophageal reflux. Gastroenterologist provided a diagnosis of irritable bowel syndrome.

To investigate the underlying etiology of the patient's IBS symptoms, specifically bloating and distension, gastroenterologist conducted hydrogen breath test to assess for potential presence of small intestinal bacterial overgrowth (SIBO).

Clinical assessment involved hydrogen breath test with administration of a lactulose solution and testing of hydrogen levels measured in ppm at 15-minute intervals for 120 minutes. Test result indicated a fivefold increase above basal hydrogen breath level at 60 minutes and early increase (within 90 minutes) greater than 20 ppm (22 ppm recorded at 60-minute mark) – both considered definitive for a positive test result. Technician's interpretation, supported by review of the physician, was positive indication for small intestinal bacterial overgrowth.

Upon confirmation of SIBO, patient's gastroenterologist prescribed 2-week course of Xifaxan (rifaximin) 550 mg. Patient reported resolution of symptoms for approximately three months, upon which time all symptoms returned with the same severity and profile. Patient revisited her physician who readministered Xifaxan prescription. Again, the patient experienced alleviation of symptoms for a short time, only to have the bloating, distension, and vacillating constipation and diarrhea return.

Table 50.4 Patient medication list

Current medications (over-the-counter and prescription)				
Name	**Dosage**	**Frequency**	**Length of time**	**Reason for taking**
Enablex (darifenacin)	7.5 mg	Nightly	4 years	Frequent urination sensation
Crestor (rosuvastatin calcium)	10 mg	Daily	10 years	High cholesterol
Zoloft (sertraline HCl)	50 mg	Daily	5 years	Depression
Align probiotic (*B. infantis* 35624™)	1 capsule (1 billion CFU)	Daily	10 years	IBS
Dulcolax (bisacodyl)	300 mg	Daily	5 years	IBS
Lo/Ovarol-28 (ethinyl estradiol and norgestrel)		28 days/month	35 years	Heavy menstruation

After a third course of Xifaxan, physician advised against additional administration of the antibiotic therapy due to potential complications. Patient continued to see mild improvement immediately following course of Xifaxan, only to have symptoms return, upon which time she sought out clinical nutrition intervention and adjunct therapeutic options.

50.5.1.4 Diagnosis

Collection of health history data illustrated several additional points of interest identified via use of the IFM framework of antecedents, triggers, and mediators (Table 50.5).

Antecedents

Early, and particularly repeated, childhood antibiotic treatment influences the development of the gut microbiota both quantitatively and qualitatively, leading to modulation of immune function and long-term health implications [47, 48]. Patient also reported a high incidence of first-degree relatives with alcohol/substance abuse history and her challenges with eating disorders. At the time patient sought my services, she was enrolled in and actively attending Food Addicts Anonymous (FAA).

Triggers

Psychological stress is acutely associated with irritable bowel syndrome. Stress serves as a trigger for IBS symptoms by activating the HPA axis and resulting release of cortisol, epinephrine, and norepinephrine, all of which may influence gastrointestinal activity.

Declining ovarian hormones (i.e., estrogen and progesterone) are associated with an increase in GI symptoms [49]. The patient reported discernable changes in IBS symptom severity during two distinct life events: (1) initiation of menarche and (2) onset of menopause. Both stages are associated with variation in ovarian hormone and specifically with fluctuation of estrogen and progesterone – with decreased physiological levels experienced during menses and transition to menopause.

Table 50.5 Relevant IBS patient antecedents, triggers, and mediators

Antecedents	1. Multiple courses of antibiotic intervention in childhood 2. Potential genetic predisposition to psychosocial substance use/abuse as indicated by patient-reported family history of alcohol dependency and own experience with eating disorder
Triggers	1. Biopsychosocial stress 2. Menopause
Mediators	1. Psychological stress: caregiver for terminally ill mother with cancer 2. Foods – patient-reported suspicion of certain foods but unable to identify precise food triggers

Mediators

Around the time of the increase in IBS symptoms, the patient had assumed a more active role as the caregiver for her mother, who was terminally ill with metastatic cancer. This psychic trauma coincided with a significant intensification of her IBS symptoms, owing to the increased psychological stress.

Although the patient had made some degree of dietary changes over time to self-manage her symptoms, she was inconsistent with these nutritional modifications and was also unclear as to which foods seemed to mediate increases in her bloating, pain, gas, and bowel irregularities. The patient had prepared a 3-day food log for evaluation and intake, which reflected a standard, generalized diet with the following inadequacies:

- Inadequate fiber intake
- Inappropriate intake of fats (inadequate essential fatty acids relative to total fat intake)
- Inadequate protein intake
- Inadequate mineral intake (iron, zinc, calcium, potassium, magnesium)
- Inadequate vitamin intake (A, D, E, K, folate, B12)

After a thorough review of biomarkers, health history, food journal, and patient-reported symptoms, the following PES statement was developed:

PES Statement: Disordered eating pattern related to altered GI function as evidenced by 3-day food intake survey and patient-reported symptoms of excess bloating, gas, stool frequency and type (Bristol type 5/6), and positive test result for presence of small intestinal bacterial overgrowth per clinical parameters.

50.5.1.5 Intervention

The therapeutic nutritional intervention consisted of a structured low FODMAP diet with accompanying education and resources for practical implementation. As discussed earlier, the low FODMAP dietary intervention has proven to be among the most efficacious therapies for patients with IBS. Based upon this patient's clinical presentation, the elimination of fermentable fibers was clinically relevant owing to the presence of bacterial overgrowth in the small intestine. Guidelines for dietary compliance were provided, with a specific focus on consumption of bioactive substances lacking from the existing diet, specifically, strategies to enhance protein status, bioflavonoids, omega-3 fatty acids, and aforementioned micronutrients. Recommendations were also provided to ease the digestibility of foods through avoidance of raw vegetables and cooking of relevant foods.

From a behavioral perspective, the patient was encouraged to continue attendance at Food Addicts Anonymous meetings. Patient attributed these meetings and support system as integral in providing insight into her eating habits.

50.5.1.6 Dietary Supplement Protocol

To rectify existing vitamin D insufficiency, as evidenced by serum 25(OH)D, patient began supplementation of vitamin D3 (cholecalciferol) at 2000 IU daily. As 2000 IU (50 mcg) per day is generally required to increase vitamin D blood levels by increments of 20 ng/ml (50 nmol/L) over the course of several months [50, 51], selection of this dosage would provide clinical utility and replete the patient to sufficient status. Supplementation in this scenario was warranted owing to the patient's lab chemistries, inadequate intake, potential GI malabsorption issues, and lack of daily UVB exposure resulting in insufficient cutaneous production.

In addition to vitamin D3 supplementation, a targeted supplement protocol was developed to address the patient's refractory SIBO.

Various herbal compounds exhibit antimicrobial properties and have been used in traditional medicine for centuries. Caprylic acid has displayed the ability to eradicate resistant gram-positive, gram-negative, and fungal biofilms [52]. Berberine sulfate has also been shown to decrease bacterial adherence to mucosal or epithelial surfaces and be an effective antimicrobial and has exhibited antisecretory activity in vivo [53]. A search of the US National Library of Medicine National Institutes of Health (► PubMed.gov) database results in over 2600 publications exploring the antimicrobial activity of essential oils, including oil of oregano (*Origanum vulgare*) [54]. The antibacterial effects of oil of oregano are associated with the presence of their phenolic components, carvacrol and thymol, which have shown potent bactericidal effects against an impressive array of bacterial strains:

- *Staphylococcus aureus*
- *Escherichia coli*
- *Bacillus cereus*
- *Pseudomonas aeruginosa*
- *Klebsiella pneumoniae*
- *Acinetobacter baumannii*
- Aeromonas sobria
- *Enterococcus faecalis*
- *Salmonella Typhimurium*
- *Serratia marcescens*
- *Yersinia enterocolitica*
- *Shigella flexneri*

An in vivo trial employing a compounded herbal formula exhibited efficacy in the resolution of bacterial overgrowth in the small intestine and remission of associated IBS symptoms [42].

As repeated courses of Xifaxan were unable to resolve entrenched dysbiotic gut ecology, alternatives were leveraged to remediate the bacterial overgrowth and gastrointestinal symptoms. Patient was provided with recommendations to incorporate 1 capsule qd of oil of oregano (36 mg carvacrol and thymol; 60–75% carvacrol oregano oil) and 1 capsule qd of a proprietary blend of botanical extracts (GI Microb-X™ from Designs For Health™) that includes the following:

- Tribulus extract (*Tribulus terrestris*)(aerial) [standardized to contain 40% saponins] 200 mg
- Magnesium caprylate (yielding 120 mg caprylic acid; 10 mg magnesium) 150 mg
- Berberine sulfate (*Berberis aristata*)(root) 100 mg
- Grapefruit extract (Citrus paradisi)(seed) 100 mg
- Barberry extract (*Berberis vulgaris*)(bark) [standardized to contain 6% berberine] 50 mg
- Bearberry Extract (*Arctostaphylos uva-ursi*)(leaf) [standardized to contain 20% arbutin] 50 mg
- Black walnut powder (*Juglans nigra*)(hull) 50 mg
- Artemisinin (from sweet wormwood) (*Artemisia annua*) (herb) 15 mg

50.5.1.7 Monitoring

Throughout the entire intervention period, the patient maintained detailed food journals noting dietary intake and symptoms, with attention given to the timing of GI symptoms relative to meal consumption and psychological stress. The patient reported this as being an invaluable tool as it allowed her to become more mindful with her eating habits and more keenly aware of her body response and mental state.

Monitoring of IBS symptoms was continuous through use of the iPhone application mySymptoms Food and Symptoms Tracker (© 2016 SkyGazer Labs Ltd), which provides recording, tracking, and analysis of dietary intake, along with various metrics around physical symptoms of digestion, stress, and energy levels.

At eight weeks of the dietary and supplement intervention, patient reported near remission of IBS symptoms. Bloating, gas, abdominal pain, and distension had completely resolved, belching was considerably decreased, and bowel function had improved with the patient experiencing near-daily bowel movement of Bristol type 3/4.

50.5.1.8 Evaluation

The protocol was continued for another four weeks, at which time the patient returned to her gastroenterologist for a follow-up hydrogen breath test. Diagnostic report exhibited hydrogen never exceeding 3 ppm. Technician and physician confirmed negative readings and the absence of SIBO.

Nutritionally, the patient continued exclusion diet of high FODMAP foods, with gradual reintroduction and periodic inclusion of certain vegetables and fruits to tolerance. Abstention from wheat-/gluten-based foods and cow's milk products continued as patient recognized a marked improvement when those substrates were avoided.

IBS-SSS was administered again, with severity score decreasing to mild severity at 125. From a psychological perspective, patient reported a significant improvement to mood and quality of life. Patient also expressed satisfaction for the resolution of many of her symptoms and gratitude for the nutritional and lifestyle techniques that conferred her with a sense of self-efficacy in managing her IBS.

51.1 Impact of Nutrition and Lifestyle on Respiratory Health and Disease

51.1.1 Overview

Lung disease is far more prevalent worldwide than commonly thought. In fact, death from chronic lung disease is increasing, and as of 2017, chronic obstructive pulmonary disease (COPD) has become the third leading cause of death in the United States in the past decade, disproportionately affecting the elderly [1]. Another lung disease, asthma, affects 1 in 13, or about 25 million Americans, according to the Centers for Disease Control and Prevention and the National Center for Health Statistics [2]. This is 7.6% of adults, more women than men, and 8.4% of children. Asthma is the leading chronic disease in children [3]. This disease has been increasing since the early 1980s in all age, sex, and racial groups. In Europe, lung disease represents 15% of all deaths – the fourth leading cause. According to the World Health Organization (WHO), in 2008, 9.5 million people died from acute or chronic lung disease, representing one sixth of the global total deaths [4].

Worldwide, four respiratory disease categories appear in the top ten leading causes of death in 2010 [5]. Specifically, COPD was the third leading cause of death, followed by lower respiratory infections as the fourth, lung cancer as the fifth, and tuberculosis as the tenth [4]. The major risk factor is smoking, leading to 50% of all lung disease-related deaths in Europe, where smoking is more prevalent (28% prevalence) than in the United States (15% prevalence) by nearly twofold [6, 7]. Lung cancer, particularly non-small-cell lung cancer (NSCLC) subtype, is the leading cause of cancer-related death worldwide [8]. Added together, lung disease rivals the position for the top cause of death.

Throughout the life cycle, diet and lifestyle are important modifiable risk factors in the development, progression, and management of obstructive lung diseases, such as asthma and COPD [9], as well as restrictive lung diseases such as pulmonary fibrosis and sarcoidosis. Inflammation, in particular, seems to be the leading contributor toward the progression of lung diseases. As with many diseases, maintaining a healthy lifestyle, including sufficient sleep, low stress, regular exercise, a whole foods diet rich in phytonutrients from plants (fruits and vegetables), and potential anti-inflammatory supplements, is beneficial in supporting the body during these difficult diseases.

> Inflammation, in particular, seems to be the leading contributor toward the progression of lung diseases.

High inflammatory foods should be avoided, such as fried foods and foods disproportionately high in carbohydrates, sugar, alcohol, and excessive protein. A healthier suggestion would be a diet with more than half of all food consumed as vegetables, about one third as protein, and the remainder (one sixth) as other foods, such as fruits, dairy, grains, or starches. Some dietary supplements may also be recommended for their anti-inflammatory benefits, which will be discussed later in the chapter.

As human life expectancy increases, we can expect to see more chronic disease. The World Health Organization estimates that by 2030, chronic lung disease will account for 20% (one fifth) of all deaths [10], up from one sixth in 2008. Despite these growing numbers, relatively little human nutrition research exists for respiratory health, compared to other, less prevalent, diseases. Investigators in the areas of aging and lung biology suggest some hope, using genetics and animal models, as well as epidemiological research, to further the general medical approach to lung disease.

51.2 Anatomy and Physiology

51.2.1 General Anatomy

The pulmonary system is composed of the upper and lower respiratory tracts. Air flows in through the nose or mouth, past the frontal and maxillary sinuses, down the pharynx (throat), past the larynx (voice box), and then down the trachea. This makes up the upper respiratory tract. Once past the trachea, the air divides into the left and right bronchi, which supply the left and right lungs, each divided into five sections called lobes. The bronchi then divide into smaller bronchioles, at the end of which are air sacs called the alveoli. This makes up the lower respiratory tract [11] (◘ Fig. 51.1).

The diaphragm is the central muscle that is used for breathing. The intercostal muscles, located between the ribs, and the abdominal muscles are helpful for breathing out when the breath becomes labored, such as during exercise. The neck muscles and the muscles in the collarbone area help with breathing when the other muscles are compromised or impaired. In some neurological diseases, such as amyotrophic lateral sclerosis (ALS) [see ▶ Chap. 51, Newton], nerve damage from the brain to breathing muscles can result in impaired movement of these muscles and thus impaired breathing.

In certain cases, such as in lung cancer when a lobectomy, removal of part of the lung, is required, there is an expected decrease in short- and long-term pulmonary function and oxygenation. However, respiratory muscle strength may be preserved [13]. In a pneumonectomy, removal of the entire lung, dramatic changes in thoracic anatomy take place, such as elevation of the hemidiaphragm, hyperinflation of the remaining lung, and influx of fluid into the post-pneumonectomy space [14, 15].

51.2.2 Cellular Physiology: Membrane Structure Determines Function – Very Important Barrier

There are phagocytic macrophages on the cellular surface of the alveoli, Type I epithelial cells and Type II epithelial cells. Phagocytic macrophages destroy inhaled bacteria and serve

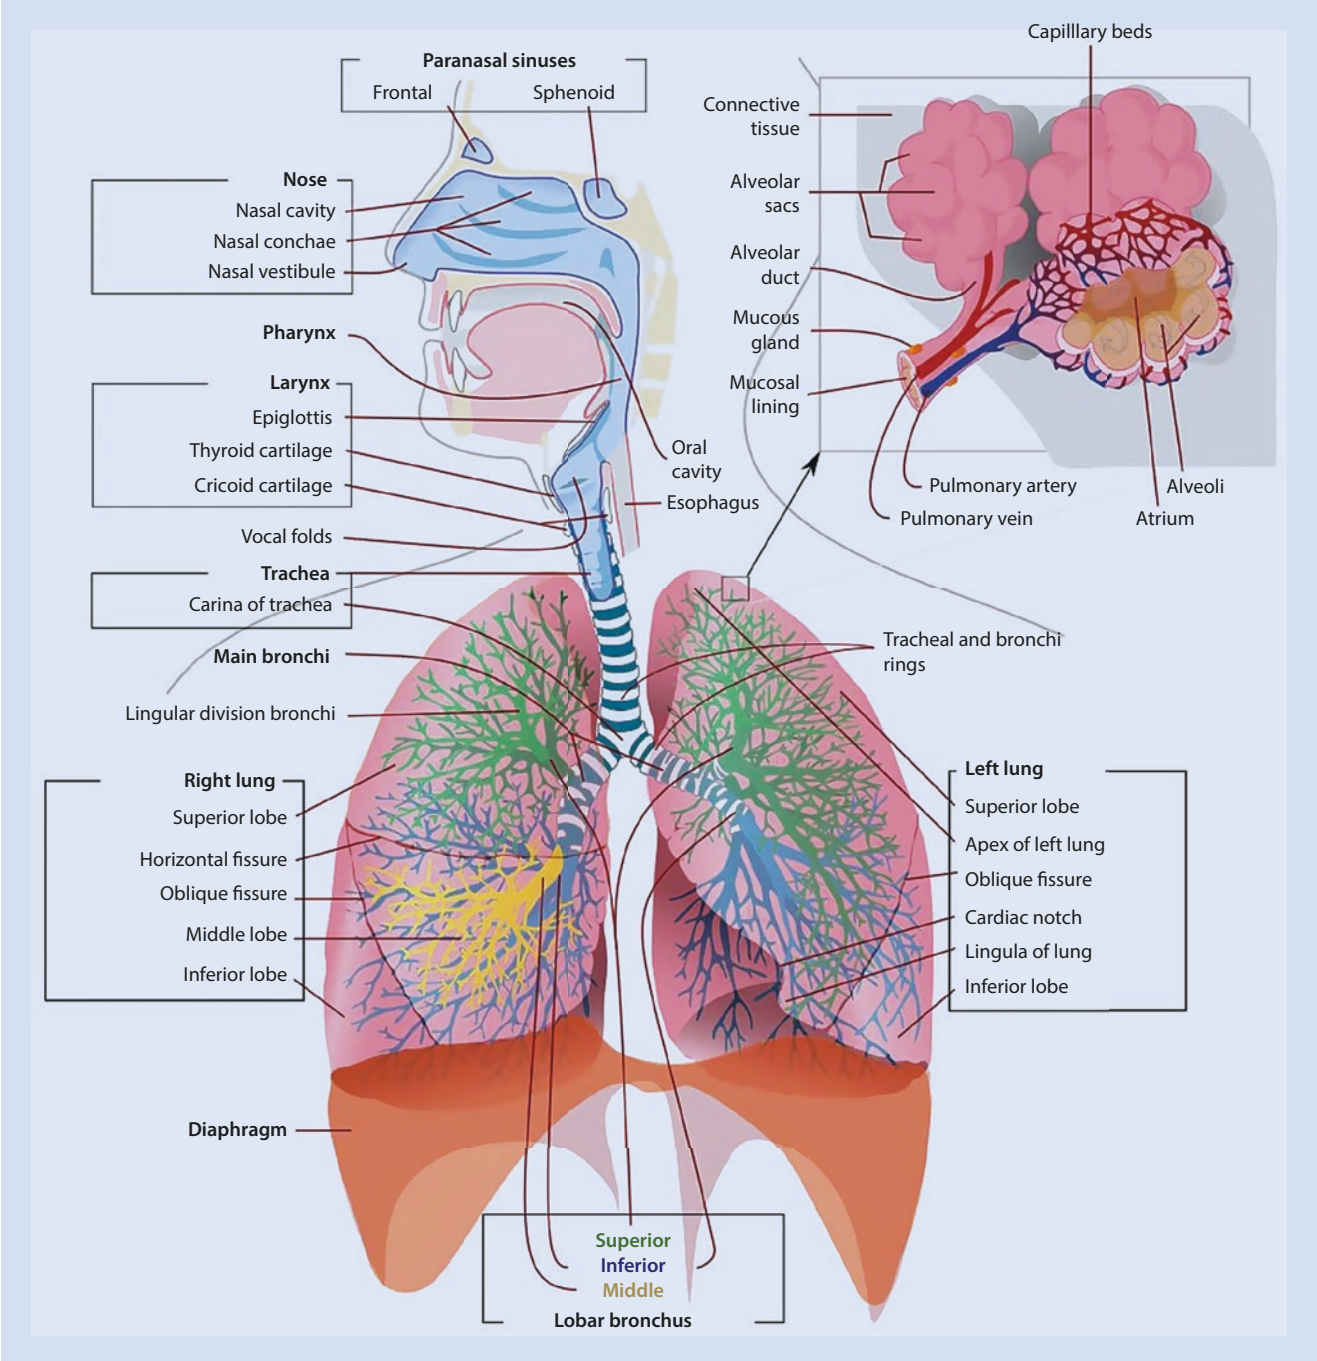

Fig. 51.1 Anatomy of the human respiratory system [12]. (Reprinted with permission from: ► https://en.wikipedia.org/wiki/Respiratory_system#/media/File:Respiratory_system_complete_en.svg)

an important role in suppressing or activating the immune response to antigens and pathogens, similar to dendritic cells discussed below. Macrophage function has been shown to be inhibited by cigarette smoke [16]. Alveolar macrophages also secrete enzymes, arachidonic acid metabolites, growth factors, immune response components, cytokines, and lymphocytes [17].

Type I cells are responsible for maintaining the structure of the alveolar wall, whereas Type II cells and Clara cells are responsible for the production of pulmonary surfactant (composed of 85–90% lipid and 10–15% protein as lecithin and myelin), which is essential for lung function. The surfactant reduces surface tension, facilitating easier stretching and collapsing of alveoli during respiration [18]. Diseases associated with inadequate surfactant production are acute/adult respiratory distress syndrome (ARDS) and infant respiratory distress syndrome (IRDS) [19]. IRDS is seen in premature babies born prior to 32 weeks of gestation due to immature development of pulmonary surfactant, which only begins to develop around the 20th week of gestation [18].

Dipalmitoylphosphatidylcholine, phosphatidylglycerol, and cholesterol compose the lipid portion of the surfactant, where apoproteins and proteins found in blood plasma compose the protein portion [18, 20]. The importance of cholesterol is minimized in today's medical community. Those with higher levels of cholesterol tend to have more in their fatty cell membranes which resist pathogenesis at a cellular level. Low cholesterol predicts a greater risk of dying from gastrointestinal, neoplastic, or respiratory diseases. It occupies 30–40% of our cell membranes, enhances the mechanical strength of the membrane, and reduces permeability [21]. It suppresses main-phase transition of the lipid bilayer [22].

Collagen, a fibrous protein, along with elastin and proteoglycans, is a fundamental component of the connective tissue that composes the lungs, and collagen is present in the blood vessels, bronchi, and alveolar interstitium [23]. Connective tissue in the lung is key for the passive diffusion of oxygen and carbon dioxide that characterizes alveolar-capillary gas [18]. Collagen homeostasis is vital to maintaining respiratory function, where collagen production and degradation are balanced. Dysregulated collagen homeostasis that favors collagen production over degradation can lead to pulmonary fibrosis and compromised lung function [24]. Some key nutrients to consider for collagen synthesis and cross-linking to maintain connective tissue integrity are vitamin C, vitamin B6, iron, copper, zinc [25], riboflavin, thiamin, and pantothenic acid [11].

The airways of the respiratory system (with the exception of parts of the nose and mouth) have cilia, special hairs coated with mucus that trap pathogens and other particles that enter with the air that is inhaled. Cilia are responsible for triggering this mucus upward toward the pharynx where these particles or bacteria can be coughed out or swallowed. Mucus present in the lungs can also trap inhaled particles such as viruses, bacteria, and smoke particulates [11, 12].

Along the lining of the respiratory tract, there are several types of cells that are involved in immune response, such as secretory cells (i.e., goblet cells and Clara cells) and mast cells. Ciliated epithelium and mucus secreted by glands present on airways, goblet cells, and the secretory products of Clara cells serve an important mechanism for lung protection. However, excessive goblet cells or hypertrophy of mucous glands may result in increased viscosity of mucus seen in pathologies like bronchitis [16]. Ciliary function is also impaired by cigarette smoke [16].

Dendritic cells are also found in the airway lining from the trachea to the alveoli. Immature dendritic cells phagocytize bacteria or other antigens, where they then mature and travel to lymphoid tissues to communicate with the immune system. This delivery of antigens can promote tolerance of the antigen by releasing anti-inflammatory cytokines. Conversely, this delivery can also trigger the opposite response if the antigen is recognized as a pathogen, where T lymphocytes are activated and inflammatory cytokines are released [16].

One potential cause of infections in the upper respiratory tract or bronchial tubes, such as bronchitis, or deep in the lungs, such as pneumonia, is when cilia become damaged and do not trap inhaled germs and particles as effectively. In diseases such as cystic fibrosis, thick mucus secretions can accumulate in the airways and lungs, making it hard to clear and thus increasing risk for infection. In asthma, specific inhaled particles can trigger a reaction causing the airways to narrow, restricting breathing [12].

Surface enzymes and factors can also be found in the lining of the airways that compose the majority of the innate immune system of the respiratory tract. These include:

- Lysozymes: found in leukocytes with bactericidal properties
- Lactoferrin: a bacteriostatic agent (inhibits bacterial reproduction) synthesized by lymphocytes and glandular mucosal cells
- Alpha-1 antitrypsin: an antiprotease to protect lung tissue from excessive enzymatic activity
- Interferon: an antiviral substance that may be produced by lymphocytes and macrophages
- Complement: participates as a cofactor in antigen-antibody reactions [16]

51.2.3 Gas Exchange

Gas exchange takes place in the alveoli so oxygen can enter the body to support metabolic function and the carbon dioxide product from these functions can be removed. This is accomplished through millions of capillaries in the alveoli. These capillaries in the alveoli then connect to arteries and veins that move blood throughout the body. The pulmonary artery supplies carbon dioxide-rich blood to these capillaries within the alveoli to remove carbon dioxide, and the oxygen-rich blood then gets delivered to the heart through the pulmonary vein. The lungs also serve the vital function of maintaining acid-base balance through changes in minute ventilation. These changes affect the pH of the blood by either retaining or excreting carbon dioxide [11].

Poor physiologic management of CO_2 and bicarbonate can lead to the conditions of respiratory acidosis and respiratory alkalosis. Respiratory acidosis is characterized by higher blood concentrations of CO_2 and H^+, caused by hypoventilation or decreased rate of breathing. Hypoventilation can have acute or chronic etiologies, resulting from COPD, interstitial lung diseases, respiratory muscle fatigue (i.e., extended asthma attack), or mechanical abnormalities (i.e., deformities).

Respiratory alkalosis is characterized by lower blood concentrations of CO_2 and H^+ due to hyperventilation, or increased rate of breathing. Possible causes of hyperventilation can also be chronic or acute, such as pneumonia and fever, increased stress and anxiety, liver disease, stroke or meningitis, pregnancy, overuse of aspirin and/or caffeine, excessive mechanical ventilation, or increases in altitude [18].

A pulse oximeter tool can be used to measure the percentage of oxygenated hemoglobin in an individual's blood to determine their overall respiratory status. Typically, oxygen

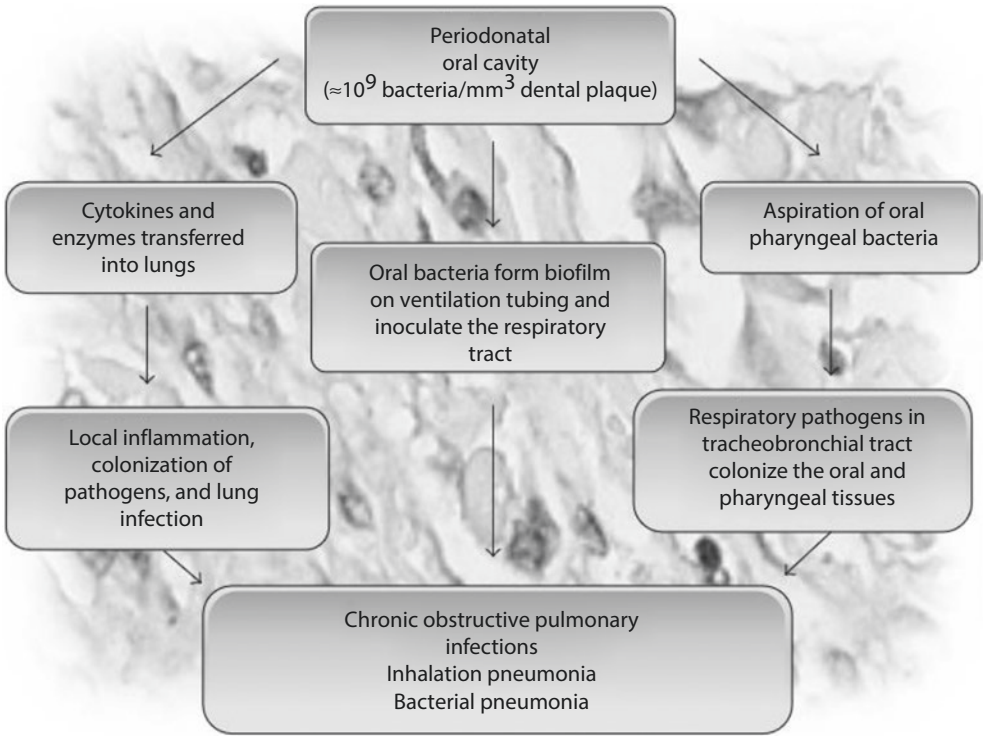

Fig. 51.2 Possible role of periodontal infection in respiratory disease. (Reprinted from Nagpal et al. [27]. With permission from Creative Commons)

saturations of 92% or less are indicative of central hypoxia [26]. Pulse oximetry is especially useful for assessing individuals with asthma and COPD [26].

51.2.4 Oral Health Connection

Oral health must also be considered as a contributing factor to respiratory health [27]. For example, in patients affected with periodontal disease, 1 mm of dental plaque could contain around 10^9 of bacteria. One potential mechanism of this connection is aspiration of bacteria from the oropharynx into the upper or lower respiratory tracts, leading to their adherence to the alveolar and bronchial lining, potentially colonizing respiratory ducts and causing respiratory infections. In addition, cytokines and enzymes associated with inflammation of periodontal tissues can be transferred into the lungs, potentially triggering or exacerbating lung infections [27] (Fig. 51.2).

A systematic review done in 2013 examined oral health in the elderly and its association with risk of aspiration pneumonia. This review suggested that maintaining oral health, such as brushing after each meal, cleaning dentures once per day, and professional oral healthcare, potentially reduced the amount of potential respiratory pathogens that resulted in lower incidence of aspiration pneumonia [28]. Several other systematic reviews have found that adequate oral hygiene plays an important role in preventing pneumonia, particularly in clinical settings where there is increased risk for hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP), as well as in older populations [29]. In addition, associations have been made between COPD and the risk of periodontitis, although systematic reviews have established that these associations are preliminary and further studies are needed [29].

Another important consideration in respiratory health is orofacial development and structure. Anatomical obstructions at the level of the nose and pharynx, such as those caused by allergic rhinitis and hypertrophy of the tonsils, pose an increased risk for obstructive sleep apnea syndrome and respiratory infections due to lack of airflow through the upper respiratory system [30].

51.2.5 Microbiome

It has been established that the lung has a microbiome of its own that may have a large impact on health and disease [31]. The fungal microbiome, or mycobiome, may also have a significant impact on respiratory health, although more research is needed to determine definitive associations [31]. Dysbiosis may occur in the lungs with a bacterial infection. A few specific bacterial strains have been studied, and one, in particular, *Pseudomonas aeruginosa*, seems to grow in inflammatory conditions. It then seems to encode inflammatory components causing further inflammation. Anti-inflammatory nutrients could help stop the cycle, and vitamin D use has some research supporting this. Recurrent bacterial respiratory infections may damage lungs and lead to worse outcomes in future lung disease [32].

An increased interest in research of the relationship of the airway and gut microbiome is indicating potentially positive results regarding the use of probiotics in pediatric populations that may aid in asthma prevention and intervention

[33, 34]. The gut-lung axis has also been established, where the microbiomes of the lung and gut have been immunologically linked and are thought to have an impact on respiratory disease [35, 36].

51.2.6 Autophagy

The autophagy mechanism within our microenvironment provides a constant "cleanup" system to recycle cell debris from microscopic biowaste generated by dynamic cellular biochemistry [37]. Enzymes such as neutrophil elastase function like garbage disposals recycling waste molecules. Alpha-1 antitrypsin is a thermostat-like control factor that signals the proteolytic enzymes to stop and protect healthy tissue from being affected. Antiproteases in the lung, such as alpha-1 antitrypsin, are required to prevent the overactivity of neutrophil elastase to prevent the degradation of healthy lung tissue. Those with the genetic mutations of A1AT deficiency are at disadvantage, and subsequent lung tissue damage can occur promoting lung diseases like COPD, asthma, bronchitis, and emphysema.

Key components of lung structure are elastin and collagen, which provide support for the bronchioles and clusters of alveoli (acini). The key enzyme present in these cells is neutrophil elastase, which is responsible for the destruction of respiratory bacteria. Protease and antiprotease imbalance in the lung resulting in emphysema can be caused by alpha-1 antitrypsin deficiency and nicotine in cigarette smoke or polluted inhalant exposure [18]. IFMNT approaches to the A1AT-deficient patient assess for nutrient insufficiencies for some of the important connective tissue, collagen, and elastin system key nutrients: vitamin C, vitamin D, biotin, balanced fatty acids, and gut microbiome. When insufficiencies or deficiencies are identified, appropriate food and dietary supplementation interventions can be recommended. It should be noted that if an individual is identified with A1AT deficiency genotype, the status of liver health should also be assessed, as A1AT pathophysiology can express in liver cirrhosis.

More recent studies of respiratory disease [38] have revealed the relationship with bacterial or viral infections exacerbating the individual's genotype eliciting expression of the associated diseases. One of the most recognized inherited conditions of altered autophagy mechanisms is alpha-1 antitrypsin deficiency, with 80–100 genetic variants affecting severity of lung expression.

Low levels of circulating A1AT allow potentially harmful enzymes like neutrophil elastase to remain in the lungs unchecked. Low levels of A1AT, and the consequent proliferation of neutrophil elastase, leave lung tissue vulnerable to destruction, resulting in a decline in lung function.

51.2.7 Category of Respiratory Diseases

There are several categories of lung disease and many diseases within those categories (Table 51.1).

51.3 Micronutrients Important for Lung Function: Food-Based and Supplemental

Some micronutrients and phytonutrients have important antioxidant and methyl-donating properties important for the lungs and therefore have great role in a nutritional approach to lung health.

51.3.1 Iron

Iron's interaction with the lungs is essential. It carries oxygen from the lungs to the peripheral parts of the body, as well as carbon dioxide back to the lungs to be exhaled. However, too little or too much iron can pose a problem for the lungs. Before iron administration, it is important to rule out hemochromatosis, or iron overload, for an individual.

Iron-deficiency anemia often presents in many chronic diseases including those of the lung, such as COPD, lung cancer, and IPF [57]. Increased mortality, decreased quality of life, increased hospital admissions, and cost of treatment have been reported for those with chronic disease and low iron [58]. Anemia of chronic disease (ACD) is usually at the root of this. ACD is often the result of inflammation. Inflammatory proteins, including IL-6, stimulate the production of hepcidin in the liver, which inhibits absorption and increases storage of iron resulting in a functional iron deficiency. Typical iron markers, such as transferrin saturation, total iron binding capacity (TIBC), and ferritin, are also affected by inflammation and are less useful markers in chronic disease. Soluble transferrin receptor (sTFR) seems to be a lesser known marker that is less affected by inflammation [59].

Because of the difficulty with iron absorption, intravenous iron is often used to replete deficiencies. As iron is a pro-oxidant, researchers studied any negative repercussions. There does not seem to be any increased oxidative stress with intravenous iron, but glutathione, the body's endogenous super antioxidant, does seem to decrease, likely in response to the pro-oxidative activity of iron. In a recent study, administration with vitamin E was seen to eliminate these negative effects [57].

Excessive iron can also be problematic for lung health for those with the genetic mutation for hemochromatosis (HFE). Disorders of iron overload are increasingly being recognized as risk factors for most of the chronic diseases like cardiovascular, Alzheimer's, and cancer [60]. High iron can catalyze the formation of highly reactive hydroxyl radicals, oxidative stress, and programmed cell death. In the instance of lung cancer and other cancers affecting the lungs, tumors sequester iron for their own growth, usually leaving the patient with iron-deficiency anemia. In fact, 90% of cancer patients undergoing chemotherapy are iron deficient. Inflammation also plays a role in iron homeostasis. The pro-inflammatory cytokines cascade down to affect the proteins that regulate

Table 51.1 Table of lung diseases

Category	Disease	Definition	Source
Obstructive lung disease	Asthma	Chronic inflammatory lung disease, triggered by either an IGE allergic reaction or nonallergic factors and results in reversible airway obstruction and inflammation of the airway	[11]
	Chronic obstructive pulmonary disease (COPD)	Disease that restricts airflow through either inflammation of the lining of the bronchial tubes or destruction of alveoli Increased risk of emphysema if genetic variant of alpha-1 antitrypsin deficiency and smoking or exposed to high levels of air pollution	[11]
	Bronchiectasis	A disorder of the airways that leads to airway dilation and destruction, chronic sputum production, and a tendency toward recurrent infection	[39]
	Bronchiolitis	Airway injury that can be caused by infections, irritants, toxic fumes, drug exposures, pneumonitis (typically viral), organ transplants, connective tissue disorders, vasculitis, or other insults	[40]
	Dyspnea	Shortness of breath or difficulty breathing	[11]
	Emphysema	Thinning and destruction of the alveoli, resulting in decreased oxygen transfer into the bloodstream and shortness of breath. Increased risk of emphysema if genetic variant of alpha-1 antitrypsin deficiency and smoking or exposed to high levels of air pollution	[11]
	Alpha-1 antitrypsin deficiency	A deficiency of A1AT, a protein produced in the liver that protects the lungs from excessive neutrophil elastase, an autophagic enzyme. A1AT may also accumulate in liver and cause liver disease	[55]
	Obstructive sleep apnea syndrome (OSAS)	A sleep disorder characterized by repetitive upper airway obstructions despite respiratory effort causing sleep fragmentation caused by repetitive arousals	[56]
Restrictive pathophysiology-parenchymal disease	Idiopathic pulmonary fibrosis (IPF)	Disease in which tissue deep in the lungs becomes thick and stiff, or scarred, over time. The formation of scar tissue is called fibrosis	[41]
	Asbestosis	Fibrotic lung disease resulting from extensive inhalation of asbestos fibers	[42]
	Desquamative interstitial pneumonitis (DIP)	Form of idiopathic interstitial pneumonia that is more common in cigarette smokers but may be seen in nonsmokers, in patients with underlying connective tissue diseases or those exposed to inorganic dust/particles	[43]
	Sarcoidosis	Immune-mediated systemic disorder that is characterized by granuloma formation of the lung parenchyma and the skin	[44]
Restrictive pathophysiology-neuromuscular weakness	Amyotrophic lateral sclerosis (ALS)	Progressive neurological disease that affects the motor neurons of the nervous system	[11]
	Guillain-Barre syndrome	Progressive immune system attack on the peripheral nerves, usually following an infectious illness such as a respiratory infection. May eventually cause respiratory distress syndrome	[11]
Restrictive pathophysiology-chest wall/pleural disease	Kyphoscoliosis	Kyphoscoliosis: a deformity of the thoracic cage that results in restriction of the lungs and impairs pulmonary function	[45]
	Ankylosing spondylitis	Autoimmune inflammatory disorder characterized by inflammation of the axial skeleton and peripheral joints	[46]
	Chronic pleural effusions	Chronic accumulation of fluid between the two outer membranes surrounding the lungs	[11]
Pulmonary vascular disease	Pulmonary embolism	Blood clot that typically originates from thrombi in the deep venous system of the legs and travels to the lungs	[47]
	Pulmonary arterial hypertension (PAH)	Progressive disorder of primary pulmonary arterial vasculopathy characterized by a mean pulmonary arterial pressure >25 mm Hg at rest (>30 mmHg during exercise)	[48]

Table 51.1 (continued)

Category	Disease	Definition	Source
Malignancy	Adenocarcinoma	About 40% of lung cancers are adenocarcinomas. These cancers start in early versions of the cells that would normally secrete substances such as mucus	[49]
	Squamous cell (epidermoid) carcinoma	About 25–30% of all lung cancers. These start in early versions of squamous cells, which are flat cells that line the inside of the airways in the lungs. Often linked to a history of smoking and tend to be found in the central part of the lungs, near the bronchus	[50]
	Large cell (undifferentiated) carcinoma	About 10–15% of lung cancers. It can appear in any part of the lung and tends to grow and spread quickly. A subtype of large cell carcinoma, known as large cell neuroendocrine carcinoma, is a fast-growing cancer that is very similar to small-cell lung cancer	[51]
	Small-cell lung cancer (SCLC)	About 10–15% of lung cancers are SCLC. Typically start in the cells lining the bronchi and parts of the lung such as the bronchioles or alveoli	[52]
Infectious diseases	Pneumonia	Inflammation of the lungs, usually caused by bacteria, viruses, or fungi	[11]
	Bronchitis	Inflammation and eventual scarring of the lining of the bronchial tubes accompanied by restricted airflow, excessive mucus production, and persistent cough	[11]
	Tracheitis	Bacterial infection that can develop in the trachea	[53]
	Infant respiratory distress syndrome	Also known as hyaline membrane disease (HMD) or respiratory distress syndrome, this condition affects the alveolar ducts and terminal bronchioles in which the hyaline membrane is a fibrinous material composed of blood and cellular debris, caused by the absence of proper surfactant production due to an immature or poorly developed lung	[54]
	Upper respiratory infection (URI)	Acute infections involving the nose, sinuses, pharynx, larynx, trachea, and bronchi, referred to as the common cold	[11]
	Bronchopulmonary dysplasia (BPD)	Chronic lung disorder which may affect infants who have been exposed to high levels of oxygen therapy and ventilator support	[11]
Other	Cystic fibrosis	Disease characterized by abnormally thick mucus secretions from the epithelial surfaces of many organ systems, including the respiratory tract, the gastrointestinal tract, the liver, the genitourinary system, and the sweat glands	[11]
	Acute lung injury	Clinical and radiographic changes in lung function associated with critical illness (acute respiratory distress syndrome is most severe form)	[11]

iron homeostasis [61]. Iron can also impair cytokine secretion, which can leave those with an iron overload much more susceptible to infection, increasing the morbidity and mortality of infectious diseases, including those of the lung [59].

Oxidative stress may contribute to injury of lung tissue, causing further fibrosing in those lung diseases with that characteristic. Allele variants in the genes associated with iron homeostasis (C282Y, S65C, and H63D HFE) are significantly more common in those with idiopathic pulmonary fibrosis (IPF) than those without IPF (40.4% IPF patients vs 22.4% non-IPF) and are associated with higher iron-dependent oxygen radical generation [62].

Iron is implicated in lung pathology. Monitoring iron status and using supplements or diet to aid the body in increasing or decreasing the iron load are imperative for the nutritionist working with lung disease patients. Choosing a good non-constipating form of iron is important, such as iron glycinate.

51.3.2 The B Vitamins

The B vitamins are also important to monitor for lung health. Vitamin B6 and its bioactive form, P-5-P, are typically known to protect DNA from mutation or damage [63]. However, there is mixed evidence on its role for lung cancer. Some research has shown that it is helpful for lung cancer patients as it is important for apoptosis when using chemotherapy, because it sensitizes cancer cells to apoptosis [63]. However, research in 2017 showed that adult male smokers taking greater than 20 mg vitamin B6/day for long periods tended to have a greater risk for lung cancer. Many variables, including genetic variants, form of B6, and the status of other co-nutrients may be at play [64]. Other studies showed that men in the top quintile of vitamin B6 serum concentration had about one half the risk of lung cancer, and specifically, vitamin B6 and folate were inversely associated with risk of lung cancer [65].

Because of disagreement in research, particularly with smokers or former smokers, using food first for B vitamins may be a prudent way forward. Good sources of vitamin B6 are fish, chickpeas, chicken, potatoes, turkey, bananas, ground beef, and winter squash.

Pyridoxal kinase (PDXK) is the enzyme that converts pyridoxine and other vitamin B6 precursors to its bioactive form of P-5-P. Dysfunction of this enzyme is a good prognostic for lung cancer and other lung diseases. *MTHFR 1298AA* genotype is associated with a higher risk of lung cancer in women but not in men. The *MTHFR 677TT* genotype was associated with a significantly decreased risk of lung cancer in women but not in men. In contrast, the *MTHFR C677T* and *A1298C* polymorphisms interacted with smoking status in men but not in women [66]. Methylation gene testing is imperative to understand the patient's status.

Some studies suggest that a higher intake of riboflavin (vitamin B2) may protect against lung cancer in smokers [67]. Folate deficiency was also associated with asthma and attacks of shortness of breath [8].

51.3.3 Acid/Alkaline

Correcting acidosis may preserve muscle mass in diseases where wasting is an issue, such as COPD or IPF. For those receiving chemotherapy, a higher pH (more alkaline status) is helpful for muscle mass protection. High alkaline diets contain more fruits and vegetables, and those supply more magnesium, which is needed to activate vitamin D. As discussed below, vitamin D is extremely helpful for lung health.

Sleep quality involves maintaining adequate 7–8 hours with good sleep hygiene (see ▶ Chap. 34). Good REM cycling, feeling refreshed upon awakening, and other characteristics of good sleep play significant roles in maintaining healthy acid-base balance.

Dietary intake of the minerals magnesium, potassium, sodium, chloride, and calcium promotes the balance of acid-base microenvironment. After exposure and tissue retention of toxic minerals and metals, these substances can contribute to perturbations in the acid-base metabolic milieu.

Some conditions reduce oxygen intake and should be addressed. One of the most common oxygen-impairing conditions is sleep apnea, altered sleep with random halting of breathing during sleep that is often accompanied by snoring. Other limiting conditions are respiratory diseases like COPD, A1AT deficiency, asthma, cystic fibrosis, etc.

51.3.4 Vitamin A

Vitamin A is an important antioxidant and a general umbrella term for several fat-soluble retinoids, including retinol, retinal, and retinyl esters. There are also other substances that are provitamin A carotenoids or precursors to vitamin A. Two forms are found in foods, the preformed forms of retinol or retinyl esters, which are found in dairy, fish, caviar, and meats (especially liver), and the provitamin A carotenoids, including the most important and common provitamin A carotenoid, beta-carotene, as well as others including alpha-carotenes and cryptoxanthin, which are found in plant-based foods. Our bodies must convert these two forms within our cells to retinal and retinoic acid, the active forms of vitamin A in the body. New studies of the gene, β-carotene 15,15′-monooxygenase (BCMO1), which is responsible for the enzymatic conversion of β-carotene to vitamin A, are revealing that individuals with heterozygous or homozygous BCMO1 SNPs have 30–60% less efficient conversion than those with normal gene function (see ▶ Chap. 17) [68]. Other carotenoids found in food, such as lycopene, lutein, and zeaxanthin, are not converted to vitamin A but have other antioxidant benefits in the body. Most vitamin A is stored in the liver as retinyl esters, and deficiency is not visible until these stores are nearly depleted.

Vitamin A's role as an antioxidant helps the lungs in several ways, including maintaining alveolar epithelium cells and preventing development of respiratory tract infections. Most of the developed world's population does not have a risk of deficiency due to sufficient vitamin A intake. However, most people with cystic fibrosis have pancreatic insufficiency, which reduces the ability to absorb fat and therefore the fat-soluble vitamins A, D, E, and K. According to a study in 2002, between 15% and 40% of people with cystic fibrosis had a vitamin D deficiency, also a fat-soluble vitamin. With the addition of pancreatic replacement treatments, better nutrition, and vitamin A supplementation, deficiency has become rare. However, improved vitamin A status has not been thoroughly studied as of 2018, and therefore it is largely unknown if an improved vitamin A status has any effect on cystic fibrosis [69].

Vitamin A deficiency has been shown to be associated with emphysema in rats. Smoke exposure significantly decreases vitamin A concentration in lung tissue, significantly more in those with COPD [70].

Retinoic acid seems to play a beneficial role in the treatment of IPF. A review showed that in all studies, retinoic acid decreased fibrosing, the formation of collagen, and reduced the expression of alpha-smooth muscle actin (alpha-SMA), all hallmarks of IPF [71].

It is important to not take large doses of vitamin A if one is in a malnourished state as it can cause toxicity and should be monitored with blood testing of vitamin A retinol. Nourish the body with all foods and all nutrients slowly.

The non-provitamin A carotenoids have also shown some benefit. Lycopene, found in high amounts in guavas, watermelon, tomatoes, papaya, grapefruit, sweet red peppers, asparagus, purple cabbage, mangos, and carrots, slowed forced expiratory volume (FEV) decline in former smokers [70].

51.3.5 Vitamin D

Vitamin D's importance with lung health cannot be understated. Vitamin D deficiency, or even insufficiency, is linked to

accelerated decline in lung function, increased inflammation, and reduced immunity in chronic lung diseases. Vitamin D has a role in the regulation of inflammation, immunity, cellular proliferation, senescence, differentiation, and apoptosis. Sufficient vitamin D levels are correlated with better asthma control, better immune response related to respiratory infections, and reduced severity of exacerbations with COPD and asthma when exposed to inflammation-causing pathogenic activity [72].

Vitamin D is obtained through sunlight on the skin (without sunscreen) and very few dietary sources. Therefore, supplementation is generally recommended. Higher vitamin D levels are shown to be protective in many lung disease states. Sufficient levels improve treatment response with medications and reduce asthma severity [68]. With infectious diseases of the lung, higher vitamin D concentrations are shown to have a protective action [6]. Vitamin D has a protective effect on lungs of smokers, and higher levels of vitamin D inhibit the pro-fibrotic phenotype of lung fibroblasts and epithelial cells. Current data suggest an inverse association between serum vitamin D and lung cancer risk, and vitamin D deficiency at 16–20 weeks' gestation is associated with impaired lung function and asthma at 6 years of age [73].

Lower levels of vitamin D are associated with an increased risk for respiratory infections, cystic fibrosis, chronic obstructive pulmonary disease, and interstitial lung disease [74].

51.3.6 Vitamin C

Vitamin C is an important antioxidant that helps decrease oxidative damage in the body, including in lung tissue. It is also essential for lipid metabolism. It is present in the airway surface liquid and creates an interface between the epithelial cells and the external environment. Vitamin C is a cofactor in collagen synthesis, which can aid in repair of bronchial and alveolar tissue when damaged. It also provides beneficial control of lipid peroxidation of cellular membranes, including those surrounding as well as those within intracellular organelles. Vitamin C has some of the best lung protective capabilities, according to current research.

Vitamin C may also diminish oxidative attack on nonlipid nuclear material and is an antioxidant component of plasma and extracellular fluids surrounding the lungs. It is an antioxidant that not only fights oxidative stress but also reduces oxidized vitamin E and glutathione, allowing them to become active as antioxidants again. Vitamin C is anti-inflammatory and is helpful in all inflammatory states of the lung, even allergies.

There are many ways in which vitamin C, along with its antioxidant partners, glutathione, vitamin E, vitamin A, and plant-based phytonutrients, affects lung health. It is well established that increased levels of vitamin C in the diet improve health outcomes for smokers and their offspring, as smoking depletes vitamin C [75, 76]. Vitamin C is also helpful in fighting infectious diseases such as respiratory infections and pneumonia, COPD regardless of smoking status, asthma, and lung cancer [77]. Specifically, in certain lung cancers, vitamin C, along with other nutrients such as lysine, proline, epigallocatechin gallate, and zinc, can inhibit the proliferation of certain carcinoma lines and induce apoptosis, as well as inhibit lung cancer metastasis [78]. Even in lung transplants, vitamin C is helpful against oxidative stress by reducing glutathione and lowering lipid peroxidation, along with vitamins A and E [79, 80].

The literature suggests these benefits can be achieved at 500–3000 mg/day. Check iron status before administering vitamin C supplementation as vitamin C doubles iron absorption from foods.

51.3.7 Vitamin E

Vitamin E's primary role is as an antioxidant, breaking free radical chain damage and preventing peroxidation of lipid molecules. This vitamin also is promising with regard to beneficial effects on lung function preservation. Oxidative stress and inflammation are key features in many lung diseases; therefore nutrients with antioxidant capacity can be useful. A few studies suggest that alpha-tocopherol found in sunflower and olive oils has a beneficial effect on FEV (forced expiratory volume), whereas gamma-tocopherol found in canola, soybean, and corn oils has a negative effect on FEV [81]. However, from these authors' perspective, this is likely due to the source and type of the oils, which can be inflammatory, rather than the form of vitamin E. For example, a recent study showed that gamma-tocopherol was protective in allergic asthma [82]. In addition, sufficient levels of vitamin E, in the alpha-tocopherol form, were found to reduce susceptibility of the elderly to acquiring pneumonia. Some of the positive effects of vitamin E are synergistic with vitamin C [83].

51.3.8 Phytonutrients

Phytonutrients have been found to have two effects with respect to lung disease: one is a symptom-improving pattern, and the other is a rate-reducing pattern [84]. Idiopathic pulmonary fibrosis (IPF) is largely characterized by reduced antioxidant and increased inflammatory action. Recent literature is showing the ability of certain flavonoids, in particular quercetin, to reduce inflammation and act as a strong antioxidant countering the pro-oxidant environment of IPF. Quercetin is recognized as the most potent ROS scavenger. Taken together with glutathione, the impact is even greater, and it seems to help improve the antioxidant and inflammatory status more for those with IPF than non-diseased controls [85].

Curcumin has been shown to slow or limit fibrosing in murine studies related to lung, liver, or kidney fibrosing [86–89]. It has also been shown to attenuate metastatic melanoma in the lungs when delivered in a nanoparticle [90]. The potential for curcumin is interesting and hopeful.

Fisetin and fenugreek have also been studied as useful phytonutrients that help combat inflammation in lungs

[91, 92]. Fisetin is found in apples, strawberries, persimmons, cucumbers, and onions, among many other fruits and vegetables. Fenugreek is a plant used frequently in South and Central Asian cooking, where both the seeds and leaves are used. There are now supplements available for both of these phytonutrients. This is a reminder to eat a primarily plant-based diet when combating inflammation and to broaden our palates to include healthy foods and ingredients from other cultures than our own.

Lastly, the powerful antioxidant cannabidiol (CBD), from the cannabis and closely related hemp plants, is a powerful shield against oxidative stress, prevalent in lung disease [93].

51.3.9 Minerals

The research is not robust regarding lung function and minerals, and most has been done with regard to cystic fibrosis where bone density is associated with general nutritional status, including minerals. There have also been many studies trying to determine a correlation between mineral status and COPD, where, again, the research shows that mineral status is not predictive but overall nutrient status may fall if not monitored. In contrast, one study in Japan showed an inverse association between dietary calcium and the risk for COPD [94]. In an NIH-AARP Diet and Health Study, magnesium, iron, selenium, zinc, and copper intakes, both dietary and supplemental, were studied with respect to lung cancer. Mineral *supplementation* did not affect lung cancer risk, yet *dietary* intake of calcium, along with vitamin D, and iron reduced the risk, and dietary intake of magnesium increased risk [95]. Boron has been shown to be protective against lung cancer, along with other nutrients, at levels of 3 mg/day [96].

There is some research showing that selenium is helpful, particularly for smokers, for improved FEV. Higher magnesium status is correlated to better FEV but is not yet seen as an association. This may be due to magnesium's role as the vitamin D activator. There have been a few studies showing increased copper levels are related to decreased FEV. Some recent research has also shown that dietary zinc and iron are associated with reduced lung cancer, but the same was not seen with calcium, copper, magnesium, or selenium [97]. Low mineral bone density is prevalent at a higher rate among cystic fibrosis patients, and therefore supplementation with vitamin D, vitamin K2, magnesium, calcium, and the trace minerals can be helpful [98].

51.3.10 Alpha Lipoic Acid

Alpha-lipoic acid (ALA) is a powerful antioxidant endogenously produced in the human body from foods such as yeast, organ meats, spinach, broccoli, and potatoes and is both water- and fat-soluble. ALA, along with N-acetyl cysteine (NAC), glycine, and vitamin C, is an important precursor to glutathione, which is a powerful endogenous antioxidant and the primary antioxidant in the lungs. ALA has been shown to be anti-inflammatory in lung tissue in those with acute lung injury, and the proposed action is via inhibition of the NF-kappaB signaling pathway [99].

ALA has also been shown to downregulate some cancer-promoting actions prevalent in lung cancer, likely by this same pathway [100]. It also may alleviate nicotine-induced lung oxidative stress [101].

51.3.11 NAC

N-acetyl cysteine (NAC), another precursor to glutathione, is a powerful antioxidant on its own as well. In relation to the lungs, NAC helps the clearance of mucus in the lungs by pulmonary cilia. This has been shown to be effective at 400–600 mg/day in divided doses [102]. There is significant research on NAC and lung health, showing improvement with nearly all lung issues, including nearly 40 studies showing improvement for bronchitis [103], infectious diseases by reducing the bacterial count [104], smokers, and people with asthma and COPD, through both its antioxidant effects and by reducing the viscosity of sputum and mucus. At an oral dose of 1800 mg/day, the mean glutathione concentration in lung tissue increased by 49% on one study [105]. There are additional studies showing improvement for those with COPD, asthma, cystic fibrosis, pulmonary fibrosis, and symptoms related to allergies or other infections. The dose that has been studied and has been shown to be most useful is 600 mg twice daily and more effective if nebulized [106, 107]. Both ALA and NAC supplementation should be accompanied by vitamin B6 and the complex of B vitamins to prevent an elevation in liver enzymes (Fig. 51.3).

51.3.12 Micronutrient Testing

There are several specialty labs that conduct micronutrient analysis and functional testing, such as Genova Diagnostics and SpectraCell. These tests can be useful for evaluating levels of individual nutrients as they function in the body, rather than just in serum, which is not an accurate indicator of tissue or functional status.

51.4 Macronutrients Important for Lung Function: Food-Based and Supplemental

51.4.1 Fats and Fatty Acids

Patients suffering from COPD, interstitial lung disease, and other diseases tend to have muscle and weight loss related to respiratory acidosis, and increasing weight and muscle mass helps with quality of life. Respiratory acidosis occurs with CO_2 buildup where the lungs are no longer able to effectively exchange O_2 and CO_2. Nutritional supplementation should attempt to reduce metabolic CO_2 production. Fat

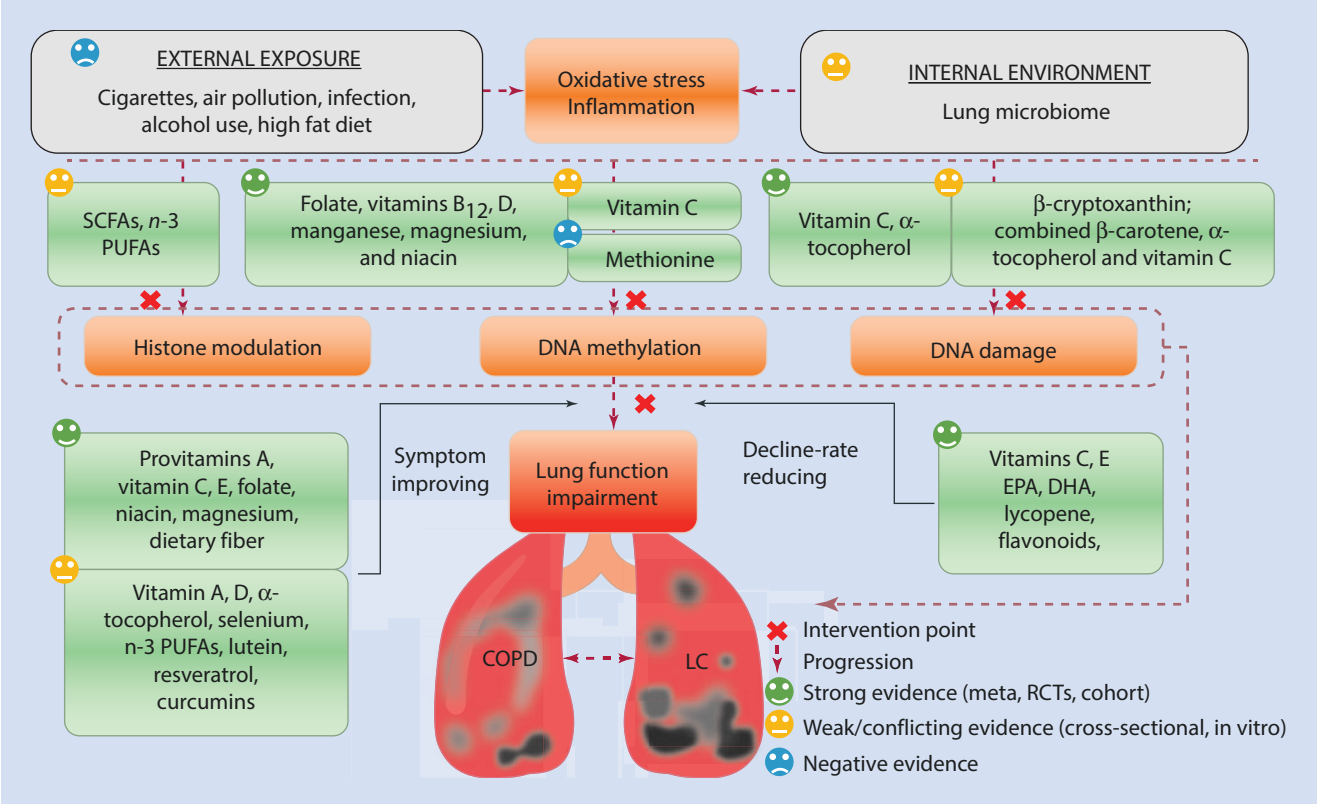

Fig. 51.3 Micronutrients and phytochemicals in the pathogenesis of chronic obstructive pulmonary disease (COPD) and lung cancer (LC). Summary of potential protective micronutrients and phytochemicals in the pathogenesis of chronic obstructive pulmonary disease (COPD) and lung cancer (LC). External and internal factors lead to oxidative stress and inflammation and thus initiate COPD and LC pathogenesis. Interventions against external exposure are not satisfying, while targeting the lung microbiome is promising. Recent studies have revealed strong evidence on protective nutrients in DNA methylation and damage, but studies on histone modulation are limited to animal or cell experiments. Epidemiological studies about micronutrients and phytochemicals in later key event lung function impairment are abundant and have identified different intervention patterns, including symptom improvement and a decline rate-reducing pattern. PUFA, polyunsaturated fatty acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; SCFA, short-chain fatty acid; RCT, randomized controlled trials [108, 109]. (Reprinted from Zhai et al. [70]. with permission from Creative Commons License 4.0: ▶ https://creativecommons.org/licenses/by/4.0/)

metabolism produces less CO_2 than carbohydrate metabolism, so emphasizing a higher fat, lower carbohydrate diet can be helpful [110].

In general, a high intake of omega-6 fatty acids is associated with poorer forced expiratory volume (FEV) in patients with lung disease because of their pro-inflammatory nature. However, a complete fatty acid panel or a red blood cell membrane fatty acid test would reveal more details about the status of an individual's omega-6 pathway. Certain omega-6s and the work of their corresponding metabolizing enzymes such as elongase and delta-5 or delta-6-desaturase may allow healthful omega-6s (linoleic (LA), gamma-linolenic (GLA), lipoxins [111], prostaglandin 1 series metabolites) to flow down an anti-inflammatory pathway instead. Important cofactors for this pathway are vitamin B2, vitamin B3, vitamin B5, vitamin B6, biotin, vitamin C, zinc, and magnesium.

Lipid metabolism dysregulation is understood to be part of the pathogenesis of idiopathic pulmonary fibrosis. In IPF, free fatty acids play a role in the proliferation of fibroblasts. Certain fats, in particular palmitic acid, oleic acid, and linoleic acid, are elevated in the lungs of those with IPF, whereas stearic acid is low. Stearic acid is found in meat, poultry, fish, grain products, and milk and milk products. The palmitic, oleic, and linoleic acids enhance the TGF-ß1-induced expression of α-smooth muscle actin (SMA) and collagen type 1 in MRC-5 cells, which can lead to fibrosis. Stearic acid inhibits the levels of these fibrosing cells. Stearic acid also improves the thrombogenic and atherogenic risk factor profiles [112].

In one study on patients with COPD, omega-3 fatty acids were found to reduce inflammation in bacterial infections of the lungs without suppressing the ability to clear the bacteria. Those taking EPA, DHA, ALA, and GLA had improved exercise capacity and had lower risk of developing COPD [113].

Although results have been mixed over the years possibly due to doses used in studies, a recent 2018 prospective study showed that PUFAs (omega-3s) from fish help prevent lung cancer and can be part of treatment during lung cancer. In general, the strongest evidence for improved lung function and slowing decline is with the EPA and DHA forms of omega-3 fatty acids [114]. Because of toxicity issues in fish, increasing quality supplements vs fish intake may be more prudent.

51.4.2 Protein

Protein is essential for all lung conditions, and lack of it can result in poorer pulmonary function, decreased exercise capacity, and increased risk exacerbations. Since many lung diseases have oxidative stress as a characteristic, it can cause protein carbonylation which may negatively affect DNA expression and lipid membranes. Nutritional supplementation with added protein and healthy carbohydrates can increase body weight and muscle strength and improve quality of life. Those with COPD, interstitial lung diseases, and others that affect oxygen absorption and CO_2 exhalation have greater levels of hypoxia and sometimes respiratory acidosis, which exacerbates the loss of muscle through oxidative stress and inflammation.

Supplementation of free essential amino acids versus complete proteins has been shown to help prevent muscle wasting among COPD patients. Muscle-building exercise is often prescribed for those with COPD and interstitial lung diseases [115]. Supplemental L-carnitine at 2–6 g/day for 1–2 weeks increased the capacity of COPD patients to rehabilitate and build muscle and helped inspiratory muscle strength.

51.4.3 Carbohydrates

Carbohydrates should be monitored for sufficient but not excessive levels. More CO_2 is produced with the utilization of carbs versus fats for energy. Therefore, with gas exchange being an issue with most lung disorders, a slightly higher fat and lower carbohydrate diet may be indicated. It is worth mentioning fiber for a moment, as it is mostly delivered in carbohydrate-rich foods. There is evidence that consuming whole fruits and vegetables higher in dietary fiber is associated with reduced severity of asthma and COPD [116]. A diet that derives its carbohydrates from vegetables and fruits rather than from processed carbohydrates such as grains, breads, pasta, or added sugars will deliver fewer carbohydrate grams.

51.5 Endogenous Essential Respiratory Metabolites

51.5.1 Glutathione

Glutathione (GSH), a tripeptide composed of cysteine, glutamine, and glycine and produced from methionine, is in every cell in the body. It is the most powerful and abundant endogenous antioxidant in the airway epithelial lining and is responsible for detoxification of electrophilic compounds, the scavenging of free radicals, and modulation of cellular processes such as DNA synthesis and repair, differentiation, apoptosis, and immune function [117]. It is also a heavy metal chelator. It is more effective than some other antioxidants because it is intracellular and extracellular. In isolated type II alveolar epithelial cells, extracellular glutathione inhibits hyperoxia-induced injury, inhibits pro-inflammatory cytokine release, and promotes cell growth. It is obviously very important to maintaining lung function as this is the inflammatory process that begins lung cell or tissue damage, as mentioned above. The highest levels of glutathione concentrations in the body are in the lungs, liver, and brain. GSH depletion leads to activation of NF-kB (pro-inflammatory signaling) and increased pro-inflammatory gene transcription and cytokine release from histone deacetylase suppression in epithelial cells. Total and reduced GSH concentrations are much lower in people with ARDS, pulmonary fibrosis, and hypersensitivity pneumonitis than observed in healthy adults. Alterations in alveolar and lung GSH metabolism are widely recognized as a central feature of many inflammatory lung diseases such as idiopathic pulmonary fibrosis, acute respiratory distress syndrome, cystic fibrosis, and asthma [118].

We make glutathione in the body with cysteine and methionine, and it is difficult to take exogenously because digestion can destroy it. The precursors of cysteine (essential), glutamine, and glycine and cofactors (vitamin C, vitamin E, vitamins B1, B2, B6, and B12, folate (B9), minerals selenium, magnesium, and zinc, and alpha-lipoic acid, see below) are therefore recommended so that the body can produce it on its own. The two enzymes necessary to produce it, gamma-glutamylcysteine synthetase and glutathione synthetase, must also be functioning well. We also recycle glutathione if the precursors and cofactors are available. Cysteine is usually the most rate-limiting precursor, and many people supplement with N-acetylcysteine to provide the body with this nutrient. Although glutathione is produced in every cell of the body, the greatest production is in the liver, so focusing on liver health is important to maintain good glutathione production. Production declines with age and with lung disease, as well as other conditions.

There are very few foods containing glutathione; they are raw or very rare meat, especially liver, unpasteurized milk and other unpasteurized dairy products, and freshly picked fruits and vegetables, such as avocado and asparagus. However, as mentioned earlier, it may be destroyed during digestion. Glutathione contains sulfur molecules, which may be why foods high in sulfur help to boost its natural production in the body. These foods include:

- Cruciferous vegetables, such as broccoli, cauliflower, Brussels sprouts, and bok choy
- Allium vegetables, such as garlic and onions
- Eggs
- Nuts
- Legumes
- Lean protein, such as fish and chicken

Other foods and herbs that help to naturally boost glutathione levels include:

- Milk thistle (a liver-regenerating herb)
- Flaxseed
- Guso seaweed
- Whey

Glutathione is also negatively affected by insomnia. Getting enough rest on a regular basis can help increase levels.

Addressing a drop in glutathione for lung health involves maintaining good levels of the precursors and cofactors mentioned above. A good way to bring in the less abundant amino acid cysteine is to take N-acetylcysteine (NAC). Doses of 400–600 mg were more effective than placebo in reducing symptoms [117]. Supplemental selenium can also help with glutathione production. Glutathione supplementation has also become more effective. There are several forms, from capsules to topical liposomal, which have shown good absorption.

Inhaled GSH has good research for use in cystic fibrosis (CF), chronic otitis media with effusion (OME), HIV seropositive individuals, idiopathic pulmonary fibrosis (IPF), and chronic rhinitis. It is not recommended for asthma due to significant side effects, and additional evidence is needed to determine if use with emphysema is recommended although theoretically it should be useful. It is also not recommended to use inhaled GSH during cancer chemotherapy treatment as it may interfere with the medication's actions. The mechanism of action of inhaled glutathione is limited to the upper airways and lungs and does not seem to affect serum levels. Before considering inhaled GSH treatment, the patient should undergo urine sulfite sensitivity testing using a readily available special test strip called "EM-Quant 10013 Sulfite Test." If positive, inhaled GSH should not be used as bronchoconstriction may occur.

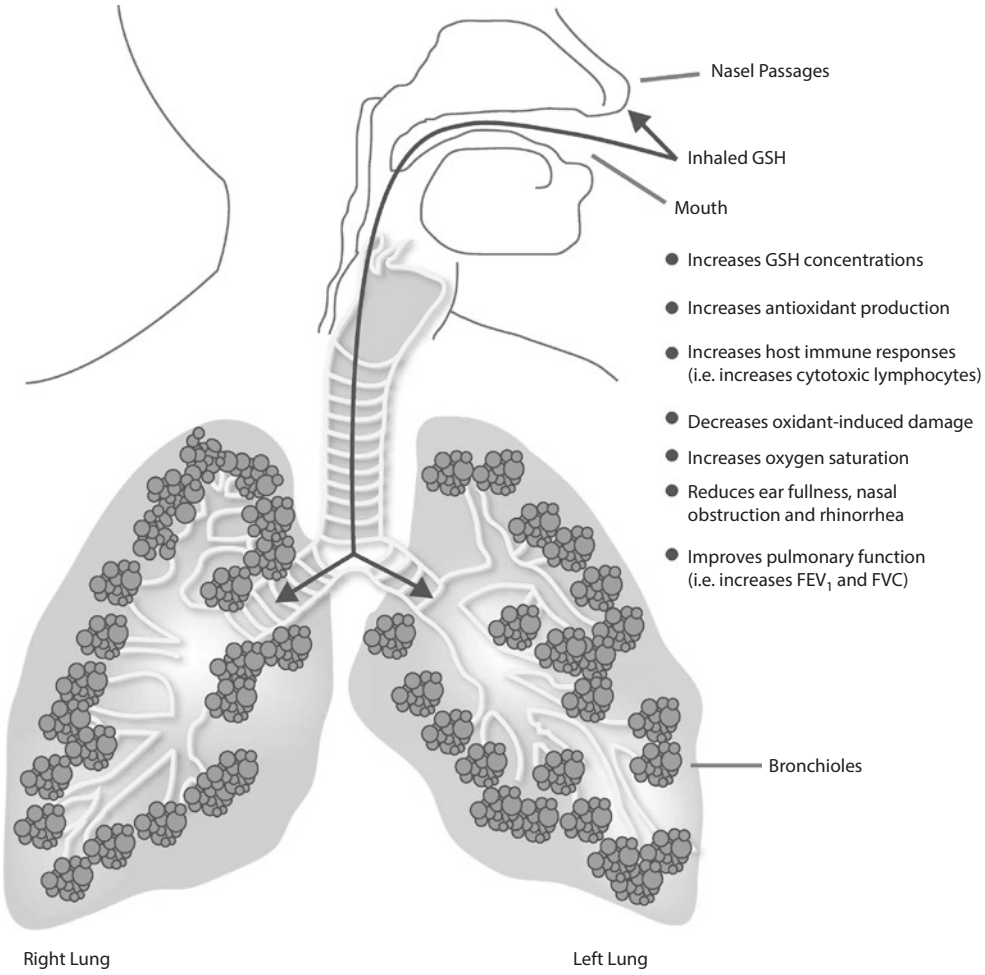
The recommended dose is 600–5000 mg per day, depending on response, and whether inhaled GSH is considered safe. Efficacy should be tested using a baseline pulmonary function test and a follow-up test after a prescribed time later [119] (◘ Fig. 51.4, ▶ Box 51.1). There are also serum tests for glutathione levels.

Box 51.1 Glutathione Cofactors

These cofactors are vitamin C; vitamin E; vitamins B1, B2, B6, and B12; folate (B9); minerals selenium, magnesium, and zinc; and alpha-lipoic acid.

What do the glutathione cofactors do that makes them so important?

- Direct cysteine toward glutathione production and increase cellular uptake of cysteine
- Help form the glutathione molecule out of the three precursor amino acids
- Help recycle glutathione from its oxidized GSSG form back to its reduced (active) GSH form
- Help maintain glutathione levels and keep the GSSG-GSH ratio balanced
- Recycle each other, improving overall antioxidant activity
- Stimulate the activity of the whole glutathione enzymatic system



◘ **Fig. 51.4** Inhaled GSH's mechanism of action. GSH, reduced glutathione; FEV1, forced expiratory volume in 1 s; FVC, forced vital capacity [119]. (Reprinted from Prousky [35]. With permission from Creative Commons License 3.0: ▶ https://creativecommons.org/licenses/by/3.0/)

Vitamin C – As an antioxidant, it assists glutathione in this function and has been shown scientifically to raise glutathione levels short term; it is recycled by glutathione from its oxidized state back to its active state, thus strengthening antioxidant defenses; vitamin C also recycles vitamin E and alpha-lipoic acid

Vitamin E – As an antioxidant it also assists glutathione in eliminating free radicals much like vitamin C; it is also required for the proper functioning of glutathione enzymes; it recycles vitamin C and alpha-lipoic acid

B vitamins – Vitamins B1 and B2 maintain glutathione and its enzymes in their active forms; vitamin B2 participates in the formation of a glutathione molecule; vitamin B6 influences glutathione synthesis indirectly as it is important for the proper functioning of amino acids including GSH precursors; vitamin B6 increases the amount of magnesium (a vital cofactor) that can enter cells; folate (B9) pushes cysteine toward glutathione production rather than homocysteine production; folate and vitamin B12 work together in amino acid metabolism and protein synthesis. You can read more vitamin B12 deficiency and its effect on immune health at ► http://www.immunehealthscience.com/vitamin-b12-deficiency.html

Selenium – Part of the enzyme glutathione peroxidase (GPx). Glutathione peroxidases, also known as selenoproteins, are a family of antioxidant enzymes that speed up the reaction between glutathione and free radicals

Magnesium – Required for the proper functioning of the enzyme gamma-glutamyl transpeptidase (GGT) involved in the synthesis of glutathione

Zinc – Zinc deficiency reduces glutathione levels, especially in red blood cells. However, zinc levels above normal have pro-oxidant properties and reduce glutathione too

Alpha-lipoic acid – An antioxidant produced by the body; it has been scientifically proven to enhance and maintain glutathione levels by stimulating enzymes involved in the synthesis of glutathione; it also helps increase the cellular uptake of cysteine, the crucial building block of glutathione; in addition, alpha-lipoic acid recycles vitamins C and E

Based on data from Ref. [124]

51.5.2 CoQ10

Co10 is a fat-soluble compound produced endogenously and also available through food and supplementation. It is required in the production of ATP, is a powerful antioxidant, and therefore is helpful against oxidative stress, an important issue in lung disease. CoQ10 achieves its strong effects through a set of different mechanisms. It influences genes through its epigenetic effect to reduce inflammation, helps with the immune system, and even reduces aging by reducing systemic oxidative stress and mitochondrial aging [120].

Lungs are the most susceptible organ to oxidant damage because they interact directly with oxygen. Therefore, it makes sense that antioxidants, and those that especially affect the lungs, are helpful in tissue and lung cell preservation [121].

CoQ10 levels are significantly lower in those with COPD and asthma with insignificant amounts of research on the levels of CoQ10 with other lung issues. It has been shown that supplementing patients with CoQ10 resulted in measurable benefits. In one study, patients with COPD using steroids to reduce inflammation were able to reduce their steroid dosage when using CoQ10 [122]. In another study, benefits were shown for COPD patients during exercise, measuring performance, tissue oxygenation, and heart rate at a low dosage of 90 mg/day [123]. The levels of CoQ10 in the blood have been shown to indicate the degree of systemic oxidative stress, which implies it could be used as a marker to assess COPD [121]. Several studies confirm the beneficial role of CoQ10 in decreasing oxidative stress, cardiovascular risk, and modulating inflammation during aging. Dosage levels of 1200 mg/day of CoQ10 have been shown to be therapeutic. However, in the reduced, more absorbable form, ubiquinol, 400 mg/day, was shown to be as effective.

51.6 Anti nutrients and Inhibitors of Lung Physiology

There is a wide range of toxins and anti-nutrients that can significantly impact the respiratory system. This can occur through acute or chronic exposure to these agents.

The Earth's air is the source of oxygen, and the lungs provide access to that oxygen to support life. The human need for oxygen is precarious because humans can only survive for about 6 minutes without the precious gas. From about 1760 to sometime between 1820 and 1840 in Europe and the United States, the ramp-up of new industrial revolution manufacturing processes opened a new era of increasing chemical and heavy metal atmospheric contamination. These pollutants can enter the body through breathing the polluted air. The more concentrated atmospheric pollutant densities cluster around areas of dense population. The dirty air provides a serious direct threat to those with respiratory diseases. An integrative and functional approach to assessing an individual with respiratory disease needs to include consideration of potential environmental contributors to the etiology of a condition. ◘ Table 51.2 lists environmental pollutants that are known to promote lung pathology.

A 2016 study published in the *Canadian Respiratory Journal* examined exhaled fractional nitric oxide (FeNO) – an indicator of inflammation in the lungs – in school children at three different schools located three different distances from a large steel mill [127]. Steel processing is known to be a source of ambient iron, nickel, lead, copper, vanadium, and zinc. The study found statistically significant differences in FeNO between the two closer schools compared to the farthest school from the mill, indicating potential increased lung inflammation caused by heavy metals and/or air pollutants [127].

51.6.1 Toxic Metals

Although acute metal toxicity is possible, chronic, low-grade exposure is more common and may contribute to respiratory complications and disease. An individual's ability to

Table 51.2 Environmental pollutants related to promoting respiratory disease

"Silent hazards" ingested or inhaled hazardous substances undetected until disease and death results and investigation is mounted to identify the cause [125]	
Natural sources – weather, geology, and pathogen exposure	
Dust	All respiratory stress
Volcanogenic air pollution	All respiratory stress
Mold/mycotoxins	Pneumoconiosis, COPD, all respiratory stress
Infection: viral, bacterial	Pneumococcal pneumonia Viral pneumonia
Anthropogenic – caused by human activity	
Smoking/tobacco	Lung cancer
Dental: mercury amalgam	Acute mercury inhalation poisoning
Dental: fluorosis/fluorine vapor	Pulmonary fluorosis [126]
Asbestos (construction materials/dust particles)	Lung cancer, mesothelioma
Nuclear radiation accidents/job exposure	Pulmonary inflammation, scarring, cancer
Coal mining	Pneumoconiosis, black lung disease
Coal combustion/mercury vapor	Acute mercury inhalation poisoning

eliminate these metals via detoxification in conjunction with gastrointestinal health and other factors can serve as important factors in whether or not these metals accumulate in the body.

51.6.1.1 Arsenic

Chronic arsenic exposure may be linked to respiratory complications [128]. Chronic arsenic ingestion via contaminated drinking water may be connected to respiratory symptoms such as chronic cough, shortness of breath, blood in sputum, and abnormal breath sounds [129]. Arsenic can also be ingested through foods such as rice and rice products, shellfish, and seaweeds, which have been shown to have high levels of inorganic arsenic (more toxic than organic arsenic found in fish) [120]. However, ingested inorganic arsenic is typically biotransformed and excreted in the urine [130]. That said, altered biotransformation has been observed depending on an individual's age, gender, nutritional status, and genetic polymorphisms responsible for the biotransformation of inorganic arsenic [130]. Chronic inhalation versus ingestion may result in irritation of the throat and respiratory tract [131]. Individuals most affected by arsenic exposure are children, nursing children, and infants of exposed pregnant mothers [132].

51.6.1.2 Cadmium

Acute inhalation of cadmium may lead to dyspnea and coughing [133]. Long-term exposure to cadmium has been reported to contribute to emphysema, dyspnea, and inflammation of the nose, pharynx, and larynx [123]. Individuals most affected by cadmium toxicity are those with occupations with cadmium exposure, such as those who work in certain types of factories, women, due to higher intestinal absorption because of low iron stores, and residents of Asia due to high intake of rice grown in contaminated soil [134].

The 2013 US National Health and Nutrition Examination Survey (NHANES) demonstrated an association between obstructive lung disease and serum lead and cadmium concentrations in the blood, where cadmium was shown to partially mediate the association between smoking and obstructive lung disease [135]. In the 2015 Korean NHANES, obstructive lung function was found to be associated with higher serum blood levels of cadmium and lead as well [136].

The specific mechanism of heavy metal burden and its effects on respiratory health must be further investigated. Although testing and treatment of heavy metal burden have its limitations, it is worth considering as heavy metal accumulation can wreak havoc on the body. An example of heavy metal testing that can be used in practice is urine provocation testing with a chelating agent, such as FDA-approved DMSA. Eliminating heavy metals from the body can be potentially harmful and requires careful monitoring and guidance by an experienced healthcare professional.

51.6.2 Air Pollutants

Air pollutants that are used as indicators of air quality are carbon monoxide, lead, nitrogen dioxide, ozone, particles, and sulfur dioxide [137]. Air pollution has been shown to have adverse effects on human health [138]. A 2017 systematic review and meta-analysis done in China showed an association between respiratory disease and ambient nitrogen dioxide, which is increased through fuel combustion, industrial production, and fuel exhaust [129]. Diesel exhaust particles in particular have been associated with an increase in cytokines such as IL-2, IL-6, and IgE in nasal mucosa [139]. Nitrogen dioxide in particular can potentially contribute to respiratory disease as it is a free radical that is highly reactive and poorly water-soluble and can be deposited in the lungs when inhaled [138]. In another study performed in England, air concentration of nitrogen dioxide was significantly associated with respiratory hospital admissions [140].

Other pollutants, such as fine particulate matter and ozone, have been shown to significantly affect respiratory function in COPD patients [141]. Increased ozone exposure has also been associated with increased airway inflammation and respiratory symptoms along with decreased respiratory function in children [142].

Optimization of nutrition and antioxidant status is essential to combating the potential health effects of air pollutants.

Several studies have shown that nutrients such as vitamin C, vitamin E, vitamin D, omega-3 PUFA, and B vitamins have demonstrated a protective effect against the damage done by particulate matter [143]. It would be reasonable to assume having adequate stores and ability to utilize these nutrients may protect against other insults to the respiratory system as discussed in this section through their anti-inflammatory properties.

51.6.3 Chemicals

Acute and chronic exposure to certain chemicals can also pose a risk to respiratory health. Obtaining a full occupational and social history when assessing individuals is important in order to identify any potential exposure to chemicals.

One of the most well-known and common toxic chemical exposures that affects respiratory health is cigarette smoke. Smoking cigarettes has been identified as a main cause of COPD [144]. Increased oxidative stress from inhaling cigarette smoke appears to activate the NF-KB inflammatory pathway, increasing the production of pro-inflammatory cytokines such as interleukin (IL)-1, IL-6, and IL-8 and tumor necrosis factor-α (TNF-α) [144]. It also appears to reduce anti-inflammatory cytokines such as IL-10 [145].

Electronic cigarettes, or E-cigs, have been increasing in popularity in recent years and are marketed as a better alternative to tobacco cigarettes. However, recent evidence suggests that the vapor and associated chemicals produced by E-cigs may be harmful to the respiratory system, although further research is needed to determine the mechanism [146, 147].

Exposure to metalworking fluid aerosols has been associated with asthma, hypersensitivity pneumonitis, impaired lung function, allergic alveolitis, and sinusitis [148]. A 2015 review also identified an association between occupational exposure to pesticides and increased risk of asthma and chronic bronchitis [149].

There are many chemicals that are toxic when inhaled. For example, inhalation of chlorine is toxic to the lungs, where low doses can cause airway injury and high doses can cause both airway and alveolar injury [150]. These injuries can manifest as dyspnea, hypoxemia, pulmonary edema, and pneumonitis [150]. High doses of carbon dioxide, such as that released from dry ice, can also induce respiratory failure.

51.7 Stress

51.7.1 Stress Overview

Stress may also play a role in respiratory health and the body's ability to combat insults imposed on the respiratory system.

From a physiological standpoint, it is worth noting that acute stress via activation of the sympathetic nervous system increases ventilation through the production of glucocorticoids [139]. Repeated acute stress may also affect growth and repair mechanisms [139].

Chronic biological stress in the form of infections can also be inflammatory and negatively affect the immune system and may affect an individual's susceptibility to respiratory complications. See the *Chronic Infections and Respiratory Health section on page #* below for further information on this association.

However, appropriate amounts of physical stress, such as in the form of exercise, can be beneficial to respiratory health. Some research has indicated a benefit of aerobic exercise to respiratory muscle strength in cystic fibrosis patients [151].

51.7.2 Biological Stress

Chronic stress can be defined as recurrent acute stress or inability to moderate acute stress responses [139]. This can be in the form of physical or emotional stress. Chronic stress and negative emotions such as depression, anxiety, and anger may be linked to endocrine and immune processes [152].

Immunoglobulin E (IgE) and cytokine production, as well as respiratory inflammation, are markers that characterize the asthma response and have been shown to respond to stress in some capacity [139]. It has been hypothesized that increased stress may increase susceptibility to air pollution given its effects on the inflammatory response [139].

Another connection between emotions and respiratory health is acknowledged in East Asian medicine, noting the association between the lungs and feelings of sadness, grief, and anxiety [153] (◘ Table 51.3).

51.8 Disease States

51.8.1 Asthma

51.8.1.1 Background

Asthma is a chronic inflammatory lung disease, triggered by either an IgE allergic reaction or nonallergic factors, and results in reversible airway obstruction and inflammation of the airway [11]. It is characterized by recurrent episodes of wheezing, breathlessness, coughing, and chest tightness [11]. Severe asthma or asthma that is chronic or poorly controlled may lead to airway and lung remodeling that involves deposition of fibrotic tissue which leads to constriction of the bronchi [18].

Although the exact mechanisms have not yet been identified, compromised nutritional status, such as deficiencies in selenium, zinc, and vitamins A, C, D, and E, has been connected to asthma [155]. The pathophysiology of asthma, nutrition considerations, genotypic characteristics, and lifestyle influences will be discussed in this section.

There are numerous potential triggers to the development and/or exacerbation of asthma which can be summarized in ▶ Box 51.2.

The various causes of asthma have led to the classification of several different subtypes and endotypes of asthma in hopes of choosing more targeted treatments.

Table 51.3 Anti-nutrients of the lung and potential mechanisms

Anti-nutrient	Mechanism/hypothesized mechanisms
Toxic metals (e.g., arsenic, cadmium)	Inhaled cadmium (Cd) is deposited in the alveoli where it is then absorbed into the bloodstream Cd is transported to erythrocytes or bound to albumin, where it is then taken up by the liver to form a complex with metallothionein (MT) Cd interferes with the absorption of zinc and competes for the same enzyme binding sites Enzymatic activity of zinc-dependent enzymes reduces Preferential binding of Cd to MT can cause zinc deficiency Altered biotransformation and excretion of ingested arsenic via contaminated water are linked to respiratory complications Chronic inhalation of arsenic may result in irritation of respiratory tract
Air pollutants	Diesel exhaust particles in particular have been associated with increase in cytokines such as IL-2, IL-6, and IgE in nasal mucosa [139] Nitrogen dioxide is a free radical that is highly reactive and poorly water-soluble and can be deposited in the lungs when inhaled [102] Rising pollen and mold counts [154] Increasing ozone [154]
Chemicals	Increased oxidative stress from inhaling cigarette smoke may activate the NF-KB inflammatory pathway, increasing the production of pro-inflammatory cytokines such as interleukin (IL)-1, IL-6, IL-8, tumor necrosis factor-α(TNF-α) Cigarette smoke may reduce anti-inflammatory cytokines such as IL-10 [145]
Stress	Repeated acute stress may also affect growth and repair mechanisms [139] IgE and cytokine production, as well as respiratory inflammation, are markers that characterize the asthma response and have been shown to respond to stress in some capacity [139] Increased stress may increase susceptibility to air pollution given its effects on the inflammatory response [139]

Box 51.2 Suspected Triggers and/or Risk Factors for the Development or Exacerbation of Asthma (1) [18]; (2) [25]; (3) [156]

(1)
- Cigarette smoke
- Air pollution
- Grass, mold, plants
- Pet dander
- Cockroach droppings
- Cold temperatures
- Viral infections (i.e., respiratory syncytial virus (RSV))
- Stress
- Physical exertion
- Decreased exposure to dirt
- Frequent use of antibiotics in early childhood and adolescence
- Overuse of aspirin and acetaminophen in early childhood and adolescence

(2)
- Food allergy
- Monosodium glutamate (MSG)
- Sulfites
- Reactive hypoglycemia
- Sodium chloride
- Trans fatty acids
- Obesity

(3)
- Maternal obesity during pregnancy
- Low vitamin D

51.8.1.2 Pathophysiology

The pathophysiology of asthma is complex and not fully understood, due in part to its heterogeneous nature, which necessitates its organization into individual phenotypes and endotypes. This organization is important to be able to utilize targeted treatments by identifying the root causes of the symptoms. However, more research is needed to more clearly identify the specific pathological mechanisms of each phenotype and particular treatment responses [156].

Two of the most common asthma phenotypes are allergic and nonallergic asthma [147]; allergic is characterized by increased Th2 immunity (Th2 high) and nonallergic defined by varying mechanisms depending on the trigger (Th2 low) [157] (see also ▶ Chap. 19).

Allergic asthma involves the ingestion of typically harmless environmental triggers (listed in Table 51.3) by antigen-presenting cells in the bronchi, which interact with immature helper T cells that, in turn, trigger an unwarranted allergic response [18]. This reaction occurs from repeated exposure to a trigger and is referred to as the type 1 hypersensitivity response [18]. This increased Th2 immunity upregulates eosinophilic inflammation, tissue damage, airway hyperresponsiveness, and bronchoconstriction [113]. Mast cell activation disorders, which is characterized by diseases and conditions related to mast cell mediators and the activation of mast cells, must also be considered when addressing allergic asthma [158].

In contrast, nonallergic asthma can be caused by other factors such as anxiety, exercise, stress, dry air, cold air, viruses, hyperventilation, smoke, or other irritants [11].

Table 51.4 A few of the proposed phenotypes and endotypes and their characteristics

Proposed phenotype or endotype	Clinical findings	Biomarkers	Epidemiology	Proposed mechanisms/genetics	Medications
Phenotypes					
Allergic asthma	Allergic rhinitis Allergen-associated symptoms	Positive skin prick tests (SPT) High IgE High FeNO	Childhood onset History of eczema	Th2 dominant Th2 pathway single-nucleotide polymorphisms	Less responsive to inhaled corticosteroids IgE antagonists (omalizumab) are typically more effective [159]
Nonallergic asthma [156]	Asthma not associated with allergic	May be neutrophilic, eosinophilic, or contain only a few inflammatory cells	Additional research needed	Additional research needed	Less responsive to inhaled corticosteroids
Severe late-onset hypereosinophilic asthma (see box below on eosinophilic asthma)	Severe exacerbations, late-onset disease	Blood and sputum eosinophils	20% of severe asthmatics	Nonatopic Genetics unknown	Oral corticosteroids, IL-5 antibody therapy potential treatment
Endotypes					
Allergic bronchopulmonary mycosis (ABPM)	Severe Mucus production	Blood eosinophils High IgE High FeNO	Adult onset Long duration Poor prognosis	Colonization of airways Human leukocyte(HLA) and rare cystic fibrosis (CF) variants	Oral corticosteroids(not inhaled) and oral antifungal agents can be effective [159]
Cross-country skiing-induced asthma (CCSA) [107]	Exposure to dry, cold air provoking wheezing Airway remodeling, thickening of basement membrane	Increased lymphocytes, macrophages, neutrophils Seldom eosinophils	Induced at very cold temperatures during strenuous exercise	Nonatopic Unknown	Usually not responsive to glucocorticoids [159]

Based on data from Ref. [157]

Individuals suffering from nonallergic asthma will tend to be less responsive to Th2-targeted treatments due to a differing immune response at play [157].

Some of the additional proposed phenotypes are eosinophilic, exacerbation-prone, exercise-induced, fixed obstruction/airflow limitation, poorly steroid-responsive, and adult-onset obesity-related [159]. Several of the proposed endotypes are summarized in Table 51.4.

The American Partnership for Eosinophilic Disorders defines eosinophilic asthma as a type of asthma characterized by especially high levels of eosinophils, more commonly developed later in adulthood, although may occur in some children [160]. Many with eosinophilic asthma do not have underlying allergies or history of allergic conditions such as eczema, food allergy, and hay fever, which are thought to be seen more in people with allergic asthma [160]. In contrast to allergic asthma, the cause of eosinophilic asthma is still unknown.

Histamine intolerance must also be considered in assessing the root cause of asthma. Ingesting histamine-rich foods and beverages such as bananas, grapes, strawberries, citrus fruits, tomatoes, nuts, chocolate, pineapples, fish, spinach, fermented foods, and beverages [161] has been shown to provoke a histamine response that may result in asthma exacerbations, among many other potential signs and symptoms [162].

Disruptions in redox, or oxidation/reduction, reactions in addition to hindered antioxidant defense have been

found to be a risk factor for asthma severity and development [163]. The levels of glutathione, one of the lung's most predominant antioxidants in both reduced and unreduced forms, are thought to be important for lung homeostasis and tied to asthma [163]. More research is needed to determine the exact differences in the pathophysiologies of the various subtypes of asthma in order to develop more targeted treatments.

51.8.1.3 Key Nutrient Cofactors for Respiration and How to Modulate Toward Optimum

Minerals such as zinc, selenium, copper, and manganese may serve as cofactors to major enzymes with antioxidant activity in the lung, such as superoxide dismutase, catalase, and glutathione peroxidase [164]. Asthma has been associated with decreased activity of these enzymes [165].

Low selenium intake has been associated with multiple chronic diseases including asthma [163]. Selenium serves as a cofactor to glutathione peroxidase, an enzyme with antioxidant activity in the lung that is responsible for maintaining GSH/GSSG redox balance [163].

Imbalance between oxidants and antioxidants seems to serve an important role in asthma. Levels of nonenzymatic antioxidants glutathione, ascorbic acid, alpha-tocopherol, lycopene, and beta-carotene, in addition to antioxidant enzymes superoxide dismutase (SOD) and glutathione peroxidase, were significantly lower in asthmatic children compared to healthy controls [165]. The amino acids glycine and glutamine, which are important in glutathione synthesis, were also found to be significantly lower in children with asthma [165].

DHA has also been found to be abundant in airway mucosa, where it is decreased in individuals with asthma and cystic fibrosis [166].

Magnesium is known to elicit the relaxation of bronchial smooth muscle, decrease responsiveness to histamine, have an anti-inflammatory effect, and decrease the susceptibility of animals to developing anaphylactic reactions [25]. It is estimated that two-thirds of the population in the Western world is not consuming the recommended daily allowance of magnesium [167]. Magnesium can be used intravenously as an effective treatment of acute asthma attacks. One double-blind controlled trial that used 1.2 g of magnesium sulfate when patients did not respond to treatment with beta-agonists found decreased likelihood of hospitalization and improved lung function [168]. Magnesium sulfate as an adjunct therapy with bronchodilators and steroids has also been shown to have a benefit in children with moderate to severe asthma [168]. Although the exact mechanism is not yet known, magnesium is thought to increase glutathione concentrations in the lung [169].

More research is needed to determine additional associations between specific nutrients and asthma. However, optimization of the nutrients discussed in this section has the potential to reduce the severity and/or progression of asthma (◘ Fig. 51.5).

51.8.1.4 Key Genotypic Characteristics of Topic and Nutritional Influence

Asthma has a strong genetic component, with more than 100 genes associated with it in varying degrees across many populations [18]. More recent potential genetic associations include Filaggrin, which encodes for the epithelial barrier; ORMDL3, which encodes transmembrane protein; beta-2 adrenergic receptor gene, expressed throughout smooth muscle and epithelial cells of the lung; and interleukin-4 receptor gene, which has a variant associated with elevated IgE [171].

51.8.1.5 Key Dietary and Food Patterns to Promote Disease or Wellness in Asthma Nutrition Status

A 2011 systematic review and meta-analysis showed that deficiencies in selenium, zinc, vitamins A, C, D, and E, and low fruit and vegetable intake could be associated with the development of asthma [155]. Although this data is tenuous due to lack of randomized controlled trials, it does give some indication of the relationship between nutrition status and dietary patterns with respect to asthma development. More research needs to be done to isolate the impact of these nutrients and dietary patterns on asthma prevention and development.

Dietary Patterns

A 2015 review conducted by Berthon and Wood noted the protective effects of the Mediterranean diet for allergic respiratory diseases as evidenced by epidemiological studies. This diet emphasizes minimally processed plant foods in the form of fruit, vegetables, cereals, beans, breads, nuts, seeds, and olive oil and low to moderate intake of dairy, poultry, fish, and wine, as well as low intake of red meat [172]. This association was the strongest in children, where the Mediterranean diet had a protective effect on atopy, wheezing, and asthma symptoms [172]. However, there is less data available to support this pattern in adults.

The same review noted an association between the "Western" diet, which emphasizes refined grains, red and cured meats, French fries, sweets and desserts, and high-fat dairy products and increased risk of asthma in children [172]. A meta-analysis and systematic review done in 2014 showed a reduction of risk in childhood wheezing with high fruit and vegetable intake and also showed negative association between fruit and vegetable intake and asthma risk in adults and children [173].

Food Allergy

In contrast, food allergy has been especially linked with allergic asthma in children [161]. A study examining food allergy in asthmatic children identified higher serum levels of IgE in asthmatic children compared to healthy controls, where all asthmatic children in the study were also identified as having a positive skin prick test (SPT) to various food allergens [174].

A study done on 322 children under the age of 1 diagnosed with asthma, with or without allergic rhinitis, was

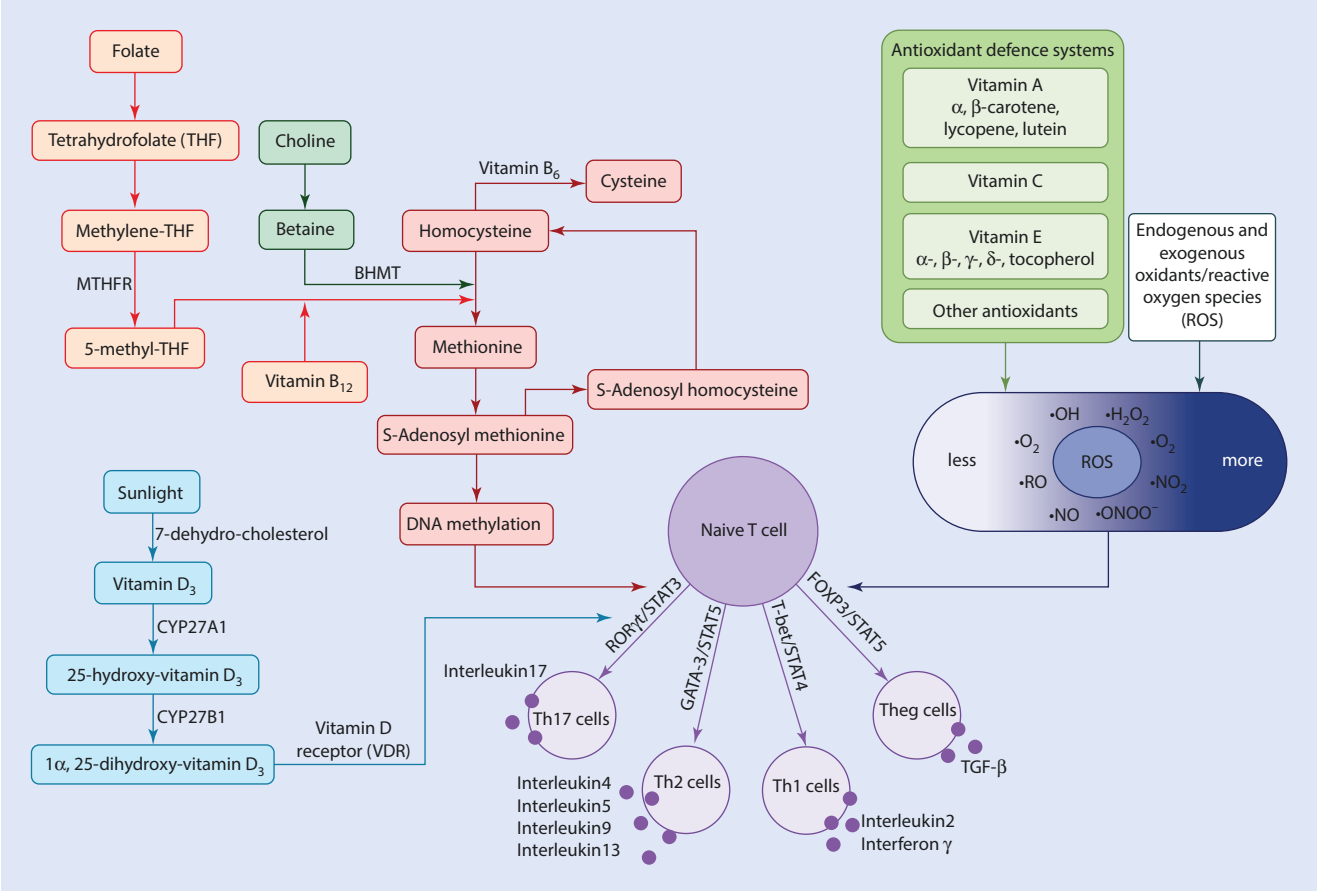


Fig. 51.5 Potential mechanisms of methyl donors and vitamins. Potential mechanisms of action of methyl donors and vitamins **a**, **c**, **e**, and **d** on Th1 and Th2 immune responses. BHMT, betaine-homocysteine methyl-transferase; RORγt, retinoic acid-related orphan receptor γt; GATA-3, GATA binding protein 3; T-bet, T-box transcription factor; FOXP3, forkhead box P3; STAT, signal transducer and activator of transcription . (Reprinted from Han et al. [170]. With permission from Elsevier)

placed on a meat-based formula of carrots, beef, broccoli, and apricots for 6 weeks. It was found that 61% had nearly complete resolution of symptoms [25]. This same study also found that the most common food triggers were milk, egg, chocolate, soy, legumes, and grains [25].

While food allergy as a cause of asthma is more common in children, hidden food allergy has been reported to be the root cause of asthma in around 40% of adults [25]. Improvement in respiratory symptoms was also seen in a small study of adults given an antigen-free elemental diet in a hospital setting [25].

Removal of food triggers has also been linked to improvement in exercise-induced asthma [25].

Identifying food allergies can be a complicated process because many of the testing methodologies such as skin prick tests (SPTs) and blood tests can yield false-positive results for up to 50–60% of cases, according to the Food Allergy Research & Education Organization [175]. A food elimination diet and/or oral food challenge can be a powerful tool in determining food allergy specific to asthma symptoms, where a dietitian or nutritionist in conjunction with physician and/or allergist can serve an important role through this process to support the individual.

51.8.1.6 Mechanisms and Relevance to Asthma as a Chronic Disease

Oxidative stress may play a key role in the development of asthma, which can also be true for the development of chronic diseases such as cardiovascular disease, diabetes, and cancer [117].

It has been shown that obesity may be a risk factor for people with and without allergy and may worsen pre-existing asthma [159]. Individuals with asthma are twice as likely to have gastroesophageal reflux disease (GERD) than people who do not have asthma, especially those resistant to treatment [159].

Celiac disease and asthma have also been linked. An Italian cohort study was done that showed a significant association between treated asthma and celiac disease, where antibiotic exposure in the first year of life was controlled for and not found to contribute to this association [176]. It has also been found that individuals with celiac disease following a gluten-free diet experienced improvement in asthma symptoms [25].

Key Toxin-Related Influences

It is well-known that toxic exposure to particulate matter, airborne pollutants, or cigarette smoke can trigger asthma symptoms [165]. More specifically, a dose-dependent

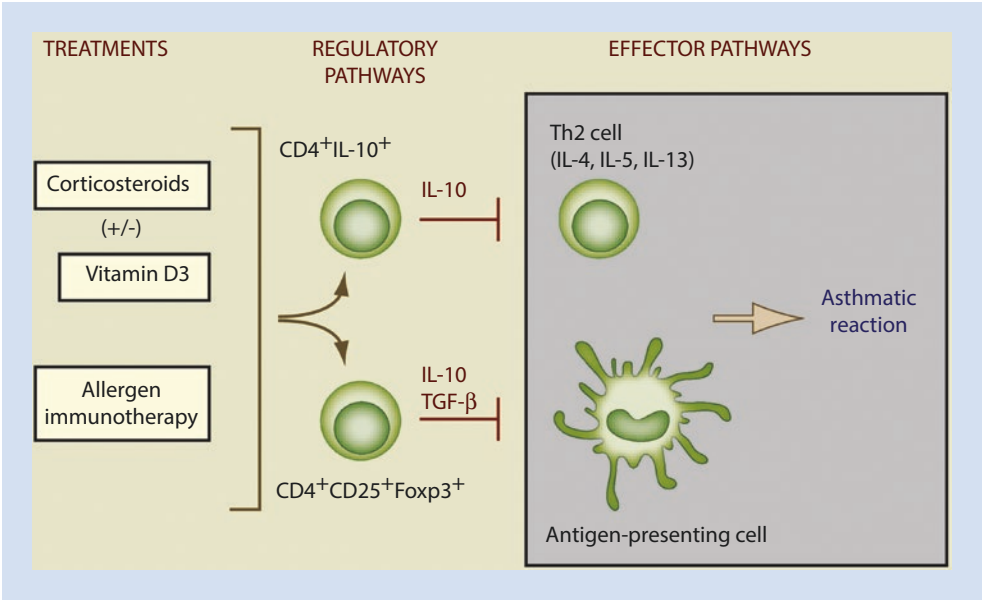

Fig. 51.6 Effect of asthma treatments on regulatory pathways. (Reprinted from Lloyd and Hawrylowicz [177]. With permission from Elsevier)

relationship between cigarette smoke exposure and rates of asthma has been shown [165]. Traffic density and asthma exacerbations have also been clearly demonstrated [165].

Certain medications may also serve as triggers to asthma. Aspirin-exacerbated respiratory disease (AERD) is considered another asthma subtype caused by nonsteroidal anti-inflammatory drugs (NSAIDS) and is characterized by asthma, chronic rhinosinusitis, and acute respiratory reactions [159]. In addition, overuse of antibiotics in childhood has been linked to asthma [18], indicating a connection between the microbiome and asthma development.

Allergic bronchopulmonary mycosis (ABPM) noted in Table 51.4 is caused by a hypersensitivity reaction to fungal colonization of the airways [159]. This is typically caused by the fungus *Aspergillus fumigatus*. Without treatment, this may lead to fixed airflow obstruction and bronchiectasis [159].

51.8.1.7 Key Lifestyle Influences

The progression of asthma is complex and multifaceted, from preconception through childhood and adulthood. Research suggests that early life events are largely predictive for regulatory mechanisms within the pulmonary immune system [177]. For example, prenatal exposure to a farming environment, one rich in microbial compounds, is thought to influence innate immune patterning in the mother which may affect the development of the neonatal immune system [177]. This influence in immune patterning can be seen through higher expression of Toll-like receptors 2 and 4 and CD14 on peripheral blood cells, which implies possible desensitization to allergens in children [178]. T regulatory cells, which serve an important role in immune regulation and are thought to play an important role in asthma by suppressing the Th2 inflammatory response to harmless air particles, have been shown to be impaired in the cord blood of neonates at hereditary risk for allergy [179].

In the 2017 study performed by Singh et al. looking at serum IgE and cutaneous sensitivity to food allergens in asthmatic children here was a negative correlation of total IgE and duration of breastfeeding, indicating a connection between breastfeeding and the immune response [174].

Additionally, reduced maternal intake of vitamins D and E and zinc during pregnancy has been associated with increased asthma symptoms in children [180, 181]. Vitamin D has been associated with the maintenance and/or development of the T regulatory cells stated earlier in mice; however more research is needed to determine a definitive association in humans [177].

A clinical trial performed on non-smoking asthmatic patients showed higher vitamin D levels were associated with greater lung function; furthermore, supplementation with vitamin D showed improved treatment response to glucocorticoids [182]. Vitamin D may also directly increase the anti-inflammatory cytokine, interleukin (IL)-10 and also enhance steroid-induced IL-10 production (see Fig. 51.6) [177]. More research is needed to determine the exact mechanism of vitamin D in asthma and respiratory disease.

51.8.1.8 Conventional Assessments

Beta-agonists, combined with corticosteroids, serve as the primary conventional therapy [183]. Typically, a short-acting beta-agonist will first be prescribed to manage symptoms as needed, where low-dose inhaled corticosteroids may also be prescribed [156]. If symptoms persist, it is recommended to evaluate problems such as adherence to use, inhaler technique, or persistent allergen exposure and comorbidities [156]. Once these are ruled out, the step-up treatment is a combination of an inhaled corticosteroid with a long-acting beta-agonist [156]. A summary of other conventional treatments and their mechanisms can be found in Table 51.5 below.

Unfortunately, conventional methods for the treatment of asthma may have harmful side effects. For example, the use of

Table 51.5 Conventional medications used in the treatment of asthma

Medication type	Medication name	Mechanism
Short-acting β2-agonists (inhaled)	Albuterol Levalbuterol Pirbuterol	Counteract the inhibitory effect on the beta-2 adrenergic receptor resulting in dilation of bronchial passages and relaxation of bronchial smooth muscle; lasts for 4–6 hours
Long-acting β2-agonists (inhaled)	Bambuterol Formoterol Salmeterol	Same as short acting, except effect lasts for about 12 hours
Corticosteroids (oral and inhaled)	Inhaled: Budesonide Flunisolide Fluticasone propionate Mometasone Oral: Dexamethasone Hydrocortisone Methylprednisolone Prednisolone	Bind to glucocorticoid receptor which leads to expression of anti-inflammatory proteins, some of which block expression of pro-inflammatory modulators
Anticholinergics/muscarinic antagonists	Ipratropium bromide	Blocks acetylcholine, which leads to dilation of bronchial airways and relaxation of bronchial smooth muscle
Leukotriene antagonists	Montelukast Zafirlukast	Block binding of leukotrienes to receptors on bronchial cells
Oral methylxanthines	Theophylline Oxtriphylline	Methyl xanthine found in tea Used less commonly due to side effects Relaxes airways due to inhibition of phosphodiesterases; acts as a functional antagonist in airway smooth muscle [171]

Based on data from Ref. [18]

systemic glucocorticoids may lead to immunosuppression, cataracts, and osteoporosis, where long-acting beta-agonists have the potential of increasing asthma exacerbation risk and death [25]. Beta-agonist desensitization is thought to be one of the reasons for increasing asthma exacerbation risk and death [184].

51.8.1.9 Integrative and Functional Medical Nutrition Therapy (IFMNT) Assessment of Asthma

Related to several subtypes of asthma and their differing pathophysiologies, it is important to first determine the subtype before deciding on treatment. For example, in an individual with allergic asthma, this could be a potentially simple fix once the allergen that exacerbates symptoms is identified. A more conventional approach may involve starting the individual on an inhaled corticosteroid or an IgE antagonist (i.e., omalizumab) [159], rather than identifying the root cause of the patient's symptoms. While medications may be warranted until the trigger is identified, finding the underlying causes may not be common practice in many conventional settings.

In contrast, the IFMNT assessment takes a much deeper dive into identifying triggers and any nutrient insufficiencies, inflammation or immune dysregulation, biochemical individuality, lifestyle, energy dysfunction, toxic load, sleep, and stress issues are taken into account. With this information, the practitioner can make more targeted dietary, lifestyle, and supplement recommendations to obtain sustained resolution of symptoms by treating the root cause (Table 51.6, Fig. 51.7, ▶ Box 51.3).

51.8.1.10 IFMNT Case Study: Asthma

Client Overview

A 26-year-old female presented with a complaint of reactive airway disease, which was diagnosed as asthma and had been prescribed inhalers. She reported that she felt like she had difficulty breathing most of her life, especially when exercising. However, her condition was not severe enough to seek help until she was 25 years of age. She reported a lot of stress during this time related to applying for a postgraduate training position. She also reported 1 year prior to diagnosis developing new allergic symptoms.

Her past medical history was significant for conditions related to airways, including chronic sinus infections, strep throat, bronchitis, and recurrent pneumonia.

She could not remember the last time she felt well but assumed it was sometime as a young child. Her nutrition and health goals were to breathe better and to not have to rely on inhalers. The following data was collected on her initial visit.

Table 51.6 Summary of an integrative and functional medical nutrition therapy assessment

Nutrient insufficiencies	**Intake-digestion-utilization (IDU):** Adequacy of nutrient-dense foods to begin to assess nutritional status Organic or nonorganic to assess toxic load and nutrient intake Food preparation and processing to assess nutrient content and identify potential contaminants (e.g., plastic endocrine disruptors) Assess food sensitivities or intolerances to identify potential triggers Microbiome status: assess comprehensive digestive stool analysis for microbiology and fermented food intake; history of antibiotics or microbiota agonists (medications, toxins, stress, etc.) Toxin intake via plastics or inhalation and skin absorption which may affect immune response Assess flavonoids intake as they are antioxidant and anti-inflammatory compounds with mast cell inhibitory action; adequacy may reduce airway reactivity Consider celiac disease and gluten intake as potential inflammatory antigens **Mineral** Assess and restore zinc, selenium, magnesium, manganese, iron, and iodine status to normal reference. Caution to not supplement or intake of food sources higher than reference **Antioxidants** Assess and restore antioxidant balance; vitamins A, C, D, and E and glutathione Assess quercetin intake (leafy vegetables, broccoli, red onions, peppers, apples, grapes, black and green tea, red wine) as it may act as mast-cell stabilizing agent inhibiting release of histamine, TNF-alpha release, formation of prostaglandin D2, reducing interleukin production Consider supplementation of quercetin if quercetin intake is low [185] **Protein status** Assess and restore to support connective tissue and immune status Ensure adequate glutamine and glycine intake **Oils/lipid/fatty acids** Assess fatty acid balance as DHA important in lung tissue integrity Assess adequate serum cholesterol and fat intake to support lipid bilayer important for cellular function in lung (epithelial cells, surfactant production, etc.) **Methylation** Assess methylation status and detoxification capacity of toxins related to asthma exacerbation; important assessment biomarkers suggested: MCV/MCH, homocysteine, methylmalonic acid, RBC Folate, genomic methylation SNPs
Inflammation/immune dysregulation	Assess asthma biomarkers to help identify root cause (see Fig. 51.7, and Quote Box: What is Periostin?) Eosinophils Exhaled nitric oxide (FeNO) Periostin IgE: Total IgE, IgE specific foods, and chemicals Diamine oxidase (DAO) Assess Th2 immunity: Th1 and Th2 Cytokine Blood Test Panel [187]
Biochemical individuality	Signs and symptoms Assess when the individual experiences wheezing, breathlessness to identify the cause, and when did the initial symptom occur? Phenotype Consider the various asthma phenotypes Associated genes: Filaggrin: codes for epithelial barrier ORMDL3: encodes transmembrane protein Beta-2 adrenergic receptor gene: expressed through smooth muscle and epithelial cells of lung IL-4 receptor gene: variant associated with elevated IgE IL-10 gene promoter SNPs A1AT (alpha-1 antitrypsin) gene Environmental history Prenatal exposure to allergens with influence on immune patterning Developmental BPA exposure [188]
Lifestyle	Activity Assess whether asthma is exercise-induced Community Evaluate hobbies, occupation, household environment, and potential exposures to allergens or asthmatic triggers as listed in Fig. 51.3
Energy dysfunction	Assess overweight or obesity, including inflammatory visceral adiposity

(continued)

Table 51.6 (continued)

Toxic load	Evaluate exposure to fungus to identify allergic bronchopulmonary mycosis Assess individual's medication history, considering short- and long-term use of conventional treatments Evaluate exposure to particulate matter, airborne pollutants, cigarette smoke, or toxic metals such as cadmium and arsenic
Sleep and stress	Assess sleep adequacy (7–9 hours with 5-hour REM sleep) and quality (good sleep hygiene with little light/sound/EMF disturbance) to support detoxification of toxins that may worsen respiratory status and aid in repair of damaged lung tissue

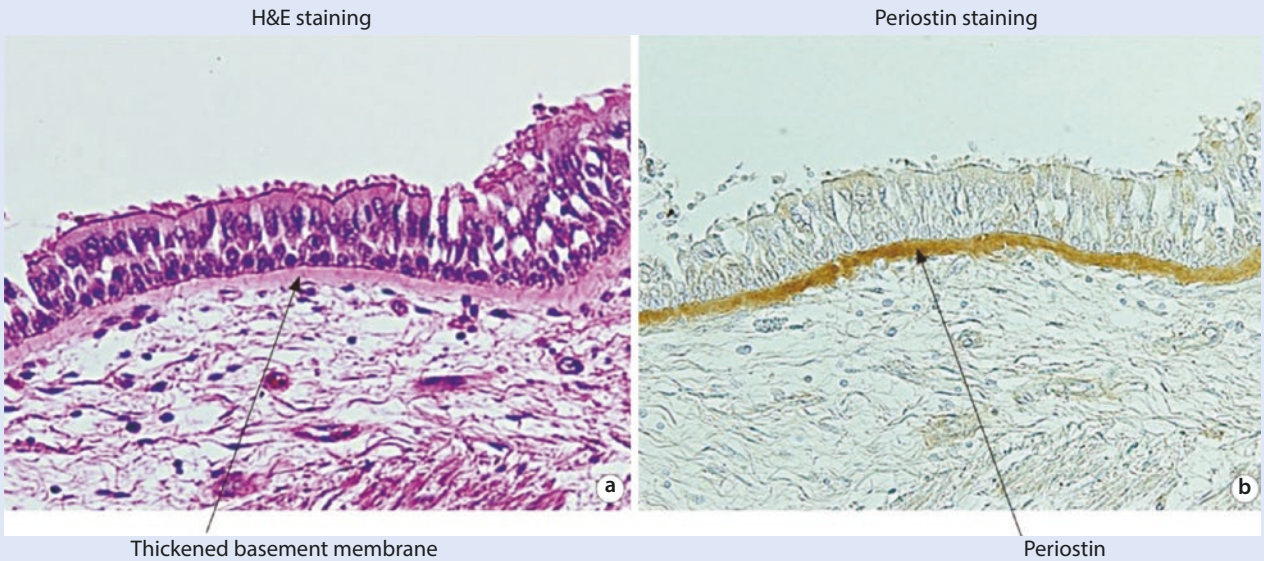

Fig. 51.7 Functions of periostin in inflammation. Functions of periostin in inflammation. Expression of periostin in asthmatic patients. The histochemical localization of periostin in asthmatic patients is depicted. The left and right panels show bronchial tissues from an asthmatic patient in H&E staining **a** and immunostaining **b** of periostin. Periostin in the right panel is stained brown and is localized in the thickened basement membrane in asthmatic patients. (Reprinted from Izuhara et al. [186]. With permission from The Korean Academy of Asthma, Allergy and Clinical Immunology)

Box 51.3 What Is the Inflammatory Influence of Periostin on Tissues and Organs?

Periostin plays a role in the pathogenesis of allergic diseases, including asthma, as it is associated as a downstream molecule of the cytokine, IL-13. Periostin is used as a biomarker for type 2 immunity and can be used to determine the potential effectiveness of medications used to treat asthma, such as anti-IgE antibodies and anti-IL-13 antibodies. Asthmatic patients with high serum periostin tend to be aspirin intolerant, eosinophilic, late asthma onset, and have a high nitric oxide fraction. High periostin can also indicate a reduced response to inhaled corticosteroids [186, 224].

Symptoms/Complaints at First Visit

Extreme exhaustion, depression, ADD, anxiety (accompanied by panic attacks), constipation, pain in legs, neuropathy in feet (numbness and tingling), rapid heartbeat, and a very severe rash on feet known as chilblains.

Past Medical History

- UTIs – recurrent as a child.
- Poor immune function (frequent infections).
- Antibiotic use (very frequent from childhood into adulthood).
- Sinus infections, strep throat, and bronchitis – she had recurrent sinus infections and strep throat about once a year every year and often this would lead to bronchitis, she could not remember if she had these issues before middle school.
- Depression, anxiety, ADD.
- Acne.
- Peptic ulcers.
- Yeast infections – multiple throughout college.
- Eczema.
- Two recent episodes of pneumonia the last episode resulted in her asthma diagnosis.
- Asthma.

- Several medical consults (cardio, rheumatologist, etc.). Most recent, rheumatologist, with suspicion of lupus. Diagnosis was not lupus; no recommendations for further care made.
- Past Surgical History
- Wisdom teeth removed
- Deviated septum surgery

Pharmaceutical Use

- Albuterol inhaler for acute asthma attacks taken prn
- Inhaled corticosteroid inhaler for long-term use; taken once daily
- Yaz birth control for acne and to prevent pregnancy; taken once daily

Timeline

Birth

- Vaginal birth, breastfed for 6 months

Childhood

- Hx of cyst on face, for which she had to undergo several treatments to remove (unsure of what the treatment was or what type of cyst)
- Parents divorced at 2 years old
- Frequent UTIs

Adolescence

- 8th grade: severe case of strep throat, undiagnosed for several weeks, led to being immobile for almost 2 weeks
- 8th–12th grade: was often sick (strep, sinus infections, bronchitis); described it as being constantly sick from fall through winter every year; also developed eating disorder during this time; had severe menstrual cramps (induced vomiting) accompanied by acne, which led to being put on birth control at age 17 as a precursor to Accutane (never prescribed); chronic constipation starting during this time

University

- Freshman – sophomore year: eating disorder was most severe during this time.
- First semester of freshman year: developed digestion issues, after eating certain foods (especially Mexican or salsas), stomach would become distended, experienced pain, and often would result in vomiting. Pain so severe during finals week she was admitted to ER with no diagnosis. CT scan revealed possible peptic ulcers.
- Junior–senior year: depression, anxiety, and inability to focus were most severe during this time which resulted in missing a lot of class and struggling as a student; suffered multiple panic attacks; gained a lot of weight (from 120 to 180 lb); end of senior year became engaged to be married – moved to Dallas, TX.

Young Adulthood

- Lived in Dallas for 6 months, continued to experience depression and anxiety and weight gain, and moved back to home state
- Initially started running (~2 miles a day) and experiencing inability to breathe, diagnosed with pneumonia, prescribed inhaler to help with running; other symptoms: eczema around the eyes and neck (after running outside), pain in calves, numbness and poor circulation in feet (pulse not detected by several health professionals), and development of chilblain rash (very painful, itching, lasts about 3–4 weeks from development to resolution); increased running – ran a half-marathon. Visited PCP and several specialists for help with chilblain rash with no resolution or diagnosis; lost a lot of weight (from 170 to 140 lb).
- Ongoing increased depression, anxiety, and inability to focus; PCP Rx Cymbalta (depression and anxiety); Cymbalta discontinued after ~2 months (did not tolerate side effects), continued psychological therapy for several months; chilblain rash continued. Stopped running long distances. Gained weight back (from 140 to 170 lb); subsequently saw blog for integrative RD and followed suggestion to eliminate gluten and focusing on whole foods diet.
- Chilblains and eczema began to resolve while following integrative RD recommendations of gluten-free diet with some improvements. However, difficulty breathing got worse, and diagnosis of asthma was made with fast-acting inhaler used for exercise; as time progressed, breathing continued to worsen, led to daily inhaler use. Weight at this time is still at around 170 lb.

Social

- Stress: very high (graduate student and completing internship)
- Sleep: variable, sometimes <6 hours and sometimes >9 hours
- Physical activity: some yoga and HIIT running
- Exposures: pet dander and Teflon cookware

Nutrition (In General)

- History of chronic dieting and disordered eating
- No known food allergies but suspected gluten sensitivity
- Consult with IFMNT nutritionist, diet whole foods, completely gluten-free diet. Minimal dairy whole fat (mostly from Greek yogurt, butter, and cheese)

Fats and Oils Questionnaire: Initial Survey

- Omega 9-MUFAs: High
- Omega-6: High (mainly from commercial meats and eggs)
- Omega-3: Low
- Saturated: High (mainly from dairy sources)
- Damaged: High (trans, hydrogenated, deep fried, charred meats)

51

Nutritional and Lifestyle Data Collected

Clinical

Anthropometrics

- Height: 5′7″
- Weight: 170 lbs
- BMI: 26.6
- Waist circumference: 34″
- Waist/height ratio: 0.51
- Blood pressure: 122/74
- Body composition: not completed at initial intake

Nutrition Physical Exam

- Acne present along the jawline and on the neck
- Appeared overweight and bloated
- Appeared tired and had trouble recalling certain details
- Tongue, nails, etc. not checked at initial intake visit

Genotypic Risks

- IL-13 c112T (+/−)
- HLA-DQA2 (+/+), HLA-DQA1 (+/−)
- VDR (+/+)
- Several (+/+) for phase II related genes
- MTHFR C677T (+/−) and several other (+/+) (+/−) for genes related to methylation and methionine/homocysteine pathways

Biochemical

Blood Lab Results

- MCV 101 (H) (79.3–98.6)/MCH: 32.0 (H) [27.0–31.0]
- Na: 137 (lower end of normal) [133–143]
- K: 3.8 (lower end of normal) [3.5–5.0]
- Bicarbonate: 23 (L) [24–32]
- Glucose: 85 (higher end of normal) [60–97]
- Creatinine: 0.54 (L) [0.70–1.40]
- ALT: 29 (L) [30–65]
- HDL: 74 WNL

Structural

- Hx eczema – breakdown of the skin
- Gut barrier likely compromised evidenced by Hx of ulcers, poor immune function, yeast infections, cyst, constipation, etc.
- Nail structure very good
- Hair: reported frequent shedding, but hair structure appeared healthy

Signs/Symptoms/Medical Symptom Questionnaires (MSQ)

- MSQ total score of 87 [REFERENCE > 50 significant imbalances]
- High MSQ categories: lungs, skin, and weight

Nutrition Assessment: NIBLETS

Intake

- High dairy diet (consumed dairy products at most meals and snacks), consumed three smaller meals with three snacks in between
- Meals and snacks balanced with protein, fat, and carbs, with carbs coming from fruits and vegetables and fat mainly from full fat cheese, Greek yogurt, and butter
- Mostly nonorganic produce and commercially raised meats

Digestion, Assimilation, and Elimination

- Hx of peptic ulcers and chronic constipation (BM ~1–2 times a month)
- BMs currently at about 2 × per week on encounter

Utilization, Cellular, and Molecular (*MAPDOM*)

- Hx of likely gluten sensitivity.
- Presented symptoms of possible dairy sensitivity (bloating, acne, asthma).
- Evidence for compromised intestinal barrier.
- Minerals: infrequent BMs could indicate low fiber or low mineral status (Mg); when BMs do occur, they are hard and dry (low Mg); severe menstrual cramps (low Mg); labs showed low K and Na, on Yaz birth control (low zinc and low B vitamins).
- Antioxidants: consumed adequate fruits and vegetables each day.
- Protein: has some evidence of poor/slowed wound healing as evidenced by sore on leg that has not completely healed after a year; cuts that take months to heal.
- D and fat-soluble A, E, and K vitamins – Hx of poor immune function (low D), VDR +/+ (low D and possibly A).
- Oils/fatty acids: high omega-6/omega-3 ratio, higher intake of damaged fats, very low intake of omega-3.
- Methylation: symptoms of depression, anxiety, ADD combined with MTHFR C677T snp and on Yaz (low B6 and folate).

Inflammation

- Eicosanoid fatty acids status – suspect issues with PGE1 series pathway to control inflammation due to following signs and symptoms: allergies, autoimmune condition (asthma), peptic ulcers, eczema, and severe menstrual cramps
- Immune function – suspect gut dysbiosis due to following S&S: poor immune function, yeast infections, Hx frequent antibiotic use, cyst, and constipation

Body Composition

- Genetic makeup that indicated prone to gluten and dairy sensitivity, low vitamin D status, and impairment in methylation

Lifestyle

- Low exercise, high stress, and food sensitivities

Energy

- Fatigue

Toxin Load

- Known genetic SNPs in phase 2 detoxification.

- Dairy could be considered a toxin contributing to overall toxic load on body.

Sleep and Stress

- Either sleeps too much or not enough
- Reported high stress due to completing dietetic internship and master's degree at the same time, also Hx of long-term stress with parents' divorce at young age and stress related to relationships

Nutrition Diagnosis

- Suspect dairy sensitivity related to impaired GI structure and genetic susceptibility evidenced by autoimmune condition (asthma), Hx of strep, and HLA-DQ2 & 1 SNPS
- Altered GI function related to gut microbe dysbiosis evidenced by poor immune function, constipation, Hx of yeast infections, cyst, and frequent antibiotic use

Plan

1. Trial of dairy-free diet for 3 months. Then add back sources of dairy (separately) to see if symptoms return. Log any symptoms experienced during the reintroduction of dairy in a food journal.
2. Supplements:
   - Vit D + K2 (5000 IU + 90 mcg) daily
   - Natural Calm Mg (daily, morning and night)
   - Fish oil (2000 mg daily)
   - Broad spectrum probiotic + fermented foods
   - BioActive B complex (includes 50 mg P5P B6 and 800 mcg 5 THF)
   - 260 mg GLA evening primrose oil and zinc
3. Aim to eat three larger meals a day, allowing space in between of ~ 5 hours; increase omega-3 intake by adding in small fatty fish, such as sardines or anchovies, once per week and taking fish oil; decrease omega-6 intake, switch from conventionally raised meats to organic, pasture-raised; and replace fat in diet from dairy with coconut sources, more nuts, and avocados.

Follow-Up

- Patient presented ~6 months after the initial visit (September 2015). Her breathing had improved immensely. She was able to stop taking her Albuterol inhaler before exercise, recently stopped daily inhaler.
- After dairy-free diet for 3 months, reintroduced dairy (cheese, butter, yogurt). Asthmatic symptoms returned about 2–3 days after the addition of each. Noticed the more dairy consumed, the worse her symptoms became.
- At time of appointment, diet whole foods, gluten-free, and dairy-free. Weight loss 10 lb within the first month of going dairy-free, continued to lose some weight. When reintroduced dairy symptoms of bloating and increase in weight, which resolved returning to dairy-free diet.
- BMs are regular now at ~ *2 × daily*.

Anthropometrics

- Height: 5′7″
- Weight: 155 lb
- BMI: 24.2
- Waist circumference: 32 inches
- Waist/height ratio: 0.477

Medical Symptom Questionnaire (MSQ)

- Highest categories: lungs and eyes (had recent accidental exposure to a little bit of dairy)

Fats and Oils

- Omega-9: HIGH, healthy
- Omega-6: Lowered and increased GLA
- Omega-3: Normal, healthy
- Saturated: Normal, balanced healthy sources
- Damaged: Reduced 45%

Outcome

This patient case followed some common patterns in the development of chronic disease and the comorbidities that are common, especially autoimmune conditions like asthma. The first is the genetic susceptibility of the individual; several SNPs are prone to dairy sensitivity. Second, significant evidence for gut dysbiosis, promoted compromised gut barrier, can contribute to the development of dairy sensitivity. Third is the exposure to dairy protein antigen. Diet history evidenced trigger for asthmatic condition.

Additionally, inflammation, immune dysfunction, and methylation issues present. Signs and symptoms significant for decrease in PGE1 series anti-inflammatory pathways. Low dietary omega-3s potential contributor to asthma. Immune dysfunction evidenced by extensive history of infection-antibiotic use. Genomic SNP MTHFR C667T gene, which indicated a greater need for folate. The use of Yaz birth control and symptoms of depression, anxiety, and ADD known further to deplete B6 and folate.

The diet and supplements recommended targeted control of inflammation, restore gut ecology, promote proper methylation, and replete nutrient insufficiencies. Results from 6-month follow-up showed successful outcome in helping improve breathing and wean her off of inhalers.

This case is an example of the IFMNT approach able to address the complexity of the whole patient story and bring the metabolic priorities into a manageable intervention program for the individual.

51.8.2 Chronic Infection and Respiratory Health

51.8.2.1 Upper Respiratory Tract Infection

One study found that the composition of the nasopharyngeal microbiota in children was linked to the frequency of upper respiratory tract infections and acute sinusitis [189]. A study that intranasally inoculated mice with *Lactobacillus*

fermentum reduced the amount of *S. pneumoniae* in the respiratory tract and increased the number of macrophages in the lung and lymphocytes in the trachea [189]. These findings may indicate a benefit of manipulating the upper respiratory tract microbiota with orally or nasally administered probiotics in the prevention and/or treatment of upper respiratory tract infections.

51.8.2.2 Fungal, Viral, and Bacterial Infections

Allergic bronchopulmonary mycosis (ABPM) is caused by a hypersensitivity reaction to fungal colonization of the airways. This is typically caused by the fungus *Aspergillus fumigatus*. Without treatment this may lead to fixed airflow obstruction and bronchiectasis [159].

Guillain-Barre syndrome (GBS) is a rare neurological disorder in which the body's immune system attacks the peripheral nervous system, known as the network of nerves located outside of the brain and spinal cord [190]. It is often preceded by a bacterial or viral infection. There are several potential mechanisms in which these infections trigger GBS. If an individual contracts a *Campylobacter jejuni* bacterial infection, antibodies made to fight this infection can attack axons in motor nerves, which can potentially cause paralysis and respiratory failure [190]. *Campylobacter* can be ingested via contaminated food or other exposures [190].

Pérez-Guzmán 2005 states that hypocholesterolemia is common among tuberculosis patients and suggests that cholesterol should be used as a complementary measure in antitubercular treatment [8].

51.8.3 Alpha-1 Antitrypsin Deficiency (A1AT Deficiency)

Alpha-1 antitrypsin (A1AT) deficiency is an underrecognized disease in the United States, with around documented 100,000 people suffering from it, according to the Alpha-1 Foundation. This deficiency is inherited through autosomal codominant transmission, meaning affected individuals have inherited an abnormal AAT gene from each parent [191]. Individuals with this deficient allele present with AAT levels at less than 35% to low-end normal levels [191].

However, it is also possible for individuals with a variant of this allele to be asymptomatic given different environmental conditions or lifestyle factors, such as refraining from smoking to reduce lung disease development risk [191] (▶ Box 51.4).

51.8.3.1 Lungs

A1AT deficiency most often manifests in the lungs as chronic obstructive pulmonary disease (COPD) (i.e., emphysema or bronchiectasis or "genetic COPD"). A1AT deficiency is often undiagnosed because people with genetic COPD experience the same symptoms as people with COPD, such as [191]:

- Shortness of breath
- Wheezing
- Recurring chest colds
- Low exercise tolerance
- Year-round allergies

Box 51.4 Genomic Variants of Alpha-1 Antitrypsin Deficiency

Normal genotype M M

- Most common abnormal genes are called S and Z
- Abnormal variant combinations:
  - ZZ (highest risk)
  - SZ (lower risk increasing if smoker, inhalant pollutants)
  - MZ (lower risk of carrying an A1AT gene variant; considered "carriers")
- Alpha-1 is the most commonly known genetic risk factor for emphysema
- Up to 3% of all people diagnosed with COPD may have undetected Alpha-1
- Alpha-1 can also lead to liver disease. The most serious liver diseases are cirrhosis and liver cancer
- The World Health Organization (WHO), American Thoracic Society (ATS), and the European Respiratory Society (ERS) recommend that everyone with COPD be tested for Alpha-1

Alpha-1 is a progressive disease that benefits from early detection. It can cause serious lung diseases, such as COPD and emphysema when undiagnosed. In some cases, Alpha-1 can also cause liver disease [225]

Symptoms related to the lung [225]:

- Shortness of breath
- Wheezing
- Chronic bronchitis, which is cough and sputum (phlegm) production that lasts for a long time
- Recurring chest colds
- Less exercise tolerance
- Year-round allergies
- Bronchiectasis

The only way you will know for sure if you have genetic COPD due to alpha-1 is to get tested.

51.8.3.2 Liver

A1AT deficiency can manifest in the liver as cirrhosis.

Symptoms Related to the Liver

- Unexplained liver disease or elevated liver enzymes
- Eyes and skin turning yellow (jaundice)
- Swelling of the abdomen (ascites) or legs
- Vomiting blood (from enlarged veins in the esophagus or stomach)

51.8.3.3 Skin

A1AT expresses sometimes in the skin as panniculitis [191]. Panniculitis typically appears as raised red spots on the skin, which may break down and give off an oily discharge. While panniculitis spots (called nodules) may appear anywhere on the body, the most common places are the thighs, buttocks, and areas subject to injury or pressure.

51.8.3.4 A1AT Biochemical Mechanisms

The alpha-1 antitrypsin (A1AT) protein protects the body, especially fragile lung tissues, from the damaging effects of a powerful enzyme called neutrophil elastase that is released from white blood cells. In A1AT deficiency, a genetic mutation reduces levels of the protective protein in the bloodstream. A1AT deficiency can lead to chronic obstructive pulmonary disease (COPD), specifically emphysema, and liver disease. Smoking, which can inhibit what little A1AT protein an affected person does have, increases the risk of lung disease.

Alpha-1 antitrypsin deficiency is completely determined by mutations in a single gene. The severity of symptoms is mostly a function of which mutations a person has and how many copies. However, smoking can greatly increase the risk of lung disease due to AAT mutations.

23andMe reports data only for the PI∗M, PI∗S, and PI∗Z versions of the gene that encodes AAT. Keep in mind that it is possible to have another mutation that causes this condition that is not included in this report [192]. A1AT deficiency is a genetic disorder that reduces circulating levels of a protein that protects the lungs by trapping A1AT in the liver, where the protein is produced, and prevents A1AT from entering circulation. A1AT deficiency can lead to chronic obstructive pulmonary disease (COPD), specifically emphysema, and liver disease.

When a disease-causing mutation is fairly common, as the PI∗S and PI∗Z mutations are in Europeans, it suggests that the mutation actually conferred an evolutionary advantage at one time. Some researchers have suggested that several thousand years ago when the PI∗Z and PI∗S mutations first arose, these versions of the gene for A1AT gave people a survival advantage by creating an environment in their lungs that helped fight off infections. The scientists theorize that the antimicrobial benefits of the AAT mutations outweighed the cost of an increased risk of COPD and liver disease in the era before antibiotics were available [193].

51.8.3.5 Liver Cirrhosis

In contrast to lung disease, manifestation of liver disease related to A1AT can be referred to as a "toxic gain of function," due to accumulation of mutant A1AT protein rather than protease deficiency within the liver [144].

51.8.4 Pulmonary Fibrosis

51.8.4.1 Overview

When taken together, fibrotic lung diseases are the leading cause of mortality worldwide. Under the umbrella of interstitial lung disease (ILD), pulmonary fibrosis (PF) is the most common. Any ILD that involves scarring of the lungs falls in the pulmonary fibrosis category. Pulmonary fibrosis is the scarring of lungs, which destroys tissue over time, making it impossible to transfer oxygen from inhaled air into the bloodstream. There are more than 200 different diseases under the pulmonary fibrosis umbrella. Because PF is often misdiagnosed or goes undiagnosed, there is not an accurate count of those with these diseases. However, it is estimated that as many as 1 in 200 adults over 60, or 200,000 people in the United States, are affected [184]. There are more than 50,000 deaths from IPF every year in the United States. More people die each year from idiopathic pulmonary fibrosis than from breast cancer [194].

There are other forms of interstitial lung disease including the newly identified pleuroparenchymal fibroelastosis, cryptogenic organizing pneumonia (COP), desquamative interstitial pneumonitis, nonspecific interstitial pneumonitis, hypersensitivity pneumonitis, acute interstitial pneumonitis, interstitial pneumonia, sarcoidosis, and asbestosis [195].

Symptoms include cough and dyspnea, restrictive pulmonary function tests with impaired gas exchange, and progressive lung scarring. The disease progresses with an initiation of inflammation. Fibrosing starts with the action of transforming growth factor-β (TGF-β)-dependent differentiation of fibroblasts to myofibroblasts, which then express α-SMA (smooth muscle actin) [196].

After the TGF-β-dependent differentiation of fibroblasts to myofibroblasts, which express α-SMA, there is sustained, excessive deposition of collagen by the myofibroblasts in the lung interstitium leading to the progressive lung damage in patients with PF [185]. Research published in 2011 supported the idea that dysfunctional type II AECs (alveolar epithelial cells) facilitate lung fibrosis through increased susceptibility to injury, leading to excessive and dysregulated remodeling [197]. The disease seems to progress in steps, and inflammation is not typically present continuously, except during certain periodic episodes of deterioration (◘ Fig. 51.8).

There are five main categories of PF causes: drug-induced, radiation-induced, environmental, autoimmune, and occupational. Of these five, four have identifiable causes. Some of the autoimmune diseases that can lead to PF are rheumatoid arthritis, scleroderma, Sjogren's syndrome, polymyositis, dermatomyositis, and antisynthetase syndrome.

Idiopathic pulmonary fibrosis (ILP) is defined as PF with an unknown cause, including a genetic cause for some families [see ◘ Fig. 51.9]. The symptoms of ILP are a dry, hacking cough, shortness of breath, fatigue, chest discomfort, loss of appetite, and unexplained weight loss, all caused by the fibrosing of the lungs.

Diagnosis can be difficult, and PF is often misdiagnosed as COPD or other more common lung diseases. In addition, in the recent past, path to a true diagnosis was invasive. Since damage to the lungs, even through a diagnostic biopsy, can trigger further lung damage or a period of fibrosis, many physicians or patients are cautious with a biopsy approach to diagnosis. Since the current treatments are limited, one must evaluate whether defining the exact form of PF is necessary for treatment and follow-up. Difficulty breathing, crackling sounds while breathing, and low oxygen levels are the first indicators. Clubbed fingernails may also be a symptom.

High-resolution CT scans are performed, which can show scarring. The pulmonologist will ask many questions

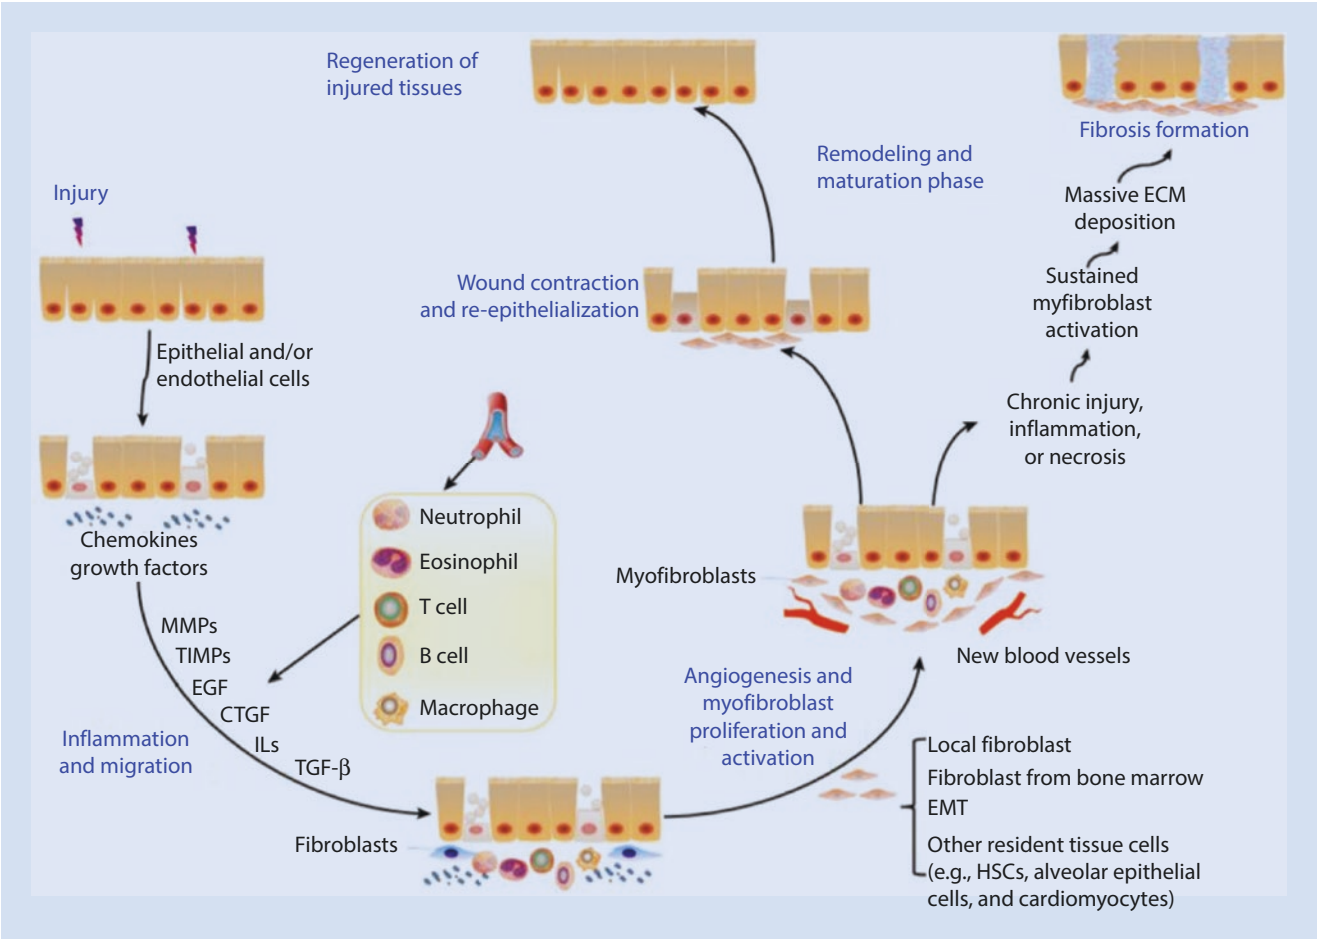

Fig. 51.8 The cellular and molecular mechanisms of fibrosis in multiple organs. The cellular and molecular mechanisms of fibrosis in multiple organs. Once an injury occurs in an organ, epithelial and/or endothelial cells are impaired, which results in the release of chemokines and growth factors, including IL-13 and TGF-b1. Macrophages and monocytes are recruited and activated, both of which further release cytokines and chemokines and further induce fibroblast activation. Activated fibroblasts transform into a-SMA-expressing myofibroblasts and migrate into the wound along the fibrin lattice. ECM is excessively accumulated, and some parenchymal cells (hepatic stellate cells in the liver, tubular epithelial cells in the kidney, alveolar epithelial cells in the lung, or cardiomyocytes in the heart) are further differentiated into myofibroblasts or fibroblasts by the stimulation of cytokines and chemokines, especially for TGF-b1. After the inflammatory phase, two events occur. One is the regeneration of injured tissues followed by wound contraction and reepithelialization. In contrast, once chronic injury, inflammation, and necrosis occur, myofibroblasts are perpetually activated, and excessive ECM is deposited, finally resulting in fibrosis formation. CTGF, connective tissue growth factor; ECM, extracellular matrix; EGF, epidermal growth factor; EMT, epithelial-mesenchymal transition; HSC, hepatic stellate cell; IL, interleukin; MMP, matrix metalloproteinase; TGF, transforming growth factor; TIMP, tissue inhibitors of metalloproteinase. and order more blood tests to try to distinguish between the 200 forms of PF. The future is pointing to molecular endotyping as a more accurate way to diagnose. Molecular endotyping includes genetic, metabolic, transcriptional, and environmental factors to help determine the pathophysiology [199].

Genetic research has been progressing for a couple decades with illuminating results. There are more than a dozen genetic variants that have been associated with this family of diseases. Researchers now believe at least 20% of idiopathic pulmonary fibrosis (IPF) patients with multiple family members suffering from IPF have some common familial genetic variants, which may allow researchers to eventually drop the term idiopathic and further define various forms or categories, with differing progression or outcome. The name given to this version of interstitial pneumonias is familial interstitial pneumonia (FIP) [200] [see Fig. 51.10].

Currently two categories of genetic focus have been defined: those genes related to telomere biology (shorter telomeres) and those related to surfactant protein processing. The genes related to shorter telomeres are *TERT*, *TERC*, *hTR*, *DKC1*, and *RTEL1*. More mutations have been found in the *TERT* gene, which encodes the protein component of telomerase, than any other gene. Further research may allow targeted therapies to affect the genetic expression associated with the development of IPF [201, 202]. A common variant within the promoter of the *MUC5B* gene is the most replicated single-nucleotide polymorphism related to familial and sporadic forms of IPF as well as early radiographic findings of IPF [203] (Figs. 51.9 and 51.10).

51.8.4.2 Conventional Treatment

Conventional treatment is typically palliative. The American Thoracic Society recognizes that supplemental oxygen and transplantation are the only suggested treatments for IPF. Supplemental oxygen is prescribed, and the need for oxygen increases over the progression of the disease. Keeping the oxygen saturation level over 90% (normal is in the upper 90s) is ideal and is how healthcare providers determine the level of supplemental oxygen to be used. Cardiovascular exercise, in this case called pulmonary rehabilitation, is recommended to maintain as much use of the lungs as possible.

Infrequently, nutrition and counseling are recommended and are placed into the category of symptom management. Nutrition can have a significant role in the management of this disease, but little implementation exists in some of the proposed protocols.

There are currently two medications available in the United States with minor impact on the disease progression: nintedanib (commonly called Ofev) and pirfenidone (Esbriet). Histopathological quantification showed similar amounts of dense collagen fibrosis, fibroblast foci, and alveolar macrophages in untreated or pirfenidone- or nintedanib-treated IPF patients [204]. Both have significant side effects, including fatigue and GI issues, and patients may have to evaluate their quality of life versus length of life. Other anti-inflammatories or immune-suppressing medications used are corticosteroids, mycophenolate mofetil/mycophenolic acid (CellCept®), or azathioprine (Imuran®). Immune-suppressing drugs may be harmful for those with short telomeres, and researchers are exploring this potentially contradictory recommendation [205].

Lung transplantation is a final effort. About 1,000 lung transplants in the United States go to those with PF, which

is half of all transplants. With the prevalence of this disease closer to 200,000, this is a small fraction of those with the disease. Some of those with the transplant go on to live productive lives, while others develop PF again, in the transplanted lungs. Overall, there is a shorter life expectancy in those with PF, because of telomere shortening. Bone marrow or immune response abnormalities have been found in some IPF cases before and after lung transplantation, which increases the associated morbidity.

51.8.4.3 Integrative and Functional Nutrition Medical Therapy

As stated above, inflammation occurs at the beginning and throughout the progression of all fibrosing diseases, including those of the lungs. Therefore, reducing inflammation is one wise strategy to slow fibrosing. There are several nutrients that can help slow or reverse the inflammation involved in the fibrosing process. The following two-part diagram shows where in the fibrosing pathogenesis each phytonutrient acts [198] (◘ Fig. 51.11).

A few of those compounds are discussed in more detail here.

Curcumin, the active constituent in the common spice turmeric, has been shown to reduce fibrotic activity in several studies. In mice, curcumin inhibited collagen secretion of IPF fibroblasts. It affects the signaling of TGF-β, in a dose-specific manner, resulting in reduced expression of α-SMA, which is responsible for inappropriate fibrosing. This was shown in vitro and in vivo in mice, with intraperitoneal, but not oral, administration. At the time of the study, oral ingestion of curcumin was not adequately absorbed into plasma, and there was greater than ten times plasma concentration of curcumin following an intraperitoneal injection [88]. However, some new oral products on the market are showing greater absorption.

The results of this study suggest more research into curcumin, including improved delivery into patients. For example, some delivery options may include nebulized curcumin directly into the lungs, binding it to highly absorbable agents for oral use or liposome-encapsulated curcumin suitable for intravenous use (already shown to be effective in an animal model).

According to manufacturers of curcumin products, some are more readily absorbed than others. One study on fibrosing suggested that a dose of around 2200 mg curcumin split into three doses taken with meals including pepper (bioperine) achieved doses that were sufficient to exert the desired therapeutic effect.

Research into using quercetin also has some promising results in slowing the progression of IPF. Quercetin reversed lung fibrosing in mice and reversed the disease progression normally caused by typical pulmonary senescence markers [206].

It is worth mentioning that N-acetylcysteine (NAC), a long-used therapeutic agent for breaking down mucus in the lungs, has not been found to be effective in those with IPF. In fact, due to its acidic nature, it has even been shown to be harmful when used in the inhaled form [207].

Several of the drugs being developed have a natural product as a model or foundation. Until a drug or gene therapy is developed that stops or reverses this disease, it may make sense for the patient to focus on anti-inflammation and reducing myofibroblast activation, the extracellular matrix (ECM) accumulation, and the epithelial-mesenchymal transition (EMT) process. The phytochemicals listed in ◘ Fig. 51.11 would be good ones to investigate.

51.8.4.4 Genetics and Telomeres

With the recent identification of genes associated with ILD, a call for gene-related therapies both related to telomere lengthening and connective tissue disease has been initiated, and this type of therapy, as with any disease, could be personalized [208]. One recent study looked at various biomarker values as a more precise way of diagnosing. The biomarker molecules were classified according to their involvement into alveolar epithelial cell injury, fibroproliferation, and matrix remodeling as well as immune regulation. Furthermore, genetic variants of TOLLIP, MUC-5B, and other genes associated with a differential response to treatment and with the development and/or the prognosis of IPF were identified. Research into personalized medicine for treatment is starting [209].

Although controversial, because of the lack of research on interpretation of the results, telomere length testing is available directly to consumers and through healthcare

◘ **Fig. 51.11** Antifibrosis therapy. The molecular mechanisms and therapeutic targets of natural products against fibrosis. **a** TGF-b exerts a profibrotic effect through Smad-dependent [Target (1)] and Smad-independent pathways [Target (2)]. In the Smad-dependent pathway, TGF-b1 directly phosphorylates and activates the downstream mediator Smad2 and Smad3 through TGF-b receptor I, and then Smad2 and Smad3 bind Smad4, which forms a complex that moves into the nucleus and initiates gene transcription. Smad7, transcribed by Smad3, is a negative regulator of TGF-b/Smad signaling, and the imbalance between Smad3 and Smad7 contributes to fibrosis. PI3K, ERK, and p38 MAPK are downstream mediators of the Smad-independent TGF-b pathway. PPARg [Target (3)] could inhibit TGF-b to reduce fibrosis, while CTGF [Target (4)], a matricellular protein, contributes to wound healing and virtually all fibrotic pathology. Additionally, Gas6 contributes to fibrosis through the TAM receptor, which further activates the PI3K/Akt pathway. Similarly, LPA triggers fibrosis through the LPA1 receptor [Target (5)] that stimulates b-catenin to induce fibrogenesis. The activation of the hedgehog pathway [Target (6)] induces the transcriptional activity of Gli to express target genes, which have an important role in interstitial fibrosis, undergoing myofibroblast transformation and proliferation. IL pathway [Target (7)] stimulates NF-kB [Target (8)] to activate TGF-b to induce fibrogenesis, while Nrf2 [Target (9)] antagonizes NF-kB activity to protect against fibrosis. **b** The chemical structures of isolated compounds and their therapeutic targets are presented. practitioners. There are a few different methods: quantitative polymerase chain reaction, or qPCR, which has a 20% variability rate, and flow cytometry and fluorescent in situ hybridization, or Flow-FISH, which has a 5% variability rate. Most research labs use Flow-FISH for research.

Telomere length is a hot topic in research, the antiaging industry, and with popular health blogs. Shorter-than-average telomeres have also been linked to heart disease and heart failure [163, 210, 211], cancer [212], diabetes [213], and osteoporosis [214]. Research has shown ways to slow telomere shortening. Some include reducing stress, meditation, practicing loving kindness (a technique encouraging compassion) [215], reducing exposure to air pollution and toxins [216], cardiovascular exercise [217], and a healthy fat and high vegetable diet [218, 219]. One study showed that 45 minutes of cardiovascular exercise three times per week resulted in longer telomeres representing 10 years of biological age, similar to those of marathon runners, compared to those who didn't exercise much or at all [220]. Intermittent fasting, which reduces oxidative stress and keeps weight in check, has exploded in the scientific literature as a way to increase longevity and slow telomere shortening [221, 222].

Nicotinamide adenine dinucleotide (NAD+) supplements may also help maintain telomere length by activating sirtuins, the antiaging enzymes; PARPs, which are involved in DNA repair; and CD38, which plays a role in insulin production. Another supplement, cycloastragenol, derived from the herb astragalus, has also been shown to activate telomerase in mice. An ingredient called TA-65 has been derived and is used in supplements [223].

Overall, a healthy lifestyle and diet seem to delay the shortening of telomeres. With relation to PF, the gene mutations involved in telomere shortening may or may not be influenced by the above interventions. More research is needed for this.

Pulmonary fibrosis is a devastating disease with no management or a known cure. The integrative and functional medicine nutritionist can help her/his patient by managing weight, encouraging a healthy diet full of anti-inflammatory foods and encouraging a healthy lifestyle with exercise and stress reduction. There is some promising research into natural supplement use to target the different areas of progression within the disease process and some ongoing drug and gene therapy development to follow.

51.9 Conclusion

The prevalence of lung disease in the United States and worldwide is growing and will continue to grow rapidly with the deterioration of Earth's atmosphere, which is caused by pollutants such as industrial and construction toxins and volcanic and wildfire particulates. Poor maternal, childhood, and adult nutrition from micronutrient-poor diets resulting in nutrient insufficiencies, not necessarily nutrient *deficiencies*, is also contributing to increased lung disease diagnoses or poorer results during treatment [226, 227]. Lifestyle choices and habits also play a role in the development of many of the lung diseases in today's world, such as smoking or vaping, which uses chemicals that are poorly studied to date. Other lung diseases have their roots in genetics.

Some key processes drive many lung diseases, with the inflammatory process being the most important, according to current literature. Nutrition can be of great help with inflammation, using a diet rich in whole foods providing micronutrients and phytonutrients. Understanding genetics is also key to unraveling the causes and potential future treatments for many lung diseases. Those patients with both genetic and environmental determinants, such as in those who smoke and have genes associated with COPD, are at the greatest risk [228].

Despite the prevalence of lung disease, there is a general lack of nutrition knowledge among practitioners, including familiarity with the research about the use of nutrition for prevention, slowing disease progression, or as a treatment of lung disease. Historically, nutrition has been used in a supportive role, primarily monitoring macronutrients to prevent weight loss, muscle atrophy, and acid/alkaline balance. Although this is extremely important, more attention needs to be directed toward emphasizing micronutrients and phytonutrients. Research is strong regarding the benefits of vitamins, minerals, and pre- and probiotics, and indeed, some integrative and functional practitioners are using vitamin and mineral nutritional therapy in oral, intramuscular, and intravenous applications, when allowed, in practice. A newer area of research is around nutraceuticals, including targeted vitamins, minerals, and plant-derived constituents concentrated to therapeutic doses. Some exciting research around the use of curcumin and quercetin, for example, has been shown to dampen inflammation to the point of disrupting the disease process (see above). The expanding knowledge of the microbiome is identifying the importance of the lung and airway microbiome in respiratory health.

More research, and indeed more education for nutritionists around the existing research, is needed to fully understand the best opportunities for the use of nutrition in the treatment or prevention of lung disease.

52.1 Introduction

Skin conditions in the United States are a common concern, accounting for nearly 110 million patient visits in a recent survey [1]. Complementary and alternative medicines were used for eight million of those visits, with recommendations for fish oil or omega-3 fatty acids, lutein, glucosamine, and Reishi mushrooms, to name a few [1]. Included in these recommendations are medical nutrition interventions and diet suggestions, individual nutrients, and a growing number of bioactive dietary components and plant extracts. These interventions are beginning to be recommended by dermatologists [2]. The skin has unique physiology, endocrine, and immune responses. Understanding this uniqueness helps direct the clinician to successful therapeutic interventions.

52.2 Overview of Skin Function and Composition

The skin is complex, highly specialized and serves multiple functions. It provides barrier function to prevent internal water loss and protects the body from external environmental agents [3, 4]. The adult human skin covers approximately a 2-square-meter area with appendages of hair and nails [4]. The skin has two main layers: dermis and epidermis. Embryologically, ectoderm, neuroectoderm, and mesoderm contribute to constituents of the skin. From the ectoderm arise the epidermis, hair, sebaceous glands, sweat glands, and nails. The neuroectoderm contributes to the melanocytes, nerves, and neuroreceptors. The mesoderm gives rise to collagen, reticulin, elastic fibers, blood vessels, muscle, and fat.

52.2.1 Epidermis

The epidermis has microscopically distinct layers. The stratum basale abuts and communicates with the dermis, followed by the stratum spinosum, stratum granulosum, and stratum lucidum. The final layer, the stratum corneum, interfaces with the external environment and is an external stratified, non-vascularized, epithelium of between 75 and 150 micrometers and can be up to 600 micrometers thick on the palms of the hand and soles of the feet. This outermost layer of the epidermis, stratum corneum, consists of keratinocytes which are dead and flattened remnants imbedded in a lipid matrix, connected by desmosomes. This unit is difficult to penetrate both by internal-to-external water loss and external-to-internal transfer of environmental materials. The lipids of the stratum corneum form a lamellar matrix, which has a unique composition that provides important properties to this organ [5, 6]. The stratum corneum contains equimolar quantities of ceramides, cholesterol, and fatty acids. Maintaining this ratio is imperative for normal epidermal barrier homeostasis, as well as for normal lamellar organization [5]. The ceramides, cholesterol, and fatty acids comprise 50%, 25%, and 15%, respectively, of the total lipid mass [5–7]. Both essential and nonessential fatty acids play roles in normal and proper skin function.

Plant- and animal-derived essential fatty acids (EFA), such as eicosapentaenoic acid (C20:5, n-3) and docosahexaenoic acid (C22:6, n-3), are transported to the epidermis from the capillaries (please see ► Chap. 10 for Essential Fatty Acid Biology and ► Chap. 12 for Structure and Function). There is also evidence that some fatty acids used in the formation of the epidermis are intrinsically made. The keratinocytes transport EFAs, such as arachidonic acid and linoleic acid, with higher specificity than for nonessential fatty acids like oleic acid (C18:1,n9) [6, 8]. EFAs are integral for normal stratum corneum function in that they help form three acylceramide species (linoleic acid esterified to the omega hydroxyl group of very long chain fatty acids –C>28–34). The ceramides are key to the barrier function and contribute to minimal transepidermal water loss [5, 9]. When considering the cofactors for the elongases and desaturases which allow intrinsic conversion of these fats, it makes intuitive sense that when the mineral and vitamin cofactors are deficient, some skin conditions worsen.

In skin conditions where there is alteration of the keratinocyte fatty acid composition, such as in atopic dermatitis and psoriasis, modulating the levels with EFA intake improves barrier defects, proliferative epidermal changes, and inflammatory processes [10–13]. On the other hand, when oleic acid has a higher predominance in the diet or is substituted for essential fatty acids, certain skin conditions worsen because of changes in proliferation and inflammation [4].

The integrity of the epidermis is dependent on the pH of the skin [14]. An acidic pH at the skin surface helps modulate the microbial barrier function and inflammation, along with the rate and degree of desquamation. Free fatty acids are a major contributor to the maintenance of the pH [15, 16]. This helps explain why environmental and lifestyle habits, such as excessive water exposure, solvents, and hygiene products, change the pH and can adversely alter the integrity and the turnover of the skin.

52.2.2 Dermis

The dermis is located beneath the epidermis and varies in thickness, depending on location. While it is usually less than 2 mm thick, it may be as thick as 4 mm in the adult back and as thin as 0.3 mm at the eyelid. The dermis houses many of the skin's "business centers" and is a rich repository of various tissue types, including the vascular system, lymphatics, and most nerves [4, 17]. Within the dermis, there are three types of connective tissue, with the most abundant being collagen, followed by elastic tissue, and reticular fibers. Also found are the Meissner's and Vater-Pacini corpuscles, which collect and interpret touch and pressure. Unmyelinated nerve endings in

the papillary dermis capture and transmit the sensations of pain, itch, and temperature. Sebaceous glands and adrenergic fibers that innervate the blood vessels, hair erector muscles, and apocrine glands are located in this important layer.

52.2.3 Skin Immunity

The immune reactions in the skin are both innate and acquired, and all Gell-Coombs reactions types 1 through 4 can be identified (please see ▶ Chap. 19). Histiocytes are macrophages that wander the skin landscape. Histiocytes accumulate hemosiderin, melanin, and the debris of inflammation. Mast cells are located around blood vessels and release histamine, heparin, and more than 100 different chemotactic and adaptogenic molecules [4]. Immune surveillance and maintenance of barrier integrity for the skin is provided by the memory T cells with the imprinting signals from the resident dendritic cells.

Chemokine expression helps drive and modulate skin immunity. Chemokines and their receptors are important for signaling migration of various cell types into areas of inflammation. One example is expression of chemokine receptor 8, CCR8, in the skin resident memory T cells resulting from skin-specific factors. Of interest, this is not seen in the mesentery or intestinal mucosal layer, which suggests this is unique to the keratinocyte layer in the skin [18]. The factors leading to chemokine expression are soluble and independent of vitamins A and D, although these vitamins play a significant role in the control of T-cell homing to both the small intestine and skin tissue [18]. In brief, vitamin A and vitamin A metabolites were shown to play a crucial role in the induction of the gut-homing chemokine receptors CCR9 and α4β7 and a feature of local $CD103^+$ dendritic cells [18]. In contrast, the situation for skin-homing T cells is more complicated. The vitamin D_3 metabolite 1α,25-dihydroxyvitamin D_3 was shown to be necessary to induce chemokine CCR10 in human T cells [18]. Furthermore, vitamins A and D, along with calcium, are important for cathelicidin and kallikrein expression. Cathelicidin is critical for innate immunity of the skin, providing antimicrobial action and immunomodulation. Cathelicidin is enzymatically controlled by the family of kallikreins, and expression is important for control of keratinocytes' immune protection [19]. These variables may further control the functions of antimicrobial peptides in the skin, which can modulate the severity of psoriasis and rosacea. Because of nutrient insufficiencies, excesses, or other bioactive immune-modulating compounds, many common skin conditions may be affected.

The epithelium and the underlying connective tissue of the dermis together form a pliable, strong, communication-rich organ system. All the functions discussed above, along with development and replacement of these tissues, are dependent on adequate nutrition from conception to the last breath.

52.3 Nutrition Deficiency and the Skin

The classic nutritional deficiencies all have skin signs and symptoms. This makes functional sense as the macronutrients consisting of protein, fats (cholesterol, essential fatty acids, ceramides, sphingomyelins), and carbohydrates (simple and complex) form the structural architecture and the micronutrients, consisting of minerals, vitamins, and phytonutrients, are the cofactors and modulators of physiologic mechanisms and healthy tissue turnover. When there is inadequacy of macronutrients, micronutrients, phytonutrients, and/or bioactives to sustain and modulate genetic, epigenetic, and physiologic conditions, the signs and symptoms of inadequacy develop. See ◘ Table 52.1. With growing understanding of genetic single nucleotide polymorphisms (SNPs) and epigenetic influences changing the expression of genes and altering tissue requirements, it is no wonder that there are so many classic nutritional deficiency signs and symptoms seen with variable occurrence. See ◘ Table 52.2. The increasing recognition of SNPs for each enzyme system modulated by nutrient cofactors and phytonutrient adaptogens is increasing the complexity of our understanding.

An exciting new frontier in health modulation and treatment is the understanding of microRNA (miRNA). The miRNA from food alters and blocks the activity of endogenous miRNA associated with disease processes [24–26]. The trans-kingdom transfer of miRNA in each bite of our food is epigenetically altering our individual health and disease processes [24–26]. This understanding gives insight to the variable penetrance of different diet and nutritional treatments when applied to inflammatory conditions of the skin. For example, in psoriasis, atopic dermatitis, and other autoimmune diseases, there are increasing or decreasing levels of miRNA with variable regulation, which seems to drive the immune balance [24]. Also, miRNAs of curcumin and resveratrol impact the degree of disease by modulating immune function [27]. This understanding has brought about an emerging frontier for the use of plants, roots, herbs, and spices, with their associated miRNA, to modulate the immune response.

When considering the results of a skin-related physical exam, a single finding may be contributed by one or a multitude of nutrient insufficiencies. A good example is cheilitis—dry, scaly, and fissured lips. See ◘ Table 52.2. Cheilitis can be caused by a number of nutritional deficiencies, including protein, zinc, or B vitamins. In contrast, a single food may trigger varied immune reactions that are manifested in many skin findings. Two examples are the gluten and milk proteins, whose proteomes trigger autoimmune reactions manifested throughout the body and skin. See ◘ Table 52.3. Just as chronic disease is associated with many underlying conditions, skin diseases are associated with a variety of intersecting causes.

52

Table 52.1 Protein, fat, carbohydrate, minerals, vitamins, phytonutrient deficiencies, and presenting signs

Nutrient	Signs and symptoms
Protein	
Marasmus: wasting and stunting less than 60% body weight for age- protein fat and carbohydrate-deficient diet	Infants <1 year, failure to thrive Dry, thin, loose, wrinkled skin Hair loss; fine brittle hair, alopecia Fissuring and impaired growth of nails Loss of subcutaneous fat and muscle mass Loss of buccal fat (monkey facies) Alopecia Angular cheilitis
Kwashiorkor: body weight less than 60–80% predicted weight with a protein- or fat-deficient diet	Children between 6 months and 5 years Failure to thrive, edema Generalized dermatitis, "flaking enamel paint" dermatosis, "cracked pavement" dermatosis Increased pigmentation on arm and legs Hair color changes (dark brown hair becomes a rusty red, light-colored hair becomes gray-white) flag sign, alopecia
Marasmic kwashiorkor-stunted growth	Combination of the above symptoms with edema of extremities, face
Protein calorie malnutrition	Skin: generalized dermatitis, "flaking enamel paint" dermatosis or "cracked pavement" dermatosis, edema, increased pigmentation on arms and legs Hair: dark brown hair becomes a rusty red, light-colored hair becomes blonde (flag sign)
Fats	
Essential fatty acids	Skin: xerosis, scaly, diffuse erythema, poor wound healing, traumatic purpura Hair: Hyper or hypopigmentation of hair, alopecia Nails: brittle nails
Minerals	
Copper (genetic—Menkes disease)	Skin: hypopigmentation, follicular hyperkeratosis, inelastic depigmented skin at nape of neck, axillae, trunk Hair: kinky or steel wool hair: short, sparse, lusterless, tangled, depigmented
Copper deficiency—acquired	Skin: poor wound healing Hair: hair loss, alopecia
Iron	Skin: generalized pruritus Hair: lusterless, dry, focally narrow and split hair shafts, heterochromia of black hair, hair loss (alopecia) or thinning Nails: fragile, longitudinally ridged, lamellate brittle nails with thinning, flattening of nail plates, koilonychias Mouth: aphthous stomatitis, angular stomatitis, glossodynia, atrophied tongue papillae
Selenium	Skin: loss of hair and nails, leukonychia
Zinc deficiency (genetic— defect in intestinal zinc transporter (ZIP4)	Skin: eczematous and erosive dermatitis, preferentially localized to periorificial and acral areas, alopecia, superinfection with *Candida albicans* and *Staphylococcus aureus*
Zinc deficiency—acquired	Skin: psoriasiform dermatitis involving the hands and feet and occasionally the knees; dry, scaly, eczematous skin around buttocks, enlarged fingers with paronychia, bright erythema of the terminal phalanges, poor wound healing, warts
Vitamins	
Vitamin A	Skin: xerosis, skin fissuring (dermatomalacia), phrynoderma, perifollicular hyperkeratosis Ocular: impaired dark adaptation, exophthalmos, corneal xerosis, ulceration, keratomalacia, corneal perforation, blindness Mouth: xerostomia, hypotonia, hypogeusia
Vitamin D	Skin: pale, increased inflammation. Tendency for thicker and increased basal cell, squamous cell, and melanoma cancers compared to those with normal vitamin D levels Pain: hyperesthetic pain response in skin lesions, increased pain sensitivity
Vitamin E	No skin-associated deficiency signs
Vitamin K	Bruising, perifollicular hemorrhages
Thiamin	Skin: edema of face, sacrum; decreased sweating or hyperhidrosis; atrophy of the skin with distal extremity hair loss
Riboflavin	Acute: Skin: erythema, epidermal necrolysis, mucositis Chronic: Skin: seborrheic dermatitis of nasolabial folds, nostrils, nasal bridge, forehead, cheeks, posterior auricular areas, flexural areas of limbs and genitalia Mouth: angular stomatitis, cheilosis with erythema, xerosis, fissuring, glossitis, magenta tongue
Niacin (nicotinic acid)	Pellagra Skin: painful pruritic dermatitis of sun-exposed skin—scaly, dry, atrophic, in intertriginous areas, dorsum of the hands (gauntlet); dorsum of feet (gaiter) macerations and abrasions may occur; Casal's necklace in the neckline exposed to sun leads to dermatitis with erythema and hyperpigmentation; malar suborbital pigmentation (butterfly distribution), scrotal dermatitis, erythema, and hyperpigmentation Mouth: angular stomatitis, cheilitis, glossitis

Table 52.1 (continued)

Nutrient	Signs and symptoms
Folate (B9)	Skin: perirectal ulcerations, perineal seborrheic dermatitis, diffuse brown hyperpigmentation concentrated in the palmar creases and flexures Mouth: glossitis with atrophy of the filiform papillae, angular cheilitis, mucosal ulceration
Cobalamin (B12)	Skin: cutaneous hyperpigmentation—diffuse, symmetric, or scattered macules with greatest concentration on hands, nails, face, palmar creases, flexural regions, and pressure points; vitiligo or hypopigmentation Hair: hair depigmentation—localized or diffuse Mouth: glossitis—atrophic red painful with atrophy of the filiform papillae in early states may be linear glossitis, angular cheilitis
Biotin and multiple decarboxylase deficiency	Skin: erythematous, crusting, scaly dermatitis around eyes, nose, mouth and periorificial areas, alopecia, glossitis, conjunctivitis
Vitamin C	Skin: follicular keratotic plugging, perifollicular purpura, lower-extremity edema with ecchymosis, poor wound healing, dehiscence Hair: corkscrew hairs, swan-neck hairs Mouth: mucosal swelling, ecchymosis and bleeding of gingiva, hemorrhagic gingivitis, necrosis, loss of teeth

Based on data from Refs. [20, 21]

Table 52.2 Classic clinical signs of potential nutrient deficiency

Classical signs	Consider deficiency
Skin	
Xerosis	Essential fatty acids, ceramides
Petechia (pinhead-sized hemorrhages)	Vitamin A, vitamin C
Pigmentation increased in sun-exposed areas	Niacin, B12
Follicular hyperkeratosis (goose flesh)	Vitamin A, possibly essential fatty acids, B vitamins, vitamin C
"Flaky-paint" dermatosis, subcutaneous fat loss, fine wrinkling	Protein
Subcutaneous fat loss, fine wrinkling	Protein-energy
Decreasing tissue turgor	Water, protein (hypoalbuminemia)
Edema	Protein, thiamin (wet beriberi)
Purpura	Vitamin C, vitamin K
Perifollicular hemorrhage	Vitamin C
Pallor	Folacin, iron, vitamin B12, copper, biotin
Seborrheic dermatitis	Essential fatty acid, pyridoxine, zinc, biotin
Thickening of the skin	Essential fatty acid
Hair	
Easily pluckable	Protein, biotin
Sparse	Protein
Straight, dull	Protein
Coiled, corkscrew-like	Vitamin A, vitamin C
Skin of the mouth, lip, oral structures	
Angular fissures, scars, stomatitis	B complex, iron, protein, riboflavin
Cheilosis (cheilitis)	Protein, riboflavin, niacin, pyridoxine, biotin, folate, zinc
Ageusia, dysgeusia	Zinc
Tongue	
Magenta tongue	Riboflavin
Fiery, raw	Niacin
Glossitis	Pyridoxine, folacin, iron, vitamin, B12
Pale	Iron, vitamin B12
Atrophic papillae	Riboflavin, niacin, iron

Based on data from Refs. [21–23]

52.4 Skin Conditions and Medical Nutrition Therapy

Many skin conditions are seen in the primary care setting and are amenable to nutrition interventions [29]. Skin conditions reviewed below have been improved by therapeutic dietary changes and oral or topical administration of nutrition therapies. See Table 52.4. The quality of evidence from data ranges from Grades 1A to 2C. In the clinic setting, the opportunity to meld medical nutrition therapy with the pharmaceutical model is increasing as clinicians are becoming more adept at uncovering the root causes of conditions. The treatments for chronic conditions are provided with the

Table 52.3 Wheat and milk proteome association in autoimmune diseases with skin manifestations

Food protein	Autoimmunities	Signs
Wheat proteomes	Multiple sclerosis Autoimmune thyroiditis Addison's disease Alopecia Type 1 DM Dermatitis herpetiformis Arthritis osteoarthritis Lupus erythematosus Autism Osteopenia-osteoporosis Autoimmune myocarditis	Xerosis, pruritus Distal temperature changes, xerosis, pruritus Pigment changes Hair thinning, loss Vascular or temperature change, ulcerations Bullous rash Tissue warmth Macular rash, hair loss Pruritus, rashes, compulsive itching, biting Tenderness over areas of osteopenia/malacia Peripheral vascular constriction
Milk proteins	Epithelial permeability Celiac disease Crohn's disease Behcet's disease Multiple sclerosis Systemic lupus erythematosus Uveitis Type 1 diabetes Autism	Increased contact, environmental dermatitis Mouth mucosal lesions Mouth mucosal lesions Mouth, peripheral ulcerations Xerosis Macular rash, hair loss, ulcerations Photophobia Vascular or temperature changes, ulcerations Pruritus, rashes, compulsive itching, biting

Based on data from Ref. [28]

increased understanding of how individual genetics, the epigenetic influences, time course of the illness, and the power of modifiable lifestyle choices, including nutrition, sleep, exercise, thoughts and emotions, and personal relationships, all converge to impact skin conditions.

Understanding of nutrient or bioactive function is important to be able to predict the signs and symptoms of insufficiency or excesses related to skin structure, immunity, and protective barrier. Understanding nutrient and bioactive function helps direct therapeutic interventions. Whole foods in the Mediterranean diet have been used successfully to treat most of the conditions listed in Table 52.4. The frank nutrient deficiencies (pellagra, scurvy, acrodermatitis enteropathica) are specifically treated with single nutrients. Excellent extensive reviews are available to provide more in-depth information for interested readers [2, 40, 156, 157].

Macro and micronutrient deficiencies impact skin health. The application of Mediterranean food plans, the modified elimination diet, and the use of probiotic supplementation are useful tools for addressing obesity-associated skin changes, autoimmune or hypersensitivity reactions to food proteins, and other selected dermatologic conditions.

52.5 Macro- and Micronutrient Deficiencies Influencing Skin Health

The skin, hair, and nail disorders have long been associated with identified nutrition deficiencies. It is well understood that the quality and quantity of food nutrients vary. Food nutrient concentrations have decreased over the last 80 years in response to soil changes, processing, and storage practices [158, 159]. It is vital to recognize the relationship of the quality of dietary intake and nutrient deficiencies in association with dermatologic findings on physical exam. Selected references expand the role of nutrients in skin health, disease, and associated findings in insufficiency, or deficiency [2, 40, 156, 157]. An abbreviated nutrient review follows.

52.5.1 Protein

Protein deficiency is evident in many clinical settings. Causes range from inadequate intake, increased tissue requirements due to turnover, altered genetics, increased need for repair, or loss through increased excretion. The essential amino acids and conditionally essential amino acids form the peptide and protein structures which allow structural collagen and keratins to form. Collagen represents 70% of skin protein and is composed of three repeated amino acids: glycine, hydroxyproline derived from proline, and hydroxylysine derived from lysine [160]. Deficiencies of total protein, glycine, and lysine lead to altered skin integrity. In association, a diet deficient in lysine is associated with hair loss [160]. Elastin, the protein that allows skin to stretch and bounce back, is composed of leucine. Diets inadequate in protein, sulfur-rich amino acids, glycoproteins, and transport proteins promote the loss of tissue integrity. Protein deficiency and insufficiency physical exam findings are summarized in Tables 52.1 and 52.2.

52.5.2 Essential Fatty Acid

Essential fatty acid (EFA) deficiency is seen in malnutrition but also in the imbalanced fat consumption patterns in the standard American diet (SAD). SAD can be deficient in essential fatty acids or have a high omega-6 to omega-3 ratio. The predominant EFA deficiencies include linoleic, linolenic, and arachidonic acid, and plasma levels are often diminished with palmitoleic and oleic acids increased. The presence of mead acid (5,8,11-eicosatrienoic acid in the plasma) is also a marker of essential fatty acid deficiency.

Eczematous and pruritic skin changes are associated with increased cell turnover, especially the periorificial areas.

Table 52.4 Skin conditions amenable to nutrition interventions: practical summary

Condition	Practical summary of the condition	Medical nutrition therapy
Acanthosis Nigricans Type 1 hereditary benign Type 2 benign Type 3 pseudo-AN Type 4 drug induced Type 5 malignant ICD10: L83	*Epidermal-metabolic disorder* 1: No associated endocrine disorder— can present at birth 2: Endocrine disorder associated insulin resistance, insulin-resistant type II diabetes mellitus, hyperandrogenic states, acromegaly, Cushing's disease, hypogonadal syndromes with insulin resistance, Addison's disease, and hypothyroidism (DeWitt) 3: Pseudo-acanthosis nigricans—associated with obesity, patients with darker pigmentation, metabolic syndrome, obesity producing insulin resistance 4: Drug induced—nicotinic acid in high doses, stilbestrol in young males, glucocorticoid therapy, diethylstilbestrol-oral contraceptives, growth hormone therapy 5: Malignant—paraneoplastic usually adenocarcinoma of the gastrointestinal or genitourinary tract, less commonly bronchial carcinoma and lymphoma [30–32]	1. Diet: low-glycemic index diet to decrease basal insulin levels [33] 2. Nutraceutical Supplementation 2a. EFA/DHA—fish oil 10–20 g 6 months [34] Improvement in insulin resistance and HOMA-IR score, IGF-1, and the acanthosis nigricans [35] 2b. Topical vitamin A (tretinoin 0.1% gel) applied to localized areas for 2 weeks [36, 37] 2c. Topical vitamin D (calcipotriol-calcipotriene 0.005% cream) twice a day for 3 months led to improvement and resolution [38]
Acne rosacea ICD10:L71	*Disorders of the sebaceous and apocrine glands* Chronic inflammatory acneiform disorder of the facial pilosebaceous units Increased reactivity of capillaries leading to flushing and telangiectasias Rubbery thickening of the nose, cheeks, forehead, and chin skin due to sebaceous hyperplasia edema and fibrosis Occurs in 10% of fair-skinned people Age of onset: 30–50 years with peak incidence between 40 and 50 years Females predominate Rhinophyma predominates in males Celtic person's skin phototypes 1 and 2 but also southern Mediterranean's, less frequently in skin types V and VI Stages: Plewig and Kligman's classifications Stage 1: persistent erythema with telangiectases Stage 2: persistent erythema, telangiectases, papules, tiny pustules State 3: persistent deep erythema, dense telangiectases, papules, pustules, nodules, rarely persistent solid edema of the central face Special lesions: Rhinophyma—enlarged nose Metophyma—enlarged cushion-like swelling of the forehead Blepharophyma–swelling of the eyelids Otophyma—cauliflower-like swelling of the ear lobes Gnathophyma— swelling of the chin Bacterial culture: *Staph aureus* Scapings: *Demodex folliculorum* Treatment: topical or systemic antibiotics, oral isotretinoin for severe disease, ivermectin for demodex, or erythema, and telangiectasias beta-blocker carvedilol 6.5 mg BID to reduce erythema and telangiectasia [39]	1. Diet: Consider dietary triggers, alcohol, coffee, tea, spice, dairy rich in branch chain amino acids and triggers of mtorc1. Diets low in essential fatty acids [40–42] 2. Lifestyle: emotional stress 3a. Associated conditions treated with Diet 3b. Consider Crohn's, celiac disease, Ulcerative colitis, SIBO, IBS (all > 1.34–1.46 RR) [42] or *H. pylori* 4. Nutraceutical supplementation [43–49] 4a. Zinc sulfate—23 mg TID × 3 mo decreased compared to placebo Zinc sulfate—50 mg BID × 3 mo no difference Zinc 60–75 mg/d for 3-mo improvement in skin compared to controls 4b. Pancreatin (8–10 × USP) 350–500 mg before meals—daily dose led to improvement in skin compared to controls [47] 4c. Brewer's yeast 2 g TID. Hansen CBS 5926 inhibits bacterial growth 60% [50] 4d. B complex 100 mg/d avoid higher doses of niacin [51] 4e. Probiotics *E. coli* Nissle 1917 25 Billion CFU 4/d × 1 month. Marked improvement with the addition of the probiotic [52] Eradication of *H. Pylori*. Improved rosacea [53] Topical: 4f. Azelaic acid—15–20% cream topical BID for 15 weeks. More improvement then with metronidazole [54, 55]

(continued)

Table 52.4 (continued)

Condition	Practical summary of the condition	Medical nutrition therapy
Acne vulgaris ICD10:L70.0	*Disorders of the sebaceous and the apocrine glands* Occurs in 85% of young people in the last half of the twentieth century. Rare in the nineteenth century Acne vulgaris affects more than 80% of teenagers and persists beyond the age of 25 years in 3% of men and 12% of women [56] Typical lesions of acne include comedones, inflammatory papules, and pustules. Nodules and cysts occur in more severe acne and can cause scarring and psychological distress Most frequently in the adolescent appearing on the face, trunk, and rarely the buttocks Manifests as comedones, papulopustules, nodules, or cysts Can result in pitted, depressed, hypertrophic scars More severe in males than females Lower incidence in Asians and Africans Pathogenesis and triggers: follicular keratinization, androgens, *Propionibacterium* acnes. Bacterial lipase converts lipids to fatty acids and produces proinflammatory mediators (IL-1 and TNF alpha) leading to the inflammatory response Contributors: acnegenic mineral oils Drugs: Lithium, hydantoin, isoniazid, glucocorticoids, oral contraceptives, iodides, bromides, testosterone androgens Emotional stress, bowel dysbiosis [57]	[48, 49, 58–79] 1. Diet: 1a. Modified elimination diet: Milk, low-glycemic index, low trans fatty acids. Diet composition: 45% protein, 35% Carbohydrate, 20% fat. This increases the saturated/monounsaturated ratio which is associated with decreasing the lesion counts and increasing the sebum flow [64] Milk consumption: Nurses' health Study II. Severe acne 22% higher in highest milk drinkers vs lowest milk drinkers [48, 49, 62, 79] Changes in the insulin levels and the associated lesions are seen within 7 days of a low-glycemic index and more binding of the insulin-like growth factors 1b. Avoid high carbohydrate diet (10% protein, 70% carbohydrate, and 20% fat) encourages high insulin response and promotes elevated IGF-1 promoting acne Insulin-like growth factor (IGF) may play a role in acne [66, 67]. Milk consumption has been associated with increased levels of serum IGF [68]. IGF is also increased by ingestion of high glycemic loads and could potentially link diet and acne. A 12-week randomized trial that compared low- and high-glycemic load diets in 43 male patients with acne found a greater reduction in lesion counts with the low-glycemic load diet [63] 1c. Remove skim milk > 1% > 2% since they contain endogenous hormones and increase acne levels 2. Nutraceutical supplementation 2a. Zinc—inhibits Toll-like receptor 2 expression. Most trials supplementation of zinc 30–150 mg (elemental) positive effect Zinc gluconate 30 mg/d—66 patients. Decreased inflammatory scores compared to control [48] Zinc sulfate (68 mg elemental) twice a day for 12 weeks. 56% improvement, decrease number papules, infiltrates, and cysts [49] Data on favorable effects of dietary factors such as zinc, omega-3 fatty acids, antioxidants, vitamin A, and dietary fiber on acne vulgaris are limited [58, 59] 2b. Selenium: (uncontrolled trial) 29 patients. 400 mcg/d of selenium 20 iu vitamin E for 6 weeks with improvement [69] 2c. Vitamin A—vitamin A levels are lower in the skin and plasma of acne victims compared to controls. High-dose vitamin A has been used 100,000 iu/d for 3 months with improvements 300,000–500,000 iu/d of water miscible vitamin A for 3–5 months (136 patients) found half the patients improved >75% and another 40% improved >50%. Partial relapse 3–6 weeks following the discontinuation. Side effects: mild hair loss and dryness of the skin and mucous membranes. Mild elevation in triglycerides [71, 72] 2d. Pyridoxine—uncontrolled study 50 mg/d of pyridoxine 1 week prior to menses and continuing during menstruation for three cycles, 72% of patients with premenstrual acne flares [70] 2e. Topical niacinamide: 4% was as effective as topical 1% clindamycin in patients with inflammatory acne. 82% improvement compared to 69% improvement in the clindamycin group Applied twice a day for 8 weeks [73–75] 2f. Topical retinoids Considerations of isotretinoin Side effects: Increase homocysteine levels (doubling after 45 days of 0.5 mg/kg/d) [76] Decrease serum 5-MTHF levels by 13.5–17.7% within 28 days [77] Carnitine-responsive hypertransaminasemia, myalgia, muscular weakness, and hypotension on 0.5 mg/kg/d isotretinoin responded to oral L carnitine dose (weight-dependent) 25 kg 2.5 g carnitine/day 50 kg 5.0 g carnitine/day 75 kg 7.5 g carnitine/day 100 kg 10.0 g carnitine/day with decreased liver enzymes and symptoms within 45 days [78]

Table 52.4 (continued)

Condition	Practical summary of the condition	Medical nutrition therapy
Acrodermatitis enteropathica ICD10:E60	*Nutritional disease* Genetic: autosomal recessive. Occurs in infants bottle-fed with bovine milk or in breastfed infants following weaning Approximately 10–40% of dietary zinc is absorbed in the small bowel; absorption is inhibited by the presence of phytates and fiber in the diet that bind to zinc, as well as dietary iron and cadmium [80] Acquired zinc deficiency in older individuals due to dietary deficiency, failure of intestinal absorption of zinc (malabsorption, pancreatic insufficiency, alcoholism, prolonged parenteral nutrition, gastric bypass surgeries—Roux-en-Y—biliopancreatic diversion) Skin: patches of plaques of dry, scaly, sharply marginated and brightly red, eczematous dermatitis gradually evolving into vesiculobullous, pustular, erosive, and crusted lesions Occur periorificial (mouth, anus) then on the scalp, hands, feet, flexural regions trunk. Fingertips glistening erythematous, with fissures and secondary paronychia, perleche secondary infected with *Candida albicans* or *Staph aureus* Diffuse alopecia, graying of hair, nail ridging, and loss of nails Red glossy tongue, superficial aphthous like erosions, secondary oral candidiasis Diagnosis Lab: low serum/plasma zinc, reduced zinc excretion Acquired zinc deficiency (cystic fibrosis, anorexia nervosa, celiac disease, alcoholic cirrhosis, Roux-en-Y, chronic diarrhea). Similar dosing Evaluate copper levels since long-term zinc supplementation can lead to zinc deficiency [40] Aberrant fatty acid metabolism, with some unknown impairment in the elongation-desaturation system of fatty acid biosynthesis. In particular, low levels of serum arachidonic acid have been reported [81, 82]	Zinc Therapy: Dietary or IV 3 × the requirement for age, daily for days to weeks. Fix root cause of the zinc deficiency 1a. Zinc therapy: 1–2 mg/kg of body weight per day. Higher doses in the presence of intestinal infections or other diarrheal states [83, 84] Higher replacement doses (approximately 3 mg/kg/day of elemental zinc) are used for acrodermatitis enteropathica, to overcome the defect in intestinal zinc absorption 1b. Adjusting for diarrhea—WHO Supplementation reduces the severity and duration of acute diarrhea in children from populations in which zinc deficiency is common. For infants and children with acute diarrhea in developing countries, the supplements are given at a dose of 20 mg/day for children or 10 mg/day for infants younger than 6 months old, for 10–14 days [80, 85–87] Recovery: 1–2 weeks diarrhea ceases, irritability, and depression can improve within 24–48 hours

(continued)

Table 52.4 (continued)

Condition	Practical summary of the condition	Medical nutrition therapy
Atopic dermatitis ICD10:L20	*Eczema-dermatitis* Acute, chronic, chronic relapsing skin disorder. Common in infancy, peaks 15–20% in early childhood Dry skin and pruritus, increased inflammation and lichenification with rubbing to further the itch-scratch cycle Diagnosis based on symptoms Family history, allergic rhinitis, asthma all related. 35% of infants develop asthma in later life Associated with skin barrier dysfunction IgE reactivity Genetic basis influenced by environmental factors. Alterations in immunologic responses to T cells, antigen processing, inflammatory cytokine release, allergen sensitivity, infection, miRNA-associated [88]	1b. Anti-inflammatory diet High maternal intake of margarine and vegetable oil during pregnancy through the first 2 years of life was associated with increased eczema in the offspring. A high maternal fish intake is inversely associated with eczema during the first 2 years in the offspring [89] 1b. Modified elimination diet IgE directed with lowering of the IgE causes stabilization and partial regression of skin manifestations [90] 2. Probiotics 2a. *Lactobacillus rhamnosus* 10–50 cfu/d decreased risk of eczema vs control (n = 474 infants) DBCP with mothers taking probiotics for 35 weeks to 6 months lactating postpartum and infant taking through 2 years of age. No reduced atopy [91] 2b. *L. reuteri*—100 million CFU for 36 weeks gestation to delivery. Less IgE associated eczema during the 2nd year 8% compared to 20% placebo. Skin prick test less common 14% vs 31% placebo [92] 2c. *L. rhamnosus* GG and *L. reuteri* 3. Zinc 10–40 mg/day 4. Riboflavin—if scrotal dermatitis is present and persistent [93] 5. Essential Fatts Fish oil 2–5 g/d- DHA 5.4 g/day (n = 21) for 8 weeks showed clinical improvement in the SCORAD (severity scoring of atopic dermatitis) compared with saturated fat control [94] 6. Vitamin D oral 1000–5000 iu/d Topical Zinc (if determined to be low <10 umol/L) has more recurrent infections than atopics with higher zinc levels. They also have higher copper levels, lower ferritin than controls [95, 96]
Dermatitis herpetiformis ICD10:L13.0	*Genetic, acquired bullous disease* IgA deposition in the skin. Antibodies to transglutaminases are major autoantigens. IgA activates complement via alternative pathway. Associated with HLA-B8, DR, DQ Distribution: scalp, extensor surface arms, back, upper gluteal area, thighs Remove wheat, gliadin Consider pharmacologic interventions: (diaminodiphenyl sulfone, sulfapyridine) (Ronaghy) [97] Associated with celiac disease, rheumatoid arthritis, hypothyroidism and Sjogren's syndrome. IgA autoantibodies toward an enzyme type 3 epidermal transglutaminase [97]	1. Modified elimination diet Gluten-free 2. Inositol—600–1800 mg/day (n = 5) 4/5 patients with marked improvement taking the supplement 4–12 months [98] 3. Niacin 50–200 mg (N = 12) 50% suppressed disease, 10/12 improvement [99]
Follicular hyperkeratosis Keratosis pilaris ICD10:E50.8	Disorder of follicular keratinization. Keratotic follicular papules and variable perifollicular erythema. Manifests in childhood or adolescence with spiny keratotic papules on the extensor aspects of the back of upper arms and distal extremities. May include phrynoderma caused by linoleic acid insufficiency, vitamin A deficiency, vitamin E, or general undernutrition, including B vitamin insufficiency [1, 100, 101]	1. Essential fatty acids 1a. Flaxseed oil 21 cc/d or linoleic acid 5 cc/d (n = 61) 100% lesion disappearance after 16–20 weeks with flax and 12 weeks with the linoleic acid [102, 103] 2. Vitamin A deficiency (Olson) Normalization to skin of children with follicular hyperkeratosis at >100,000 iu/d for 2–4 months (range 100,000–300,000 iu/day) [104, 105] 3. B vitamin and vitamin A injections (unlisted levels) over 10–14 days with >80% resolution [106, 107] 4. Vitamin C insufficiency associated with development of hyperkeratosis [108, 109]

Table 52.4 (continued)

Condition	Practical summary of the condition	Medical nutrition therapy
Keratosis		
Actinic ICD10:L57.0	Summary [110] Precancerous lesions on a spectrum from photodamaged skin to squamous cell cancer Strongest predictor of development of non-melanoma skin cancer and melanoma Increased susceptibility with cumulative UV radiation exposure, immunosuppression, prior skin cancers Risk of progression of actinic keratosis to squamous cell cancer ranges from less than 1 to 20% Risks: older age, male, fair skin that burns, blond or red hair, light-colored eyes, immunosuppression Common non-nutrition treatments: 5 fluorouracil solution or cream, imiquimod cream, diclofenac gel, cryotherapy, curettage with or without electrosurgery, shave excision	1. Diet: high fat intake increases the incidence of ultraviolet, light-induced skin cancers, reducing dietary fat intake decreased the incidence of actinic keratosis. If 40% of the calories are fat, decreasing to 20% of calories being fat decreased the incidence within 2 years of increasing number of additional actinic keratosis [111] 2. Niacinamide 500–1000 mg a day in divided dose decreased the number of new actinic keratosis and induced regression of some or all of actinic keratosis when compared to placebo groups [112–115] 3. Retinoids 3a. Oral: Vitamin A 100,000 iu/d of vitamin A for 19.8 months led to improvement in 90% of actinic keratosis and complete disappearance in 26% of the cases [116]. No side effects of the vitamin A were mentioned in the study 25,000 iu vitamin A for 3.8 years compared to placebo. 26% decrease in new squamous cell carcinoma, nonsignificant 6% increase in basal cell carcinoma in 2297 patients with at least 10 actinic keratosis (double-blind study) [117, 118] 3b. Topical retinoids have been studied for the treatment of AKs. In a 9-month randomized trial of 90 patients with multiple AKs, adapalene gel (0.1 or 0.3%) applied daily as field therapy for 4 weeks and twice daily thereafter significantly but modestly decreased the number of AKs compared with placebo and also appeared to improve the appearance of photodamaged skin [119]. In contrast, a randomized trial including 1131 patients found that long-term use of topical tretinoin 0.1% cream was ineffective in reducing the number of AKs [120]
Arsenical ICD10:L85.8	Summary [110] Precancerous lesions associated with chronic arsenic. Increased risk of becoming squamous cell cancers Highest risk for SCC (squamous cell carcinoma) with MTHFR TT polymorphism and low folate intake [121] Exposure to arsenic results from medicinal, occupational, and water source or other environmental exposures The risk of skin lesion due to arsenic exposure is modifiable by nutritional factors, such as folate and selenium status, lifestyle factors, including cigarette smoking and body mass index, and genetic polymorphisms in genes related to arsenic metabolism [122] Keratotic, yellow papules overlying pressure points on the hands and feet Latency period can up to 40 years Normally cryosurgery or curettage. 5-FU not as effective as when treating actinic keratosis	1. Check for sources of arsenic- water, diet, living conditions Remove arsenic source 2. Testing consider pre- and post-provocation testing for arsenic load determination 3. Improve methylation factors 4. Significant associations between low intakes of various nutrients (retinol, calcium, fiber, folate, iron, riboflavin, thiamin, vitamins A, C, and E) and keratotic skin lesion incidence in people exposed to environmental arsenic [122] Greater intakes of methionine, cysteine, protein, and vitamins such as thiamin and niacin increased arsenic secretion [123] Curcumin 500 mg BID × 3 months. Significantly less DNA, antioxidant damage, increased clearance (Biswas). Studies up to 10 g/day [124] Increased skin lesions in the undernourished underweight, lower BMI patients (decreased clearance) 1.65×
Seborrheic keratosis Dermatosis papulosa nigra ICD10:L82.1	Most common benign epithelial tumors. They are hereditary, small, to barely elevated with a stuck-on appearance Onset rarely before 30 years and more extensive in males Tan to black macules. Distribution on the face, trunk, upper extremities, submammary intertriginous. Darker pigmented in darker-skinned people	1. Increased association with VDR Taq1 [125] Consideration of increasing 25 OH vitamin D [126] With 30% response when placed topically [127, 128]

(continued)

Table 52.4 (continued)

Condition	Practical summary of the condition	Medical nutrition therapy
Pemphigus ICD10: L10	Serious acute or chronic, bullous autoimmune disease of the skin, and mucous membranes due to acantholysis Pemphigus vulgaris—flaccid blisters of the skin and erosions on mucous membranes Pemphigus foliaceus—scaly and crusted skin lesions IgG autoantibodies to desmogleins, transmembrane desmosomal adhesion molecules There can be environmental triggers Standard of care: modified elimination diet. Immunosuppressive agents Skin lesions: flabby vesicles, easy ruptures and weeping, scattered, discrete, localized or generalized. Erosions bleed easily. Crusts on the scalp Sites of predilection: scalp, face, chest, axilla, groin, umbilicus., mucous membranes- nose, pharynx, larynx, vagina Drug-induced pemphigus: captopril, D-penicillamine Brazilian pemphigus: black fly, *Simulium nigramanum*, triggered in the south-central part of Brazil	1. Modified elimination diet 1a. Both environmental and dietary triggers in acantholysis. The dietary factors implicated include allelic compounds in the genus *Allium* (garlic, onion, leek) 1b. The thiolic compounds can be acantholytic [129]. There is a high association of pemphigus in communities with high intake of mustard, red and black pepper, coriander, cumin seeds (India), or in communities with high tannins in the drinking water (Amazon basin) [129] 1c. Antigliadin antibodies were found in serum of the majority of patients with bullous pemphigoid raising the possibility of gluten sensitivity playing a role in pemphigoid [28, 40, 130] 2. Niacinamide or Niacinamide with tetracycline treatments. Niacinamide: case reports Niacinamide 500 mg TID [131] Niacinamide + tetracycline ($N = 18$) Niacinamide 500 mg TID + tetracycline 500 mg QID [132]
Pellagra ICD10; E52	Diet deficient in niacin or tryptophan or both. Consumption of a maize-based diet is often implicated Characteristic features: dermatitis in sun-exposed areas, diarrhea, cognitive changes leading to dementia and finally death Symmetric itching, painful erythema on the dorsa of the hands, neck, and face Vesicles and bullae may erupt and break, crusting occurs and lesions become scaly. Later skin becomes indurated, lichenified, rough, covered with dark scales and crusts Cracks and fissures and sharp demarcation with normal skin Distribution: dorsa of the hands and fingers, band like around the neck (Casal's necklace), dorsa of the feet up to malleoli and sparing the heel, and butterfly region of the face [133]	1. Niacinamide orally 100–300 mg and the other B vitamins 2. Pellagra Treatment Adult Oral: 50–100 mg 3–4 times daily maximum: 500 mg daily [134–136] Some experts prefer niacinamide for treatment due to more favorable side effect profile [81, 82, 137] Pediatric 0–5 months: 2 mg daily 6–11 months: 3 mg daily Oral: 50–100 mg 3 times daily Some experts prefer niacinamide (nicotinamide) for treatment due to more favorable side effect profile [81, 82, 137] 3. Pellagra with comorbidities 3a. Diabetes: Niacin (nicotinic acid) may increase fasting blood glucose, although clinical data suggest increases are generally modest (<5%) [138] Use niacin with caution in patients with diabetes. Monitor glucose; adjustment of diet and/or hypoglycemic therapy may be necessary. Niacin should not be used if patient experiences persistent hyperglycemia during therapy [139] 3b. Gout: May be associated with hyperuricemia. Use with caution in patients predisposed to gout. Niacin should not be used if patient experiences acute gout during therapy [139] 3c. Hepatic impairment: Use with caution in patients with a past history of hepatic impairment; monitor liver function tests. Contraindicated with active liver disease or unexplained persistent transaminase elevation. Niacin should not be used if hepatic transaminase elevations >2–3 times upper limit of normal occur during therapy [139]

Table 52.4 (continued)

Condition	Practical summary of the condition	Medical nutrition therapy
Psoriasis vulgaris ICD10: L40.0	1.5–2% of the population in western countries Chronic disorder—polygenic predisposition and triggering environmental factors including bacterial infection, trauma, drugs, alcohol, stress, weight gain Typical lesions chronic, recurring, scaly papules, plaques. Pustular eruptions and erythroderma occur There can be localized or generalized plaques, pustular psoriasis, palmoplantar pustulosis (L40.1) Peak incidence 22.5 years, children 8 years, older adults 55 years. Early onset predicts more severe long-lasting disease No gender preference Race incidence: low incidence in west Africans, Japanese, Inuits, absence in north and native south American Genetics: one parent—offspring 8%. Both parents 41% HLA-B13,B27,B57, Cw6. PSORS1 consistent susceptibility locus Triggers: physical trauma. Acute strep infections, stress flares psoriasis in 40% adults and higher in children Drugs: glucocorticoids, oral lithium, antimalarial drugs, interferon, beta-adrenergics, alcohol Pathogenesis: altered cell kinetics—shortening of cell cycle resulting in 28 times the normal production of epidermal cells and CD8+ T cells and overwhelming T-cell populations in lesions. Psoriasis is a T-cell-driven disease in the Th1 response of cytokine spectrum Acute guttate: disseminated, generalized mainly on the trunk Chronic stable: single lesions or lesions on the elbows, knees, sacral gluteal region, scalp, palm/soles Nails: fingernails and toenails involved 25%, especially with concomitant arthritis. Pitting, subungual hyperkeratosis, onycholysis, yellowish-brown spots under the nail plate, oil spot Skin: thickening of the epidermis (acanthosis) Arthritis (L40.5) seronegative spondyloarthropathies. Asymmetric peripheral joint involvement of the upper extremities, distal interphalangeal joints, with dactylitis-sausage fingers Enthesitis: inflammation of ligament insertion into the bone Bone erosions. Often associated with psoriatic nails MHC class 1 antigens, RA is MHC II antigens Incidence 5–8% rare before age 20 10% of individuals without any visible psoriasis—but a family history Increase BMI, sarcopenic obesity Alcohol, smoking Low Mediterranean diet score	1. Modified elimination diet 1a. Remove refined sugar and alcohol 1b. Gluten-free diet Observational studies: heavy alcohol consumption is associated with increased severity of psoriasis, in males but not females [69, 140, 141] 1c. Food allergy: gluten intolerance increased serum IgA and IgG antigliadin antibody positive improved psoriasis and antigliadin antibody titers with a gluten-free diet Improvement on a vegan diet [142] Treatments for Psoriasis Presentations A. *Plaque psoriasis* 1. Whey Protein Some clinical evidence shows that taking a specific whey protein extract product (Dermylex, Advitech, Inc.) 5 grams daily for 8 weeks can decrease the severity of psoriasis symptoms when compared with placebo 2. Omega-3 fatty acids: 3.6–14 g/d There is some evidence that administering fish oil intravenously can decrease the severity of symptoms in patients with acute, extended guttate psoriasis and chronic plaque psoriasis. Fish oil seems to be superior to omega-6 fatty acids for this use. However, fish oil taken orally doesn't seem to have a significant effect on psoriasis despite promising preliminary research But when administered in combination with suberythemal ultraviolet B (UVB) therapy, oral fish oil therapy seems to decrease the total body surface area of psoriasis compared to placebo Preliminary evidence suggests drinking saffron tea daily, along with a specific diet rich in fruits and vegetables, may reduce the severity of psoriasis 3. Topical treatment Vitamin D analogues Applying vitamin D in the form of calcitriol or other vitamin D analogues such as calcipotriene, maxacalcitol, and paricalcitol topically effectively treats plaque-type psoriasis in some patients, including those with chronic plaque psoriasis [143] B. *Psoriatic arthritis* [144, 145] 1. Zinc Marked improvement in arthritis, biomarkers, pain scores after 12–24 weeks of 125–600 mg of zinc sulfate in divided doses. Copper levels significantly dropped 2. Inositol—6 g/day for lithium-induced psoriasis 3. Vitamin D: 1,25 dihydroxycholecalciferol [146]. 85 patients who received oral calcitriol, 88.0% had some improvement in their disease; 26.5, 36.2, and 25.3% had complete, moderate, and slight improvement in their disease, respectively. The mean baseline psoriasis area severity index score (PASI) of 18.4 ± 1.0 was reduced to 9.7 ± 0.8 and 7.8 ± 1.3 after 6 and 24 months on oral calcitriol therapy

(continued)

Table 52.4 (continued)

Condition	Practical summary of the condition	Medical nutrition therapy
Scurvy ICD10: E54	Acute or chronic disease caused by deficiency of ascorbic acid Associated symptoms: lassitude, weakness, arthralgia, myalgia Skin lesions petechial, follicular hyperkeratosis, perifollicular hemorrhage especially of the legs Hair de-pigmented, buried in perifollicular hyperkeratotic papules Extensive ecchymosis Splinter hemorrhages Gingivitis, purple, spongy, gums that bleed easily. Loosening teeth Hemarthrosis, epiphyseal separation, scorbutic rosary Vitamin C has a half-life of 10–20 days. However, signs of deficiency generally develop after 1–3 months of inadequate vitamin C intake [147] Labs: normocytic, normochromic anemia Functional test: Hess test	1. Vitamin C. Supplementation with 1 g/day of oral vitamin C for 2 weeks is the usual treatment [147–149] Vitamin C 100–200 mg/day for a longer period [149]
Urticaria ICD10: L50.9	Diet: Food allergy—IgE—intervention. Modified elimination diet after identification of IgE reacting foods Removal of salicylates, benzoates, histamines from the diet if the removal of foods triggering igE is not therapeutic Common urticarial evokers: dairy, chocolate, eggs, fish, yeast, and wheat Removal of food additives: tartrazine (FD&C yellow #5), sodium benzoate, sunset yellow, amaranth, patent blue, indigotin, choline yellow, yellow orange, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), parabens, gum tragacanth and sulfites. Fluoride from toothpaste, municipal water supplies, and vitamin preparations Penicillin in consumed cow's milk Nutraceutical supplementation	[150] 1. Modified elimination diet Modified elimination diet after identification of IgE reacting foods Removal of salicylates, benzoates, histamines from the diet if the removal of foods triggering igE is not therapeutic Common Urticarial evokers: dairy, chocolate, eggs, fish, yeast, and wheat. 2. Removal of food additives: tartrazine (D and C yellow #5), sodium benzoate, sunset yellow, amaranth, patent blue, indigotin, choline yellow, yellow orange, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), parabens, gum tragacanth and sulfites. 3. Fluoride from toothpaste, municipal water supplies, and vitamin preparations 4. Association with antibiotics in the food supply. Pennicillin consumed in cow's milk is associated with urticaria.
Xerosis ICD10:L85.2	Further genetic evaluation: consider FADS polymorphisms FADS1 (FEN1 rs174537G > T), FADS2 (rs174575, rs2727270), and FADS3 (rs1000778). Over time rs174537T had lower arachidonic, AA/linoleic acid and higher IL-6 levels than rs174537GG, and higher oxidized LDL, lower EPA, and oxidative stress markers. The higher the arachidonic acid, the greater the urinary F2 isoprostanes, oxidized LDL and IL6. Serum and urine markers of inflammation. $N = 122$. No intervention studies. FADS SNP may play a role in incidence of xerosis	1. Nutraceutical supplementation [151–154] 1a. Flax seed oil 2.2 grams orally decreased sensitivity, total evaporative water loss, skin roughness and scaling, while smoothness and hydration increased. Water loss decreased by 10% 2.2 g fatty acids with flaxseed (alpha-linolenic acid/alpha-linoleic acid) and borage oil (alpha-linoleic acid/gamma-linolenic acid) had similar effects with the flaxseed oil group with less TEWL by 12 weeks 1b. Topical: Twice a day mineral oil or coconut oil with significant improvement in total evaporative water loss and skin pH [155]

With the increasing temporal length of EFA deficiency, there is gradual skin depigmentation and alopecia (telogen effluvium). In younger patients, there is delayed healing, capillary fragility, and a gradual diminishment of hepatic, renal, and neurologic function. Deficiencies or imbalances in free unsaturated fatty acids are also involved in psoriasis and acne. Deficiency of linoleic acid and 18-carbon polyunsaturated fatty acid results in scaly skin disorder and excessive epidermal water loss [10, 11]. In psoriasis, omega-6 arachidonic acid ratio to omega-3 EFA are up to 22 times higher than in non-affected skin [10, 11].

In other conditions, omega-6 arachidonic acid to omega-3 ratios are elevated with an inflammatory presentation most often characterized as atopic dermatitis. Atopic dermatitis is

a complex chronic inflammatory disease with altered lipid composition in the stratum corneum. This altered composition leads to decreased levels of filaggrin and excessive or lessened amounts of proteases leading to respective thinner or thicker stratum corneum. With deficiency, there is associated increased water loss and poor barrier function.

When considering atopic dermatitis, you have to consider essential fatty acid metabolism and the role of skin ceramides in skin changes [161, 162]. There appears to be a hydrocarbon chain length deficiency in the ceramides and alterations in the free fatty acid fraction of the stratum corneum lipids in patients with atopic dermatitis. Also, ceramide species greater than 50 carbon atoms in length are expressed at a much lower level than in normal skin, which correlates with higher total evaporated water loss [161]. In addition, there is altered expression of delta 5 and delta 6 desaturases, which result in deficiencies in downstream metabolites of linoleic acid [161]. Gamma-linolenic acid, safflower oil as one type, is useful in mild atopic conditions with improved function.

52.5.3 Fat-Soluble Vitamins

Vitamin A deficiency leads to ichthyosis-like skin changes with generalized fine scaling and a thickening of the stratum corneum (phrynoderma is an alternative name) [163]. The pronounced hyperkeratosis of the follicular openings is associated with effluvium and fragility of hair. There is associated impaired night vision, inability for rhodopsin reconstitution in response to bright light. The conjunctival epithelium becomes metaplastic and thickened with keratoconjunctivitis sicca (Bitot's macules) which progresses to keratomalacia with scarring and blindness [22, 163]. The constellation of vitamin A deficiency includes increased epidermal neoplasms, extracutaneous growth failure, mental retardation, asthma, and immune dysfunction. Plasma retinol levels are diagnostic.

Beta-carotene is converted to vitamin A in the intestine by the enzyme beta-carotene-15,15′ monooxygenase (BCMO1) to support vision, reproduction, immune function, and cell differentiation in many tissues, including the skin. Beta-carotene monooxygenase single nucleotide polymorphisms (SNPs), BCMO1 and BCMO2, are associated with decreased availability in conversion of beta-carotene to retinol. There is also considerable variability in the activity of BCMO1. There are five single nucleotide polymorphisms (SNPs) involved in the enzymatic conversion of beta-carotene to retinol [164]. Up to 71% of the people have at least a 50% reduction in their ability to convert beta-carotene to retinol and therefore may require supportive therapy [88].

Vitamin D, as a vitamin and a hormone, has a cascade of bioactive molecules that emanate from the skin [165]. Vitamin D deficiency has only recently been associated with skin signs or symptoms, including increased inflammation, higher associations with basal, squamous cell, and melanoma cancers [166], and increased pain and sensitivity or hyperesthetic pain response to lesions of the skin [167].

Vitamin D inhibits the activation and induces the generation of regulatory T cells. It promotes tolerance and inhibits immunity after stimulation with specific antigens. It promotes the migration of T cells from the vessels of the dermis to the epidermis. Vitamin D suppresses the expression of Class 2 MHC molecules and stimulates the production of IL-10. In the keratinocyte, it is a major regulator of cathelicidins and defensins as noted above [167]. Adequacy of vitamin D is imperative for normal cell immunity [167]. Therapeutically, it is used to treat morphea and psoriasis [146, 167]. With greater understanding of vitamin D single nucleotide polymorphisms, it is shown that the Taq1 SNP is associated with increased solar keratosis, BSM SNP with increased squamous cell cancers, and the Fok-1 Snps with increased risk of malignant melanoma, while the BSML SNP is associated with a decreased risk of malignant melanoma [121, 126, 168, 169].

52.5.4 Water-Soluble Vitamins

Thiamin is involved in carbohydrate metabolism, and a deficiency of thiamine gives rise to the classic deficiency disorder, beriberi. Moreover, thiamin deficiency is seen in patients who have had gastric bypass surgery, GI disease, alcoholism, pregnancy and lactation, diabetes mellitus, and a diet restricted to polished rice. In fact, up to 29% of patients seeking bariatric surgery for obesity are deficient at presentation [170]. Many of these patients have acanthosis nigricans, stasis dermatitis, and insulin resistance with xerosis. The obese patient has a greater incidence of thiamin insufficiency, especially when consuming a higher-carbohydrate diet [170]. It becomes a cycle of thiamine inadequacy and energy insufficiency, especially when there is a glucose-induced downregulation of thiamine transporters in the kidney. The thiamin transporters in the kidney are found in the proximal tubular epithelium (THTR-1, THTR-2) and are downregulated by 37%, which produces thiamine insufficiency in diabetes [171]. The mucocutaneous changes including edema and glossitis with glossodynia. There is associated peripheral neuropathy, confabulation (Korsakoff syndrome), and encephalopathy (Wernicke's encephalopathy). Low excretion levels of urinary aneurin are diagnostic.

As an organ, the skin uses a lot of energy. Conditions of increased turnover, such as psoriasis and atopic dermatitis, only increase its energy use. Thiamin is critical in energy production. Supplementing with benfotiamine (fat-soluble thiamin) has been associated with blocking three pathways which perpetuate tissue damage in type 2 diabetes [172]. Benfotiamine treatment leads to an increased intracellular thiamine diphosphate level, which is a critical cofactor for transketolase. Transketolase directs the advanced glycation end products (AGE) and lipoxidation end products substrates to the pentose phosphate pathway. Therefore, benfotiamine is important for reducing tissue AGE and has been shown to decrease hemoglobin A1c levels [173].

Riboflavin has impaired absorption in many settings. Diets poor in riboflavin, primary deficiencies, and diminished intestinal transport are not the only cause of inadequate riboflavin. Endocrine abnormalities (aldosterone and thyroid insufficiency), specific medications used in treatments of acne (tetracycline antibiotics) and depression (tricyclic antidepressants), other medications (galactoflavin, phenothiazines), and alcohol abuse interfere with the utilization of riboflavin [174]. Riboflavin deficiency can lead to seborrheic dermatitis scaling on the face (nasolabial folds), behind the ears, in the eyebrows, and on the scalp as well as in the genitocrural regions. There is often cheilitis, perleche, pallor, and atrophy of the tongue. Ophthalmologic blepharitis, conjunctivitis, and corneal vascularization are often seen. Riboflavin is a cofactor of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), which is involved in redox reactions. Laboratory testing in riboflavin deficiency include evaluating normochromic anemia and decreased RBC glutathione reductase activity. To correct deficiency, riboflavin can be dosed at 3–10 mg by mouth or 2 mg IV daily and is adequate for reversal of deficiency [174].

Niacin (nicotinic acid) and niacinamide (nicotinamide) are converted to nicotinamide adenine dinucleotide (NAD+), which has many metabolic roles. It is an essential cofactor for ATP production. When added to therapeutic regimens, niacinamide is a cofactor in glycosylceramide and sphingomyelin synthesis and increases the biosynthesis of ceramides and stratum corneum lipids to improve the epidermal permeability barrier. Altered barrier function from inadequate niacinamide allows the "outside to get in" and plays a significant role in the pathogenesis of atopic dermatitis and acne [175].

Niacin aids in the treatment of acne, atopic dermatitis, and psoriasis [175]. It is also therapeutic in autoimmune blistering conditions, such as pemphigus [112, 113], and in pellagra dermatitis clinically seen in undernourished populations where food access is challenged. Nutrient absorption is diminished, or there are increased requirements in many patient groups. There is a greater metabolic requirement in the chronically ill, alcoholic, those with psychiatric disorders, or those with increased exposure to environmental toxins [176]. In the metabolic disorder, Hartnup disease, or pellagra-like dermatosis, photosensitive rashes are seen. Photosensitive skin eruptions are seen in frank niacin or niacinamide deficiency.

It is felt that patients with skin cancers have a greater susceptibility to the immunosuppressive effects of sunlight [112, 113, 177]. Niacin acts as a glycolytic blockade induced by UV radiation and has been shown to be a skin-cancer chemopreventive in a randomized double-blind placebo-controlled phase 3 trial [113]. In 12 months, the rate of new nonmelanoma skin cancers was 23% lower than the placebo group. Similarly, new squamous cell carcinomas, basal cell cancers, and actinic keratosis were, respectively, 30%, 20%, and 13% lower than controls.

Because of the role of niacin in so many metabolic processes, there is often clinical association between neurologic and dermatologic conditions that can be treated with niacin or niacinamide. For example, although dermatologic findings in autistic spectrum children are multifactorial, niacinamide is a key nutrient in improving mitochondrial dysfunction with associated beneficial improvements in skin disorders in this population [178]. Autism is also associated with inflammation and increased TNF alpha in lymphocytes. When niacinamide and other B vitamins are used therapeutically for mitochondrial resuscitation, inflammation and increased TNF alpha are positively impacted [178]. Niacinamide improvement in rash-associated mast cell activation of autistic children is also well documented [179]. Therefore, it is not surprising that niacin treatment, while benefiting many of the neurologic conditions, also has a positive impact in skin conditions. Tobin cleverly states "the skin is our brain on the outside" [4]. Niacinamide and niacin are safe at higher doses [180].

Pyridoxine is a cofactor for the enzymes, transaminases, synthetases, and hydroxylases important for amino acid metabolism [22, 181]. Pyridoxine also plays a role as the cofactor for enzymes involved in the essential fatty acids, linoleic and arachidonic acid metabolism. Deficiency of pyridoxine is associated with seborrheic dermatitis-like skin changes in the periorificial distribution affecting the eyes, nose, mouth, and the cheilitis of the lips and the glossitis of the tongue. Knowing of the cofactor roles in amino acid and essential fatty acid metabolism, this is no surprise. Checking pyridoxine levels helps in the diagnosis when deficiency is suspected [22].

Pantothenic acid is a component of coenzyme A, which is involved in the Krebs cycle, fatty acid oxidation and synthesis, and synthesis of heme, cholesterol, and acetylcholine. It also plays a role in amino acid catabolism [182]. Deficiency is associated with hair loss, cheilitis, abnormal gait, ulcerations of the colon, fatty infiltrations of the liver, and altered mineral metabolism. Painful burning sensation in the feet is also reported to improve with pantothenic acid supplementation [182]. Glossitis and cheilosis that were unresponsive to other B vitamin supplementations are reported to respond to calcium pantothenate [183]. Pantothenic acid has been used in the treatment of acne and lupus when deficiency is identified [184, 185].

Biotin (vitamin H) is a cofactor in carboxylases, including biotinidase and holocarboxylase [22]. Urinary organic acid accumulation is the consequence of multiple carboxylase deficiency resulting from failure to recycle biotin. Biotin deficiency may be genetic or acquired with accompanying diagnosis by hyperammonemia and organic aciduria. Biotin is beneficial in the treatment of exfoliative dermatitis of acral skin, cheilitis, and periorificial dermatitis. In deficient newborns, erythroderma and alopecia are identified. Enteritis may also be associated with biotin deficiency states. Extracutaneous symptoms include metabolic acidosis, developmental delay, hearing loss, paresthesias, seizures, and conjunctivitis. Also known to occur in biotin deficiency states is impaired cellular immunity with a predisposition for infections, including *Candida*.

Folate deficiency is associated with mucocutaneous changes similar to B12 deficiency with hyperpigmentation of skin, glossitis, cheilitis, and mucosal erosions [22]. Diagnosis of deficiency may be made with either serum folate levels or formiminoglutamic acid (FIGLU), which is an intermediate metabolite in L-histidine catabolism in the conversion of L-histidine to L-glutamic acid. It may be an indicator of vitamin B12-folic acid deficiency, or liver disease. Folate by itself is vital to the skin, supporting many biochemical processes that impact the maintenance and function of healthy skin [186]. Medical conditions negatively impacting small intestine folate hydrolase essential for normal nutrient balance include alcoholism, celiac disease, and Crohn's disease [186] (Fig. 52.1).

Folates are photosensitive compounds. They have a role in regulating melanin production through the synthesis of guanosine 5′-triphosphate, a necessary cofactor in the synthesis of tyrosinase inhibitor tetrahydrobiopterin [188]. An increased number of cancers have been linked to folate deficiencies, including those of the colon, breast, pancreas, stomach, cervix, bronchus, blood, and skin [186]. The mechanism of cancer formation is thought to be related to DNA synthesis and repair for which adequate folate is essential. Atrophy of oropharyngeal mucous membrane is an early marker of

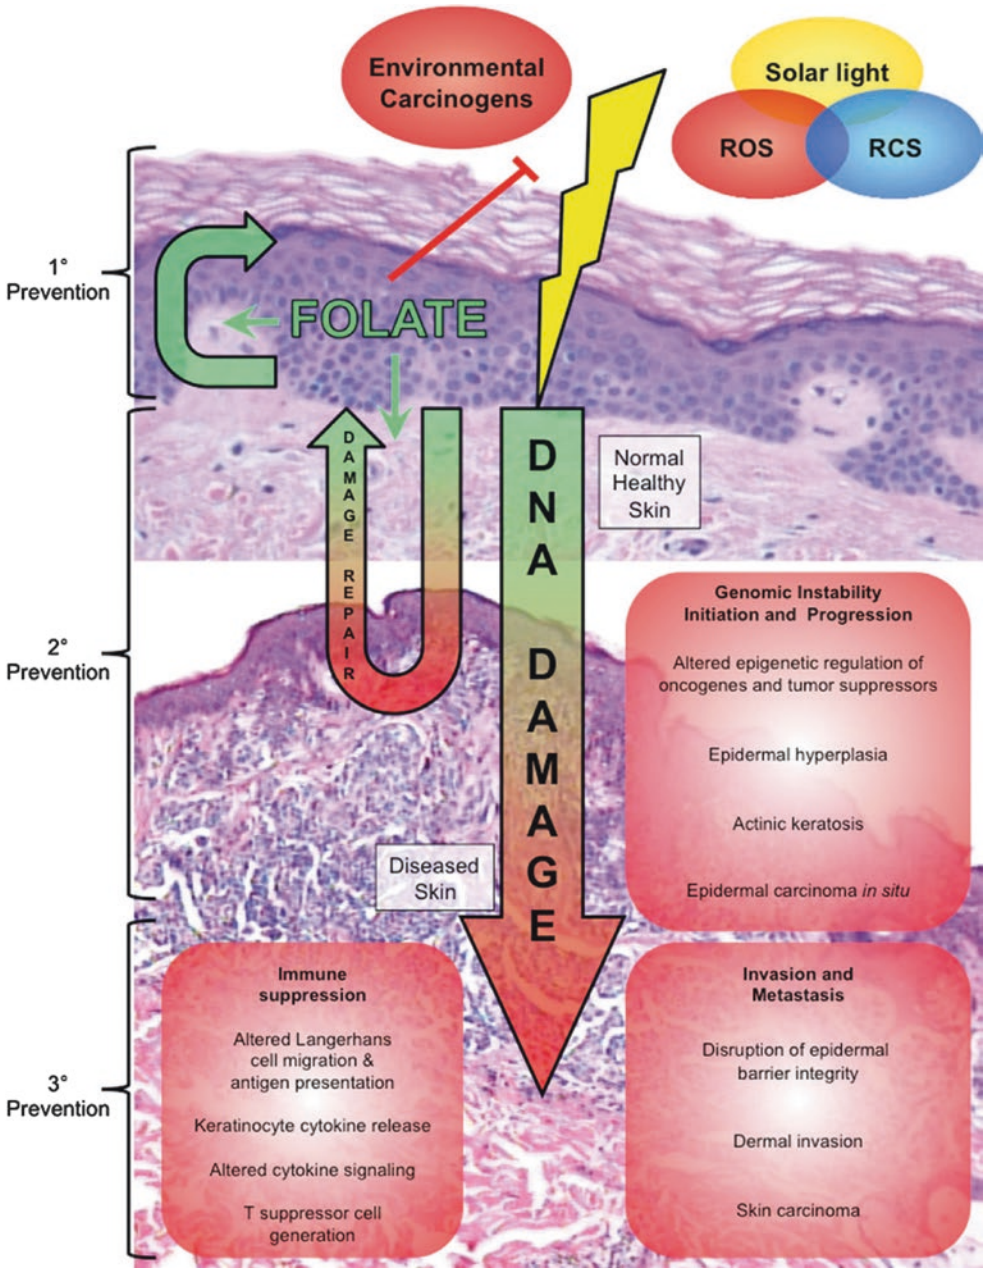

Fig. 52.1 Proposed roles for optimum folate nutrition in the maintenance of skin health and the prevention of skin cancer. (Adapted from Neyestani [187]. With permission from Springer Nature)

folate deficiency [189]. Supplementation is beneficial and generally safe.

B12 deficiency can lead to atrophic glossitis, angular cheilitis, mucositis, and symmetric acral (dorsal fingers and toes) and flexural hyperpigmentation. Poliosis, vitiligo, and alopecia areata may also occur. The differential for these symptoms includes Addison's disease [22]. Many commonly used medications decrease the absorption and bioavailability or increase the requirements of B12. All of the noted signs of B12 insufficiency are more frequent when there are single nucleotide polymorphisms, increasing the baseline requirement of B12 for the patient. Frequent antibiotic use, small intestinal bacterial overgrowth, and dysbiosis should be considered if dermatologic signs of B12 inadequacy are clinically present [20, 22].

Vitamin C deficiency results from general undernutrition, alcoholism, mental illness, or chronic modified elimination diet of foods containing vitamin C. Follicular hyperkeratosis of the extensor surfaces of extremities and perifollicular hemorrhages are frequently identified. Often petechia over mechanical pressure points or under the blood pressure cuff following evaluation is a clue. Urinary tract bleeding or microhematuria without infection can be a subtle sign. Subperiosteal hemorrhages are painful and seen in the affected. Impaired wound healing, bleeding gums, gingivitis, gingival hypertrophy, and loose teeth are frequently seen clinical indicators. The accompanying fatigue, myalgias, and muscle weakness are associated with mitochondrial dysfunction. Other symptoms can include arthralgias, diarrhea, and anemia [29, 190]. Long-standing vitamin C deficiency is associated with diffuse edema, oliguria, anemia, dyspnea, and even neuropathy (see Table 52.4—Scurvy—for details).

Clinically, supplementation is key while supportive dietary intake is added and repletion of deficiency is achieved. Vitamin C is transported into the cell, whether as ascorbic acid through sodium cotransporter or as dehydroascorbic acid via the glucose transporters GLUT1, GLUT2, and GLUT4. There are two sodium-dependent transporters SVCT1 and SVCT2 that move ascorbic acid into epithelial cells [190–193]. If a person has SVCT1 with SVCT2 SNPs, they may have an increased requirement of 200 mg/d vitamin C [191]. Women with an SVCT2 SNP (SLC23A2) have an increased incidence of preterm labor [193].

52.5.5 Minerals

Zinc is an essential component in more than 300 metalloenzymes and more than 2000 transcription factors that regulate lipid, protein, nucleic acid metabolism, and gene transcription [43, 44, 194]. Zinc deficiency is known to result in dermatitis, alopecia, and diarrhea, however only 20% with zinc deficiency present with all three. Deficiency may be hereditary or acquired. Intestinal absorption is dependent on pancreatic function, zinc-binding factors, and albumin transport. About 99% of zinc is intracellular, but zinc storage is notoriously poor. Within a month of inadequate zinc intake, deficiency (zinc < 70 mg/dl) is seen [43]. Zinc deficiency is common in conditions of epidermal barrier dysfunction, activation of the innate immune system, altered cutaneous microflora, and follicular fusiform bacterial overgrowth. Long-standing zinc deficiency is associated with diarrhea, poor wound healing, growth retardation, anorexia, anemia, hypogonadism, altered mental status, and infertility. Whether the cause of deficiency is related to poor intestinal absorption, increased excretion, increased tissue catabolism, or altered transport of zinc between tissues, organs, or physiologic compartments, zinc adequacy can be affected by many conditions (See Table 52.5).

Perioral dermatitis, perleche, migrates to involve the entire face, scalp, acral sites, and diaper area [194]. The oral mucosa shows ulcerations and glossitis. Palmar erythema with annular or collarette-like scaling is present. Alopecia is associated with the dermatitis and hair shedding, also known as telogen effluvium. Telogen effluvium without the skin changes is not as frequently associated with zinc deficiency. Zinc is also associated with seborrheic dermatitis. The constellation of cutaneous infections, weeping dermatitis, delayed wound healing, secondary infections, alopecia, nail defects paronychia, *Candida* dermatitis, blepharitis, conjunctivitis, and onychodystrophy T cell impaired immunodeficiency are related to zinc deficiency. Besides acquired or genetic zinc deficiency, periorificial dermatitis can be caused by reduced protein levels, essential fatty acid deficiency, riboflavin, pyridoxine, and biotin deficiencies but also glucagonoma syndrome, a very rare tumor of the pancreas [195]. Associated non-cutaneous findings include photophobia and night blindness.

Dietary zinc is thought to activate nuclear factor kappa B (NF-kB), expression of proinflammatory cytokines (IL-1b), tumor necrosis factor alpha, and neutrophil infiltration critical for early wound healing. Many foods can block NF-kB-mediated activation of inflammatory cytokines which may play a role in the inoculation of cutaneous immunity [43].

In a recent review, zinc was used therapeutically in dermatologic conditions of infection (leishmaniasis, warts), inflammatory dermatoses (acne vulgaris, rosacea), pigmentary disorders (melasma), and neoplasias (basal cell cancer) [43]. Table 52.5 is a useful starting point for therapeutic considerations.

Iron deficiency is associated with skin pallor, dry scaly skin, perleche, glossitis, and dull-shaggy hair. If the iron deficiency is long-standing, there is telogen effluvium and nail changes, including koilonychias [196]. The laboratory will show microcytic hypochromic anemia, low ferritin and serum iron with changes in the protein-bound transport transferrin, and low intracellular storage ferritin. Subconjunctival pallor continues to be the most predictive sign that anemia is present with a likelihood ratio of over 16. If present, the underlying cause of the physical exam finding and the anemia needs then to be pursued.

Table 52.5 Topical, oral, or injected zinc in therapy for skin conditions

Selected conditions	Dose/vehicle
Infection	
Cutaneous leishmaniasis	Oral: 2.5, 5, 10 mg/kg/day for 45 days of zinc sulfate effective and safe treatment 83–96% cure rates Intralesional: clinical cure with 2% intralesional zinc sulfate comparable to meglumine antimoniate
Warts	Oral: 10 mg/kg/day oral zinc sulfate for 2 months 87% clearance at 2 months Topical: 5–10% zinc sulfate lotion, 20% zinc oxide paste apply three times a day with 50% clearance
Herpes genitalis	Topical: 1–4% zinc sulfate for 3 months was effective in treating and preventing recurrences of herpes type 2. More studies showed 4% solution most effective
Dermatophytosis (ringworm)	Topical: 20% zinc undecylenate powder twice daily for 4 weeks showed marked clinical improvement in tinea pedis-negative tinea culture in 80% by 4 weeks
Bromhidrosis (usually from *Corynebacterium* sp.)	Topical: 15% zinc sulfate solution manages bromhidrosis and foot malodor apply once daily for 2 weeks, then three times a week for 2 weeks. 70% cure rate
Pityriasis versicolor	Topical 15% zinc sulfate solution applied once daily for 3 weeks effective in treatment
Hidradenitis suppurativa	Oral: zinc gluconate 90 mg a day showed clinical improvement
Inflammatory	
Acne vulgaris	Topical: 5% zinc sulfate in mild-to-moderate acne, treating daily Oral: Zinc sulfate and zinc gluconate useful in moderate and severe acne- equal efficacy to antibiotics minocycline and oxytetracycline
Rosacea	Oral: Zinc sulfate 100 mg three times a day effective after 3 months of therapy. But the results in other studies are mixed
Psoriasis	Topical 0.25% zinc pyrithione applied twice a day to psoriatic plaques
Psoriatic arthritis	Oral: zinc sulfate 125–200 mg BID
Pigmentary	
Melasma	Topical: 10% zinc sulfate solution applied twice a month for 3 months reduces the MASI (melasma area severity index) score
Vitiligo	Oral: zinc sulfate shows moderate efficacy when given as an adjuvant with topical steroids
Neoplasia	
Basal cell cancer	Intralesional 2% zinc gluconate efficacious in treating basal cell carcinoma
Xeroderma pigmentosum	Topical: 20% zinc sulfate solution twice daily cleared solar keratosis and small malignancies
Androgenic alopecia	Topical: zinc pyrithione 1% solution considerable hair grows, though less effective than 5% minoxidil solution
Alopecia areata	Oral: Zinc sulfate 5 mg/kg/day divided dose 62% patients with hair growth

Based on data from Ref. [43]

Copper in the serum is 80–90% associated with ceruloplasmin and albumin [22]. Heritable copper deficiency results in Menkes syndrome, kinky hair syndrome, or steely hair syndrome and is due to X-chromosomal recessive mutation in copper (2+)-transporting ATPase (ATP7A). Features include saggy and hypopigmented skin; follicular hyperkeratosis; sparse, hypopigmented, and brittle hair (pili torti, monilethrix); and occasionally formation of trichorrhexis nodosa, nodes along the hair shaft that contribute to hair breakage. Frequently the patients lack eyebrows and eyelashes. On examination, the skin has tortuous elongated arteries due to immature elastin fibers. There are extracutaneous and neurodegenerative changes speaking to the scope of copper's role in normal metabolic function. Characteristically the affected newborns are normal at birth and over the first few months, followed by gradual hypotonia, seizures, and failure to thrive [22].

Copper is a critical component of lysyl oxidase, a copper amine oxidase that initiates covalent cross-linkage formation in elastin and collagen and is important in melanin synthesis. When deficient, there is faulty connective tissue formation. Lack of copper also impairs the function of the enzymes of catecholamine synthesis and metabolism. The biomarker changes include an increase in the dihydroxyphenylacetic acid to dihydroxyphenylglycol ratio. Copper supplementation should be undertaken with the need to balance with zinc and serum levels should be followed for both.

Selenium deficiency leads to effluvium and a whitish discoloration of nails. Cardiomyopathy, muscle pain, and weakness are seen in extreme cases [22]. Selenium is essential for glutathione peroxidase. A low activity of the enzyme and low plasma selenium are diagnostic of selenium deficiency. There is a relative narrow therapeutic intervention for selenium, and an intake of greater than 600 mcg/day can lead to toxicity.

52.5.6 Nutrition Excesses and Dermatologic Conditions

Hartnup disease and phenylketonuria are genetic amino acid metabolic conditions that respond to niacinamide and restriction of phenylalanine, respectively. The excess amino acids associated with inborn and acquired conditions have been identified and presented in Table 52.6. The more common mineral and vitamin excesses seen in the primary care clinic and on the hospital wards are outlined in Tables 52.7 and 52.8.

Table 52.6 Amino acids associated with inborn and acquired conditions

Amino acids	Skin
Hartnup disease	Autosomal recessive disorder of intestinal and renal amino acid transport. Sunburn-like photosensitive eruption similar to pellagra, sometimes blistering, onset less than 13 years of age. Post inflammatory hypopigmentation. Intermittent ataxia, nystagmus, tremor Treat with a high-protein diet, oral nicotinamide supplementation Nicotinamide is photoprotective (up to 500 mg twice a day)
Phenylketonuria (PKU)	Autosomal recessive abnormality. Lack of downstream metabolic product tyrosine with the accumulation of phenylalanine. Paucity of tyrosine results in diffuse hypopigmentation of the skin and hair (blond-haired and blue-eyed). Eczematous and early-onset atopic dermatitis, scleroderma-like skin lesions. Phenylalanine accumulation is toxic to the brain, mental retardation, developmental delay, microcephaly, seizures, behavioral psychiatric problems. Urinary phenylalanine increased. Restriction of phenylalanine in diet
Tyrosinemia	Rare disorder of tyrosine metabolism. Tyrosinemia type II (Richner-Hanhart syndrome, oculocutaneous tyrosinemia), photophobia, corneal ulcerations onset during the first year of life), painful focal palmoplantar keratoderma occur in childhood and may be delayed until adolescence. Restrict diet in tyrosine and phenylalanine will clear the keratitis and keratoderma and improve the cognitive impairment
Argininosuccinic aciduria	Fragile hair (trichorrhexis nodosa); neurologic symptoms in the first days of life
Alkaptonuria	Body cannot process amino acids phenylalanine and tyrosine; autosomal recessive defect. Grayish blue discolorations of the ears, axilla, perioral area (ochronosis), arthritis, darkening of the urine
Eosinophilia-myalgia syndrome	Scleroderma-like disorder, woody induration of distal extremities, in individuals consuming large quantities of L tryptophan

Based on data from Ref. [22]

Table 52.7 Skin findings of excess mineral/element consumption, absorption, or decreased excretion

Mineral/element	Cutaneous and systemic findings
Zinc	Vomiting, nausea, upper GI hemorrhage, vertigo, neutropenia; mucosal irritation of the gastric mucosa secondary high intake of zinc-associated copper deficiency (plum); cutaneous infections, weeping dermatitis, delayed wound healing, secondary infections, alopecia, nail defects paronychia, *Candida* dermatitis, blepharitis, conjunctivitis
Iron	Primary hemochromatosis: deposited in the liver, heart, and skin. Diffuse bronze color or hyperpigmentation of the skin in sun-exposed areas. Melanogenesis, ichthyosis-like scaling, alopecia, koilonychia. Diabetes, cardiomyopathy, liver cirrhosis. Cutaneous palmar erythema, telangiectasia
Lead/mercury	Blue-gray discolorations of the skin and gums
Silver/argyrosis	Gray and bluing of skin; grayish color with predilection of sun-exposed areas, sclera, mucous membranes, fingernails (toenails not affected) silver deposits on dark-field microscopy
Aluminum	Porphyria-like bullous changes
Arsenic	Bowen's disease, basal cell carcinoma, Mees' lines, lung cancer, vomiting, diarrhea, hepatic and renal damage, peripheral neuropathy
Chrysiasis	Deposition of gold in the skin. Diffuse bluish gray. The mucous membranes are not affected, unlike in argyrosis. Maculopapular vesiculobullous and urticarial eruptions occasionally with erythema multiforme-like rash

Based on data from Ref. [22]

52.6 Dietary Interventions

52.6.1 Mediterranean Diet

The Mediterranean diet focuses on reduced intake of meats and processed sugar-containing carbohydrates and incorporating moderate proportions of poultry, eggs, cheese, and yogurt on a weekly basis. The diet emphasizes eating fish or seafood at least twice a week. On a daily basis with each meal, there is the inclusion of vegetables, fruits, whole grains, olive oil, beans, nuts, legumes, seeds, herbs, and spices. Adults may include low-to-moderate red wine consumption and plenty of water daily. There is an emphasis on physical activity and enjoying meals with others [198].

Of note, there is variability in the food consumption patterns seen between the 16 Mediterranean countries. For example, Italy has an average of 30% total lipid intake, while Greece has 40% lipid intake, with the predominant fats for both coun-

Table 52.8 Hypervitaminosis skin findings

Vitamin	Skin and symptomatic findings
A	Pruritus, generalized scaling, dry mucous membranes, alopecia (telogen effluvium), cephalea, nausea, hyperostosis Increased transaminases and lipids Hypercarotenemia- Orange- yellow skin tint with sparing of the sclera, eyelids, ears, and axillary folds. The skin color of the palms and soles depends on the thickness of the epithelium. Common in children. Also seen in vegetarians, those with renal disease, diabetes mellitus, thyroid disease where there is either primary or secondary decreased ability to convert beta-carotene to vitamin A. Hypervitaminosis A is seen in Inuit populations
C	Vitamin C interferes with vitamin B12 metabolism with eventual symptoms of vitamin B12 deficiency especially the darkening of skin
D	Hypercalcemia, vomiting, diarrhea, anorexia, cephalea, calcinosis cutis
E	Gastrointestinal upset, cephalea, icterus in premature neonates

Based on data from Refs. [22, 108, 197]

tries being monounsaturated fats. The bioactive molecules of the Mediterranean diet include high levels of vitamin C, vitamin E, beta-carotene, selenium, flavonoids, and phenolic compounds. When considering all of the skin conditions aided by increasing essential fatty acids, bioactive components in vegetables, herbs, and spices, an initial consideration for dietary intervention should be a trial of the Mediterranean diet adjusted for the condition. For example, in patients with metabolic syndrome who demonstrate an acanthosis nigricans, psoriasis, or xerosis, shifting to a Mediterranean diet improves the markers of metabolic syndrome [199].

The Mediterranean diet is high in multiple B vitamins, most notably high levels of folate. In addition, there is a greater anti-inflammatory/photooxidative fatty acid profile with higher omega-3 and omega-9 poly- and monounsaturated fatty acids. This results in lower intake of proinflammatory omega-6 polyunsaturated fatty acids and lower omega-6/omega-9 and omega 6/omega-3 fatty acid ratios. There are lower exposure levels of prooxidants and carcinogens from iron that is heme derived from red meat, and there are reduced polycyclic aromatic hydrocarbons produced with high-temperature grilling. Instead there is a preference for gently grilled and steamed fish, low fat dairy and poultry, high levels of complex carbohydrates from grains and legumes, and small to moderate amounts of alcohol, primarily from antioxidant-rich wines [198].

The Mediterranean diet is higher in vitamin E than the average American diet, because of the inclusion of high vitamin E foods. Vitamin E decreases prostaglandin E2 production, and, as a result, T-cell proliferation and function may be enhanced. Vitamin E is a common plant-based, fat-soluble antioxidant and is found in combination with water-soluble antioxidants like vitamin C; mineral antioxidants including zinc, selenium, and others; and other fat-soluble antioxidants such as alpha-lipoic acid [198]. These compounds join the group of phytonutrients in the carotenoid family that are key to modulating immune-heightened inflammation. More than 600 different carotenoids exist in nature, and, through the Mediterranean diet, it is common to consume 40 types of carotenoids, especially when ingesting vegetables. The human GI tract can efficiently absorb 12 carotenoids, including alpha- and beta-carotene, lutein, zeaxanthin, beta-cryptoxanthin and lycopene [198].

The Mediterranean diet is recommended for many of the conditions in Table 52.4 as a primary intervention and medical nutrition therapy. Further modifying gluten and dairy intake acts to modulate treatments of acne, psoriasis, and atopic dermatitis. Rich helpings of bioactives found in the Mediterranean diet, implemented over months to years, aid in the overall balance of the essential fatty acids, carotenoids, vitamin A, and minerals including zinc, magnesium, calcium, and chromium. Targeted additions of specific essential fats, minerals, vitamins, and phytonutrient spices when indicated are also useful (Table 52.4).

By identifying the role of food, spices, herbs, and food-borne bioactive compounds provided by the Mediterranean diet, there has been rapid expansion of the understanding of mechanisms with refinement of applications for health promotion and disease intervention. For example, curcumin, berberine, and resveratrol are on a long list of nutraceuticals that, when incorporated into the treatment regimen, help shift balance from disease to health [27]. With increased research of these and similar dietary compounds influencing microRNAs, associated mechanisms of aging, cancer development, tissue restoration, and stem cell activity are coming to light. The epigenetic diet, which incorporates foods high in curcumin, resveratrol, genistein, garlic, selenium, and folate, is able to modulate methylation, modify histones, and promote overall health [200]. What is old is new again, and the incorporation of the right food, in the right setting, for the desired effect will become more mainstream. Let food be thy medicine, and medicine thy food will be realized in the Western and American health system.

52.6.2 Modified Elimination Diet

The modified elimination diet has been used by practitioners since the days of early Egyptian, Chinese, and Greek healers. There are skin conditions in which dietary intake is causative and where removal of dietary components is therapeutic (Table 52.4). Identifying foods, spices, or herbs associated with development of specific skin conditions can be difficult. In the clinical setting, clinicians trying to distinguish food allergy and immune food sensitivity by diet diary are often left to random elimination trials, since there is no perfect test for food allergy and sensitivity [201]. However, the use of modified elimination diet without prior testing, or in

response to laboratory immune globulin testing, or skin testing is well-established.

Modified elimination diet, with empiric removal of the six leading food-associated triggers for eosinophilic mucosal response without laboratory testing, is established as a therapeutic intervention [202]. Even removal of one family of foods can remove the trigger for the uncomfortable symptom of scar pruritus [203]. Changing to an oligoantigenic and histamine-free diet has been used to treat chronic idiopathic urticaria successfully and shows decrease in associated histamine levels [204]. In treating eczema and atopic dermatitis with elimination diets, 51% showed a positive response with subsequent food challenges used for verification of reaction. Food allergy prevalence was 70.8% (85/120) in the elevated eosinophil group and 34.7% (50/144) in the normal blood eosinophil group [205]. The response to an elimination diet may be fairly rapid. In one open-label trial of a modified elimination diet during which milk and milk products, nuts and nut-containing foods, egg and egg-containing foods, seafish and prawns, eggplant, and soybeans were removed, there was a significant lowering of all parameters of disease activity after 3 weeks ($P < 0.001$) for SCORAD, surface area, and severity of itching [206].

52.6.3 Modified Elimination Diet in Autoimmunity, IgE Reactions, IgG Hypersensitivity, and Other Immune Reactions

Our understanding of the immune system has evolved, and various bioactive compounds in food have been identified as contributory or causal in all four Gell-Coombs responses, which lead to type I allergic or type 2, 3, or 4 hypersensitivity immunologic skin reactions (please see ▶ Chaps. 19 and 48). It is true that nutrient insufficiency or excess can cause alterations in the immune reactions that have been previously discussed.

The laboratory evaluation using IgE serum testing for individual foodborne antibody reactions can be variable. The skin testing to determine wheal-and-flare reaction can have both false positives and negatives and only identify Gell-Coombs type I reactions. The traditional skin prick tests have marked variability if there is not a wheal-and-flare reaction less than 8 mm in diameter. These skin prick tests are influenced by many over-the-counter antihistamines, anti-inflammatory, and prescription medications including corticosteroids and leukotriene inhibitors leading to false-negative readings. Type 3 reactions, modulated mainly by IgG immunoglobulins, do not classically have the same wheal-and-flare reactions. Type 4 hypersensitivity testing is frequently determined by patch testing.

There are a variety of autoimmune responses and hypersensitivity reactions to dietary antigens, which respond to modification of the diet and removal of the known triggering antigens. The modified elimination diet has been used therapeutically to diminish immune mediated skin disorders by downregulating the antibody or T-cell response burden. Examples of conditions responsive to modified elimination diet include dermatitis herpetiformis, pemphigus, atopic dermatitis, contact dermatitis, contact urticaria, protein contact dermatitis, and photoallergic contact dermatitis [129].

In the two most common bullous disorders of the skin that are associated with diet-triggered autoimmune diseases, dermatitis herpetiformis and pemphigus, and the modified elimination diet is an essential part of the therapeutic intervention [129]. The foods that trigger dermatitis herpetiformis and pemphigus are listed in ◘ Tables 52.9 and 52.10 [129]. Foods recommended in the modified elimination diet of dermatitis herpetiformis and pemphigus are listed in ◘ Tables 52.9 and 52.10 [129]. Atopic dermatitis has responded to a modified elimination diet by removing multiple nut varieties and other foods as shown in ◘ Table 52.11.

Certain foods coming in contact with the mucosa of the mouth, esophagus, and intestine can cause degranulation of mucosal mast cells leading to urticarial reactions, just as the same foods can cause degranulation of dermal mast cells resulting in contact urticaria of the skin. ◘ Table 52.12 lists

◘ **Table 52.9** Foods recommended for elimination diet

Condition	Avoidance
Dermatitis herpetiformis	Wheat, barley, buckwheat, rye, oat Cross reactivity of alpha gliadin and different foods Gliadin, casein, casomorphin, milk chocolate, oats, brewer's yeast, instant coffee, millet, corn, rice (Vojdani Tarish)

Based on data from Ref. 129]

◘ **Table 52.10** Foods recommended for elimination diet

Pemphigus	Fruit: monica Vegetable: garlic, leek, onion, radish, red pepper Spice/herb: black pepper, coriander, cumin seeds, horseradish, mustard, red chilies, tea Fat: evening primrose oil (gamma-linolenic acid), monounsaturated (olive oil), short-chain fatty acids (butter, ghee)

Based on data from Ref. [129]

◘ **Table 52.11** Foods recommended for elimination diet

Condition	Avoidance
Atopic dermatitis	Almonds, carob, hazelnuts, peanuts, cow's milk, crustacean, eggs, maize, wheat

Based on data from Ref. [129]

Table 52.12 Foods associated with contact urticaria of the mucosal membranes and skin

Food category	Food
Fruit	Apple, apricot, banana, coffee, fig, grapefruit, kiwi, lemon, lime, mango, melon, orange, peach, pear, pineapple, plum, pomegranate, strawberry, watermelon
Nut	Almond, brazil, cashew, hazelnut, peanut, sunflower seeds
Vegetable	Artichoke, arugula, asparagus, cabbage, carrot, cauliflower, celery, chives, corn, cucumber, dill, endive, garlic, green pepper, lettuce, maize, mushroom, onion, parsley, parsnip, potato, rutabaga, seaweed, shallots, spinach, tomato, watercress, winged bean
Legume	Beans, soy, tofu
Grains	Amaranth, buckwheat, chicory rice, wheat, wheat bran
Spice/herb	Caraway seed, coriander, curry, dill, fennel, thyme
Animal protein	Beef, egg, fish, lamb, liver, milk, pork, shellfish, turkey, venison

Based on data from Ref. [129]

Table 52.13 Foods associated with contact dermatitis

Food category	Food
Fruit	Ginkgo fruit, lemon, lime, mango, orange
Nut/seed	Cashew nut oil
Vegetable	Artichoke, asparagus, broccoli, brussel sprouts, cabbage, carrots, cauliflower, celery, corn, cucumber, kale, lettuce, leek, mushroom, onion, parsnips, parsley, potato, radish, tomato, turnip
Spice/herb	Anise, basil, bay (laurel) leaf, capsicum, caraway oil, cardamom, cassia, chamomile tea, chicory, cinnamon, cloves, dill, horseradish, garlic, ginger, Jamaican pepper, mace, mustard, nutmeg, paprika, peppermint, rosemary, spearmint, turmeric, vanilla

Based on data from Ref. [129]

foods documented to cause contact urticaria of the mucosal membranes and skin.

Contact dermatitis, diagnosed with patch testing, is seen most commonly with metals, including nickel, tin, and mercury fillings. Occasionally IgG reactions involving metals found in orthodontia materials such as titanium have also been documented. Common causes of contact dermatitis induced by foods are listed in Table 52.13.

Table 52.14 Foods associated with the protein contact dermatitis

Food category	Food
Fruit	Banana, fig, kiwi fruit, lemon, pineapple
Nut	Almond, hazelnut, peanuts
Vegetable	Bean, carrot, cauliflower, celery, cress, cucumber, eggplant, endive, garlic, mushroom, onion, parsley, parsnip, potato, tomato
Legume	Peanuts
Grains	Barley, rye, wheat
Spice/herb	Caraway, curry, dill, garlic, paprika,
Animal product	Blood (pig, cow), gut (pig), mesenteric fat (pig) skin (turkey, chicken)
Animal protein	Cheese, egg yolk, fish, liver (calf, chicken), meat (cow, pig, horse, lamb)

Based on data from Ref. [129]

Protein components of different foods can stimulate immune-mediated delayed-type hypersensitivity. The combination of the immediate type I and delayed Type IV allergic responses have been identified in butchers and slaughterhouse workers. There are four principle groups responsible for the protein contact dermatitis, outlined in Table 52.14, including fruit, nuts, vegetables, legumes, grains, spices, and animal proteins [207]. The foods trigger is a Type IV Gell-Coombs reaction. It is an IgG-associated response, in which antibodies are directed against desmogleins known to be cell-cell adhesion molecules [129].

Ultraviolet A radiation from sunlight can interact with proteins that have accumulated in the skin either following consumption or after direct skin contact. Food exposed to ultraviolet A radiation has the potential to trigger photoallergic contact dermatitis after coming in contact with the skin. Hapten formation between the skin protein and the activated antigen has to occur to incite the delayed hypersensitivity reaction [129].

There are other compounds in foods that are biologically active and known to elicit photosensitive skin reactions. Psoralens are responsible for some frequent reactions and are found in the umbelliferae foods, such as carrot, celery, fennel, parsley, and the parsnip family [129]. Psoralens are compounds that bind with DNA and potentially inhibit DNA synthesis and cell division, especially when used with therapeutic phototherapy. Rutaceae, found in lemon, lime, bitters, bergamot, orange, grapefruit, and fig families, also have photoallergic contact dermatitis history [129]. Garlic exposure has also been linked to such reactions [129]. Avoidance of these foods, once the trigger has been identified, is the therapeutic preventative. Foods associated with skin phenomenon of contact photoallergy can be eliminated when identified to ease the dermatitis (Table 52.15).

52

Table 52.15 Foods associated with photoallergic contact dermatitis

Food category	Food
Fruit	Fig, grapefruit, lemon, orange
Vegetable	Carrot, celery, fennel, parsley, parsnip
Spice/herb	Bergamot

Based on data from Ref. [129]

52.6.4 Dermatologic Findings in Obesity

No discussion is complete without focusing on dietary interventions for obesity and herein as it focuses on skin changes [30]. Skin changes are common in the obese (>30.0 BMI and >23% body fat). One notable change is pseudo-acanthosis nigricans, an indicator of insulin resistance and metabolic syndrome. In acanthosis nigricans, it is important to determine the root cause. The clinician is aided by determining when the condition began. If developed in early life from childhood through puberty, it may be characterized as hereditary type I, which is benign. With weight gain and increased insulin resistance, the disorder may be either benign type 2 or pseudo-acanthosis nigricans type 3. The most common forms of acanthosis nigricans are types 2 and 3, which are associated with systemic metabolic conditions, insulin resistance, diabetes, and obesity. The majority of times (80%) acanthosis nigricans occurs idiopathically or in benign conditions such as endocrinopathies and/or heritable diseases [30].

If acanthosis nigricans develops following treatment with glucocorticoids, steroids, or niacin, it is considered drug-induced type 4. However, if it occurs de novo without any of the other of the hallmarks of types 1 through 4, the consideration of the rarest form, malignant type 5, must be entertained [208]. In malignant acanthosis nigricans, 80% occur in individuals over 40 years of age and 90% of the tumors are intra-abdominal adenocarcinoma, of which 60% are gastric [30, 31].

Any condition which results in excess insulin binding to keratinocytes and skin fibroblast IGF-1 receptors promotes acanthosis nigricans [32]. These IGF-1 receptors are upregulated in proliferative conditions. Epidermal and fibroblast growth factor receptors are both members of the tyrosine kinase receptor family, which are upregulated in the basal membranes of acanthosis-affected tissue. Epiliths or skin tags are often present in the hyperpigmented field of acanthosis nigricans. Hyperinsulinemia is more important than hyperandrogenism in the development of acanthosis nigricans [32]. This disorder improves with management of insulin resistance and weight loss as long as there are no other underlying conditions. See Table 52.4.

Intertriginous dermatitis is an inflammatory condition at skin folds, caused by heat, moisture, friction, infections, and lack of air circulation. Intertriginous eczema may be secondary to overgrowth of bacteria, erythrasma, dermatophyte, and yeast infections. Skin folds of obese patients are subject to increased friction and result in hyperpigmented areas, most commonly the inner thighs and submammary regions and often have associated skin tags (acrochordon). Other skin findings include hyperhidrosis, striae distensae, stasis dermatitis, and leg ulcers.

There is increasing association of exogenous toxicity with metabolic syndrome and obesity, and these toxins or xenobiotics are referred to as obesogens. Environmental obesogens and their effects are becoming well-known and widely characterized [176]. Since metabolism and excretion of obesogens are dependent on vitamin, mineral, and amino acid cofactors, nutritional status of the affected is critical in removing xenobiotics from fat, muscle, and bone stores. Skin changes have been associated with obesogens. For example, characteristic rashes are found on the hands and feet from arsenic toxicity known as arsenic keratosis. Rashes on the hands may also be seen in exposures to DDT, dioxins, organochlorine, and organophosphate pesticides. Careful exposure history needs to be taken and toxicity considered in the differential diagnosis of obesity [176].

52.6.5 Therapeutic Uses of Probiotics and Fermented Food in Skin Disorders

The skin microbiome is unique, as are the biofilms and resident bacteria in all organ systems. The skin microflora is altered in response to the external and internal environment. Skin microflora is influenced by topical pH and helps determine the barrier function of the skin. The immune response to the resident microflora is determined by the balance in the bacteria. The addition of certain species modulates skin allergic reactions, atopic dermatitis, and even skin sensitivity and pain [129, 209].

Certain probiotic strains have been shown to be efficacious in quenching skin allergic reactions. For example, prenatal administration of Lactobacillus rhamnosus GG has been shown to reduce atopic dermatitis in at-risk infants. The addition of the probiotic is felt to increase Th1 immune response by influencing interferon-gamma production [129, 210, 211].

A diet supplemented with *Lactobacillus johnsonii* effects the cutaneous immune system by modulating the production of serum interleukin 10. Interleukin 10 production maintains the Langerhans cells, cells important for skin immunity, and increases protective cell density when exposed to UV light. Specifically, UV radiation's deleterious effect on skin defenses is prevented by *L. johnsonii* [129, 212]. In a randomized

double-blind placebo-controlled trial using 10^{10} CFU of each *Lactobacillus paracasei* and *Bifidobacterium lactis* for 8 weeks, skin sensitivity was decreased. When compared to controls, participants receiving the active probiotic mix were found to have a 50% decrease in skin sensitivity and cutaneous neurosensitivity by day 57 [129].

52.7 Autoimmune or Hypersensitivity Reactions to Food Proteins

52.7.1 Autoimmunity-Triggered Dietary Antigens

This section expands the discussion above. When homology or similarity of dietary proteins compared to the human protein structure is greater than 65%, there is a greater incidence of human protein cross-reactivity to food components [28]. For both pemphigus and dermatitis herpetiformis, there is an autoimmune association with these bullous conditions. In dermatitis herpetiformis, IgA autoantibodies are formed against the gluten protein, type 3 epidermal transglutaminase, which is homologically similar to tissue transglutaminase. The homology is greatly responsible for the cross-antibody reaction in patients with gluten/gliadin enteropathy. With greater understanding of the multitude of proteins homologous to gluten/gliadin, it becomes clear that dietary elimination of gluten/gliadin is therapeutically necessary to treat dermatitis herpetiformis. See ◘ Table 52.9.

There is a triad required to develop a food-related autoimmune condition. Foods contain proteomes, proteins expressed by the particular food. The triad needs, first, increased mucosal permeability and translocation of the food proteomes across the GI tract; second, an individual's genetic predisposition for inflammation or autoimmunity; and, third, the above two coupled with an environmental trigger. With the understanding of the triad, proteomes of different foods have been identified and associated with different autoimmune conditions. For example, there is an association of wheat and milk proteomes with autoimmunity, many of which have manifestations ranging from increased xerosis, pigment changes, hair loss, vascular changes, or bullous rashes. When any of the skin manifestations are identified with autoimmune conditions, a consideration of the role of wheat or milk proteomes can be determined by a modified elimination diet. See ◘ Table 52.3.

There are many acnegenic components in the Western diet (Bowe 2010; Melnik). These are outlined in ◘ Table 52.16. Encouraging a Paleolithic diet as nutrition therapy for acne has been shown to be of benefit. This is detailed in ◘ Table 52.17. The dysbiotic gastrointestinal tract bacteria combined with brain-diet interactions are key in worsening acne vulgaris [58, 59, 213]. Improving gut-associated microflora balance and dietary intake are known to improve acne vulgaris.

◘ **Table 52.16** Acnegenic components of the Western diet

Nutrients	Metabolic and nutrigenomic effects	Diet sources
Hyperglycemic carbohydrates	Postprandial hyperinsulinemia; insulin-mediated hepatic IGF-1 synthesis; reduction of IGFBP3; increased bioavailability of free circulating IGF-1; reduction of SHBG; increased bioavailability of free circulating testosterone; reduced nuclear activity of FoxO1; increased expression of sebocyte SReBP-1c; activation of mTORC1; glucose-mediated microRNA-21 expression	Sugar Sweets Soft drinks Pizza Pasta Wheat bread Wheat Rolls Cornflakes
Milk and dairy products	Postprandial hyperinsulinemia; increased levels of circulating IGF-1; leucine-mediated activation of mTORC1; glutamine-mediated activation of mTORC1; palmitate-mediated activation of mTORC1; milk-/dairy-related microRNA-21-mediated proliferation and inflammation	Whole and skim milk Pasteurized fresh milk Yogurt Ice cream Whey and casein supplements Cheese
Saturated fats	Palmitate-mediated activation of mTORC1; palmitate-driven inflammasome activation	Butter Cream
Trans fats	Possible mTORC1 activation; proinflammatory signaling	Fast food French fries

Based on data from Ref. [213]
Abbreviations: *IGF-1* insulin-like growth factor 1, *IGFBP3* IGF-binding protein 3, *SHBG* sex hormone-binding globulin, *FoxO1* forkhead box O1, *SReBP-1c* sterol response element-binding protein 1c, *mTORC1* mechanistic target of rapamycin complex

52.7.2 Dermatologic Findings in Inflammatory Bowel Disease

When the patient has a chronic medical condition, nutritional requirements can be altered. As highlighted earlier with zinc, influences affecting zinc absorption, transport, and catabolism can lead to altered requirements and are eventually associated with deficiency [22, 156]. See ◘ Table 52.18. In autoimmune-related inflammatory bowel disease (IBD), chronic malabsorption of nutrients increases the incidence of nutrient deficiency-associated dysfunction (◘ Table 52.19) [214] and can manifest in skin lesions (◘ Table 52.20) [244]. Nutrient malabsorption in IBD may lead to skin findings as outlined below. When considering medical nutrition therapy, the diagnosis influences the consideration for repletion of specific nutrients. Common nutrient deficiencies are seen in association with IBD and

Table 52.17 Paleolithic-type diet for acne

Nutrients	Metabolic effects	Sources
Carbohydrates with low-glycemic index	Reduced insulin signaling; reduction of free IGF-1; increase of IGFBP3 and sex hormone binding globulin; increase in nuclear FoxO1; reduction of SReBP-1c; attenuation of mTORC1	Salads Vegetables
ω-3-Fatty acids (docosahexaenoic acid and eicosapentaenoic acid)	Inhibition of mTORC1 Inhibition of SReBP-1c; reduction of proinflammatory eicosanoids (LTB4, PGe2); inhibition of NLRP3 inflammasome activation	Sea fish Omega-3 fatty acid containing oils
Plant products and spices	Inhibition of mTORC1; activation of nuclear FoxO1; inhibition of *P. acnes* biofilm	Green tea (EGCG) Berries (resveratrol) Curcumin

Abbreviations: *IGF-1* insulin-like growth factor 1, *IGFBP-3* IGF binding protein 3, *SHBG* sex hormone binding globulin, *FoxO1* forkhead box O1, *SReBP-1c* sterol response element-binding protein 1c, *mTORC1* mechanistic target of rapamycin complex 1, *LTB4* leukotriene B4, *PGe2* prostaglandin e2, *EGCG* epigallocatechin 3-gallate

Table 52.18 Medical conditions that affect absorption, excretion, requirement, or transport of zinc

Area of abnormality	Condition associated
Poor intestinal absorption of zinc	Malabsorption due to rapid transit, pancreatic hypofunction Chronic liver and pancreatic disease Other gastrointestinal disease Alcoholism Unbalanced diet (e.g., only high fiber) Parenteral nutrition lacking zinc supplementation
Increased zinc excretion	Liver cirrhosis Renal disease Diabetes mellitus Dialysis
Increased catabolism	Cancer Chronic recurrent infections AIDS Burns, trauma
Decreased serum albumin binding	Nephrotic syndrome Liver cirrhosis

Based on data from Ref. [22]

can guide practitioners in the choice of therapy. In addition, nutrient insufficiencies can worsen the symptoms of IBD if not corrected.

52.7.3 Food Bioactives in the Treatment of Conditions

Topical application of food bioactives is being used in dermatologic treatments [245]. The advantage of topical application over oral intake is the direct application of the bioactive substance to the skin lesions and avoids GI tract absorption and assimilation. For example, resveratrol is used topically in acne vulgaris and psoriasis. When resveratrol-carboxymethylcellulose-based gel is applied topically, there is a greater than 50% reduction in symptoms after 60 days compared with 6% in the controls [246]. In psoriasis, where there is a marked increase in plaque-associated TNF alpha, 1% resveratrol ointment topically applied is associated with 50% rapid 2-week decrease in inflammatory symptoms. Following the treatment period, there is 80% significant improvement and 20% acceptable improvement compared to no improvement in controls [245]. The use of specific amino acids also has been effective. Taurine, for example, has been used in the treatment of acne, psoriasis, and atopic dermatitis [245]. Many spices and foods block NF kappa B, a main modulator of TNF alpha, including turmeric, red pepper, cloves, ginger, cumin, anise, fennel, basil, rosemary, garlic, and pomegranate [247]. Many of these spices are in chutneys, and other traditionally prepared foods and upon scientific evaluation are found to be therapeutic.

52.7.4 Conclusion

Medical nutrition therapy for the skin conditions, as reviewed above, focuses on improving deficiency, removing excess, modulating immune responses and autoimmune reactions, and eliminating hypersensitivity reactions to food protein triggers. The uses of the Mediterranean diet or the modified food elimination diet are powerful modulators of the immune response and promote health and healing of common skin conditions. Skin healing occurs by altering and improving the availability of nutrients and bioactive molecules. The patient with a wide range of dermatologic conditions can be helped by the targeted and precise application of diet, supplements, and/or topical nutrients and bioactives. Therapeutic interventions should be considered for patients whose chronic conditions may seem remote to dermatology yet may manifest in dermatologic changes such as those with inflammatory bowel disease. By leveraging medical nutrition therapy integrated with the knowledge of the underlying condition and coupled with dietary and exposure history, many patients will have marked improvement in their dermatologic condition from nutrient intervention without the need for pharmaceuticals.

Table 52.19 Nutrient deficiencies in inflammatory bowel disease

Niacin	Low plasma concentrations of niacin are common among patients with Crohn's disease (CD), but clinically apparent disease is rare. In one study of adults with CD in remission, low plasma concentrations of niacin were found in 77%. Pellagra (the clinical manifestations of niacin deficiency) has been described in adult patients with CD [214–217]
Folate	Folate deficiency was observed in 20–60% of adults with inflammatory bowel disease (IBD) in older series but is uncommon in studies from the last decade [214, 218, 219]
B12	Laboratory evidence of vitamin B12 deficiency has been reported in about 20% of adult and pediatric patients with CD [214, 220, 221]
Vitamin A	Deficiency has been described in IBD. In one study of adult patients with CD, 5% had clinically significant vitamin A deficiency characterized by impaired dark adaptation [214, 222]
Vitamin D	Insufficiency is common in patients with IBD. In one study, 25% of adults with CD had deficient serum 25-hydroxyvitamin D (25OHD, calcidiol) concentrations (<10 ng/mL). Studies in children report that 6–36% of children with IBD have deficient 25 OH D concentrations (<15 ng/mL). Several factors probably contribute to the variability in reported vitamin D concentrations, including genetic and environmental factors such as diet and sun exposure, as well as factors related to the IBD itself with malabsorption and anorexia. In addition, a study in children suggests that IBD is associated with abnormal vitamin D metabolism, reflected by the absence of a secondary elevation of parathyroid hormone (PTH) concentrations in the subset of children with 25OHD <30, and impaired conversion of 25OHD to 1,25-hydroxyvitamin D. These effects may be mediated by inflammatory cytokines, which suppress PTH and renal 1-α hydroxylase activity. One study suggests that only about 10% of patients with IBD malabsorb vitamin D [214, 223–228]
Iron	Literature reviews suggest that 35–90% of adults with IBD are iron-deficient Iron deficiency is probably the primary cause of the anemia that affects 16% of outpatients and up to 70% of inpatients. Iron deficiency has a significant negative impact on quality of life and can lead to developmental and cognitive abnormalities in children and adolescents. A study in adults with IBD and anemia demonstrated that oral iron supplementation increased hemoglobin concentration and improved quality of life without changing disease activity [214, 229–231]
Zinc	As many as 65% of patients with CD have decreased serum zinc concentrations. However, serum zinc levels vary with albumin and correlate poorly with total body zinc stores; clinically significant zinc deficiency is probably much less common. A deficient state is often reflected by a decreased serum alkaline phosphatase concentration since alkaline phosphatase is a zinc metalloenzyme [214, 215, 232–234]
Calcium	Approximately 13% of adults with CD malabsorb calcium. This can occur due to the binding of calcium to undigested fats in the intestinal lumen, loss of the ileum leading to vitamin D deficiency, and possibly as a result of genetic factors and the effects of inflammatory cytokines. The recommended intake of elemental calcium for children and adults with IBD is the same as for the general population. 1–3 years—700 mg daily 4–8 years—1000 mg daily 9–18 years—1300 mg daily Men and premenopausal women—1000 mg daily Postmenopausal women and men older than 70 years—1200 mg daily [214, 233, 235]
Selenium	Concentrations in whole blood and glutathione peroxidase activity are often somewhat lower in adults or children with IBD as compared with healthy individuals, but biochemical or clinical evidence of deficiency is rare. Deficient levels of selenium are more common among patients with CD who have undergone small bowel resection of >200 cm and in those receiving enteral nutrition exclusively [214, 236–238]
Copper	Clinical manifestations of copper deficiency include abnormally formed hair, depigmentation of the skin, and microcytic anemia. The neurologic manifestations include ataxia, neuropathy, and cognitive deficits that can mimic vitamin B12 deficiency. High flow fistulas or resections can lead to copper deficiency especially in the setting of aggressive zinc supplementation [214, 239, 240]
Magnesium	Deficiency in IBD may result from decreased oral intake, malabsorption, increased intestinal losses, or low concentrations of magnesium in a formula used for enteral nutrition. Magnesium deficiency may contribute to osteopenia [214, 241–243]

Table 52.20 Secondary nutrition-related skin lesions associated with inflammatory bowel disease

Secondary cutaneous lesions	Symptoms	Crohn's disease (CD)	Ulcerative colitis (UC)	Causation
Zinc deficiency acrodermatitis enteropathica	Erythematous patches, plaques, progress to crusted vesicles, bullae, or pustules Location: mouth, anus, limbs, fingers scalp	40%	No difference from control	Reduced mucosa available for absorption and chronic diarrhea
Iron deficiency with anemia	Koilonychias, angular cheilitis, pale skin	39%	81%	Malabsorption of iron and chronic intestinal bleeding
Essential Fatty Acid deficiency	Xeroderma, dry skin, unspecified eczema	CD > UC	UC=CD	Malabsorption

Based on data from Ref. [244]

53.1 Introduction

As a practitioner seeing chronically ill patients, have you been frustrated by the person who lands in your clinic after being ill for more than 6 months and having already visited multiple practitioners before you? This patient has not been able to recieve an effective treatment plan helping their recovery. If you are nodding your head, you are not alone! Many patients experience some level of pain, illness, or dysfunction without finding out the source of what is wrong with them or being given a solution to help them recover or reverse their condition. Counter to current medical wisdom, there are multiple factors that an individual can control in preventing and reversing many health conditions. Most ailments stem from poor physical activity and can lead to many chronic musculoskeletal and neuromuscular impairments. According to the Centers for Disease Control and Prevention, such chronic diseases and conditions as heart disease, stroke, cancer, type 2 diabetes, obesity, and arthritis rank among the most common, costly, and preventable of all health problems. As of 2012, about half of all American adults, 117 million people, had one or more chronic health conditions. One in four adults had at least two. In this chapter, we will discuss the many physiological changes that may occur in chronic illness and/or chronic pain due to inactivity [1]. There is little guidance on proper rehabilitation of this population in a safe and effective manner. We will discuss normal and abnormal tissue healing, the effects of bed rest on the body, metabolic changes associated with inactivity, and rehabilitation considerations. Besides treatment, movement alone may play a role in prevention of chronic dysfunctions. Further research needs to be conducted on effective treatment approaches and protocols for proper rehabilitation of a patient with chronic dysfunction.

53.2 Tissue Healing

Tissue healing can be divided into three phases: inflammation, repair, and remodeling [2]. Phase one, *inflammation*, is the body's first response and is essential for appropriate healing after an injury. New blood vessel formation and collagen production are critical steps that occur during this first stage and are important for healing. A healthy environment for new tissue regeneration and formation is essential for preventing prolonged inflammation, as this could disrupt blood vessel and collagen production. For the body to repair, it is vital to prevent tissue disruption and prolonged inflammation during the acute inflammatory stage. The main goal for practitioners during an inflammatory state is to protect the injured area while continuing to maintain full function in the unaffected areas.

Phase two, *repair*, can take up to 8 weeks if the proper amount of restorative stress is applied [2] or longer if this stress is inadequate. Restorative stress is defined as maintaining a careful balance in which disruption of newly formed collagen fibers is avoided, while low load stresses are gradually introduced to allow increased collagen synthesis and prevent loss of joint motion. Early gentle motion allows for alignment of collagen fibers and promotes tissue mobility. The treatment goal for this phase is to prevent excessive muscle atrophy and joint deterioration. To protect weak collagen fibers, caution should be used when adding load or resistance. Too little activity can have negative effects, causing new fibers to misalign forming adhesions. As a result, it can prevent a full range of motion.

Phase three, *remodeling*, occurs when damaged tissue is replaced with new collagen fibers. After these fibers are laid down, the body can begin to remodel and strengthen the new tissue and allow for gradual return to full activity. Closed chain [2] exercises, such as squatting, stair climbing, transferring from seated to standing positions, and balancing on one leg, have been found to best replicate these common movements. In these exercises, the distal part of the joint segment is fixed to the ground. This type of exercise is said to enhance collagen remodeling, increasing joint stability and neuromuscular control.

Healing cannot take place when inflammation, repair, and remodeling do not occur. With acute illnesses or injuries, the body can usually heal itself within 6–8 weeks. In addition, as nutrition becomes depleted on a macro- and micronutrient level, healing becomes more difficult [3]. If pain or dysfunction persists greater than 6 months, it is labeled as a chronic condition. Chronic pain can be episodic or continuous and neuropathic in nature, leading to myofascial and soft tissue adaptations, as well as biopsychosocial changes. Neuropathic pain results when nerve fibers become injured, damaged, or dysfunctional and send faulty signals to other areas and systems.

Although the pain or dysfunction may have started from disruption of one tissue, such as a muscle tear, pain begins to spread to surrounding tissues and multiple areas of the body.

It takes less stimulation to trigger firing from the nerves around the structure [4]. This creates changes in sensation, muscle control, and proprioception. Muscles and fascia react, becoming shortened or lengthened, pulling the body's frame into positions that increase stress on its structures.

As the functional limitation progresses, it is common for individuals to develop emotional and psychological dysfunctions coinciding with the changes in their bodies [5]. Time is no longer a factor as the healing trajectory is disrupted; more areas in the body are involved as the response progresses from localized to widespread. As we will discuss, chronic musculoskeletal pain issues affect the heart, gut, brain, immunity, and genetics [6]. Patients experiencing functional limitations may have impairment in ambulation, require wheelchairs, or even become bedridden. For the sake of this chapter, both chronic illness and chronic pain will be discussed as a chronic dysfunction, unless differentiation is specified.

53.3 Chronic Staircase of Change

Many changes occur to the body with onset of chronic dysfunction. Postural changes are one of the first characteristics seen in any injury or illness. The figure below demonstrates an ideal static posture in the sagittal and frontal plane (Fig. 53.1).

Any position outside that is represented in Fig. 53.1 can create excessive stress on the body. Postural asymmetries may develop due to prolonged positioning, repetitive tasks, hand dominance, or uneven loading in the body. Always sitting on one hip, crossing your legs, or sitting in a slouched position may cause these postural asymmetries to occur. Posture imbalances may also develop with repetitive motions or activities such as carrying a child on one hip.

Postural asymmetries may be asymptomatic but could foreshadow further disease or injury in a weakened muscular or spinal system. When muscles or the spinal system are subjected to stress or disease, changes in posture or alignment cause decreased flexibility and range of motion in the body. This leads to restricted lung volume, decreased chest wall and rib mobility, sluggish gut motility, and altered diaphragmatic function, making these systems work less efficiently. The results of these changes can lead to decreased function and premature morbidity.

When postural asymmetries begin to develop, muscle imbalances occur. Movement and function require a balance of muscle length and strength between opposing muscles surrounding a joint. Muscles, along with the fascia around it, may become weakened, become lengthened, or develop adhesions, creating muscle imbalances. Fascia is a thin sheath of connective tissue, primarily collagen, which attaches, stabilizes, encloses, and separates muscles and other internal organs. Fascial sheaths surrounding muscle fibers can cross multiple joints and different regions of the body. Stecco et al. [7] found with dissection of the pectoralis muscle, its fascial attachments are connected to both arms across the sternum, the cervical spine, the contralateral abdominals, and the ipsilateral trunk muscles. Fascial restrictions and adhesions are frequently found in the pectoralis muscles, latissimus muscles, hip flexors, and thoracolumbar and iliotibial band fascial sheaths.

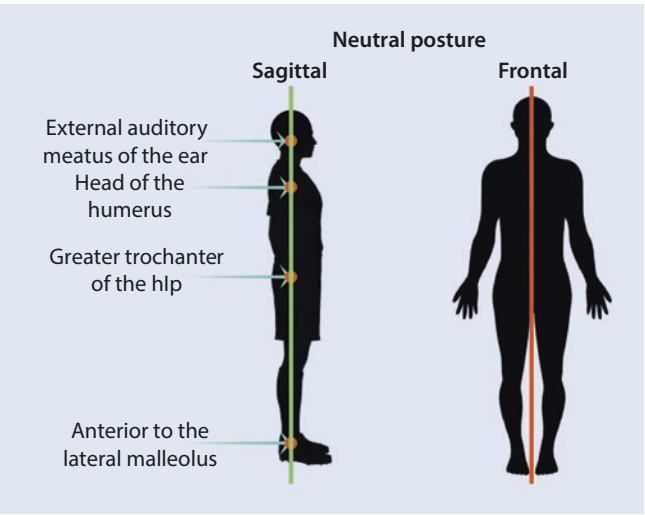

Fig. 53.1 Neutral posture

> Healing cannot take place when inflammation, repair, and remodeling do not occur. With acute illnesses or injuries, the body can usually heal itself within 6 to 8 weeks. In addition, as nutrition becomes depleted on a macro- and micronutrient level, healing becomes more difficult. If pain or dysfunction persists greater than 6 months, it is labeled as a chronic condition. Chronic pain can be episodic or continuous and neuropathic in nature, leading to myofascial and soft tissue adaptations, as well as biopsychosocial changes. Neuropathic pain results when nerve fibers become injured, damaged, or dysfunctional and send faulty signals to other areas and systems.

Progression of muscle imbalances leads to the development of musculoskeletal issues. The postural muscles [8], including the deep cervical flexors, middle and lower trapezius, transverse abdominis, gluteus medius and maximus, and multifidi (the stabilizing muscles that extend and rotate the spine), become lengthened, weak, and atrophied. These muscles are meant to provide stabilization for the body and fire aerobically and continuously. During an injury, surgery, or chronic pain, this process becomes altered. The global muscles [8] become dominant and use more energy to sustain posture, causing more fatigue. The most common global muscles include the erector spinae, hip flexors, pectoralis major and minor, rectus abdominis, and latissimus dorsi. The goal is to re-establish dominance of the postural muscles and establish length and flexibility of the global muscles.

For the body to function optimally, muscles do not work individually, they work in synergistic patterns and help create specific movement strategies. When muscle imbalances are present, altered firing patterns are seen. Greig et al. [9] studied 24 elderly women with osteoporosis, half of whom had a vertebral fracture. The women stood and quickly raised their arms in response to a light that indicated the direction of movement. The authors found that the women with vertebral fractures tended to fire both global and postural muscles simultaneously, creating an inefficient muscle pattern, leading to muscle imbalances. Those that demonstrated these muscle imbalances were shown to use poor movement strategies to keep from falling. The other group could perform the task without stiffening, due to improved balance reactions.

The body was designed to move in the upright position, against gravity, and interact with gravitational forces that

benefit the entire body, from the bones and muscles to the circulatory system. Wasting of muscles, specifically postural muscles, in the neck, back, abdomen, and legs, will occur after a few days spent in a horizontal position such as with bed rest or hospitalization (see section below). This process can happen faster or slower, depending on the individual's fitness level and lifestyle. One week of complete bed rest can lead to a decrease of 20–30% in muscle strength and cause structural changes to the muscles, bones, nerves, and blood vessels [10]. This will directly affect an individual's muscle tone, balance, coordination, and walking. One becomes more prone to falling and incurring fractures after spending several days in bed, and, as a result, it is important to start an exercise program as soon as possible. Deep vein thrombosis, swelling, and muscle weakness become a risk with prolonged bed rest. Transfers become increasingly difficult due to changes in blood pressure, muscle atrophy, and decreased tissue oxygenation.

Poor posture and muscle imbalances often cause movement patterns to become inefficient. These muscle inefficiencies lead to balance deficits. Any movement of the body or external force creates a change in the body's ability to balance. Balance is the ability of the body to right itself when tipped in any direction. The act of walking requires a significant amount of balance. While transitioning from left to right, one must be able to fully support their body on one leg and propel themselves through space. When balance is compromised, an assistive device may be used to avoid limping or compensation and prevent falling.

Muto et al. [11] found postural and balance changes in 67 women reporting chronic pain and diagnosed fibromyalgia. When compared with the control group, those with fibromyalgia and chronic pain demonstrated increased sway and decreased balance regardless of visual input and surface type. Similarly, when Radebold et al. [12] studied 16 adults with chronic low back pain in an unstable sitting position, subjects

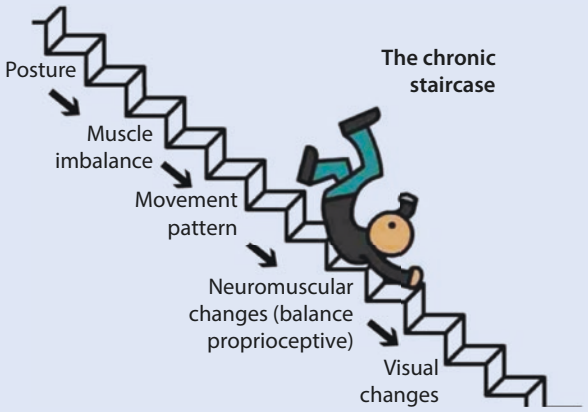

Fig. 53.2 Chronic staircase. (Courtesy of Judy Hensley, PT, DPT, MHS, OCS, MTC)

demonstrated delayed reaction time, decreased balance reactions, and required more visual feedback to weight-shift and balance compared to healthy matched controls. When balance reactions have been compromised, there is less spatial awareness and a need for more conscious effort to maintain balance. See Fig. 53.2.

As balance changes, one side of the body becomes more dominant, and visual perceptual field changes occur [13]. The eye muscles on the dominant side shift the brain's perception of midline as larger on the non-affected or now-dominant side. The ear on the affected side may bend toward the shoulder to allow the dominant eyes to take control. The eye muscles in this position give the brain input that the head is neutral. In this way, one-sided neglect is possible over time in an orthopedic dysfunction without brain trauma. Those that are inactive the majority of time, whether bedridden, wheelchair-bound, or simply deconditioned, improper positioning may also create midline shifts. (See Case ▶ 53.1.)

Case 53.1

TB, a 70-year-old male physical therapy patient, was seen for right shoulder pain from a chronic rotator cuff injury. He has a history of right total knee and hip arthroplasties. TB stands with minimal weight-bearing on his right leg and holds his right shoulder lower than his left. His shoulders are positioned behind his hips, and his shoulder and scapula are tipped forward. Atrophy appears in his right gluteals, as well as weakness in his scapular muscles and tightness in his hip flexors, pectorals, and latissimus dorsi bilaterally. Spinal stabilizers, including the multifidi and the transverse abdominis, are weak and delayed in their firing response. He leans to the right while attempting to stand on his right foot. Findings include changes in his posture, muscle balance, movement patterns, stabilization, balance, and body perception. Proprioception, his body's awareness of where it is in space, is decreased on the right, and he believes his weight is equally distributed. His perception of midline has moved more to the right, allowing his brain to perceive his left side as larger. His left eye is more dominant as it sees the right side of the body. This demonstrates a case of right-sided neglect. His recent complaint is pain reaching overhead with his right arm. A physical therapy treatment began with posture education, manual therapy to improve shoulder joint and soft tissue mobility, spinal and scapular stabilization, balance training, and spatial awareness exercises. He became more aware of a neutral posture but was unable to raise his arm standing. With the appropriate training, he became more aware of his right side and was able to control reaching overhead with the appropriate balance reactions and body mechanics.

53.4 Metabolic Effects of Activity

Physical activity is integral to our general health. In years past, increasing heart rate and exertion were the goals of most exercise scientists in promotion of heart health, weight loss, mental acuity, and disease prevention. Many bedridden and chronically ill individuals are unable to perform such rigorous exercise. There was uncertainty whether low-impact, low-intensity, or short-duration movements were worthwhile, but they have been found to be highly effective on a wide range of systems including cardiovascular, cardiopulmonary, musculoskeletal, gastrointestinal, neural, and endocrine [14]. These findings are relevant for many individuals, including those who are bedridden, recovering from surgery, suffering an illness, aging, and physically challenged.

Lipoprotein lipase (LPL) and myokines are two key factors highlighted in research regarding the effectiveness of gentle movement [6]. LPL is a molecule that is produced during muscle contraction. It plays a central role in how the body processes fats. Levels of LPL rapidly decrease after 4 hours of inactivity and are abolished completely after 18 hours of inactivity. Pederson et al. [6] found that this decrease in LPL leads to the deposit of fats being stored in our adipose tissue, rather than being metabolized by muscle for energy use. Even after moderate exercise, such as a long run in the morning, inactivity for 4 hours afterward has major effects on how we metabolize fat. Inactivity for most of the day, for example, sitting at a desk, is now considered a risk factor for metabolic disease and disorders involving poor lipid metabolism. This research reinforces the need for short, frequent periods of movement at least every 4 hours, no matter if long periods of intense exercise are part of one's daily routine [15].

Myokines are proteins/cytokines that are produced, expressed, and released by muscle fibers upon contraction with movement and exercise. They play an important role in cross talk between skeletal muscle and other organs including the adipose tissue, liver, pancreas, and gut [16]. As the body moves, muscles release myokines that then break down fat tissue to be used for energy instead of being stored around organs as fat. Myokines help regulate inflammation and prevent insulin resistance and metabolic syndrome.

The most studied myokine is interleukin-6 (IL-6). It has an important part in the transition from acute to chronic inflammation, acting as both a pro-inflammatory cytokine and anti-inflammatory myokine. With physical activity, there is an acute increase in IL-6 resulting in an increase in fatty acid oxidation, followed by an increase in systemic lipolysis. IL-6's main function is fatty acid metabolism within the muscle tissue [16].

Inflammation is a common problem for patients in the intensive care unit, frequently associated with serious or prolonged critical illnesses. (Please refer to ▶ Chaps. 42 and 48 for anti-inflammatory diets.) Winkelman et al. [17] examined the relationship between type and duration of physical activity and serum levels of IL-6 and IL-10. A study compared ten critically ill patients who were mechanically ventilated for an average of 10 days. An average of 14.7 minutes of passive physical activity, typically done with multiple bed turns associated with hygiene, increased the anti-inflammatory action of IL-6, which is associated with decreased mortality rate. The authors concluded cytokine balance may be improved by low levels of activity during prolonged critical illnesses.

Brain-derived neurotrophic factor (BDNF) is a myokine that is found in the brain and plays a key role in the regulation, survival, growth, and maintenance of neurons. Physical exercise has been shown to increase BDNF production three times its regular rate [18]. This contributes to increased cognitive function and postexercise-related neurogenesis. Those with type 2 diabetes, regardless of BMI, have decreased circulating levels of BDNF. Lack of physical activity appears to be the main contributing factor in development of type 2 diabetes [18].

The control of inflammation is key in prevention of the disease process in the human body. In the nonobese population, skeletal muscle represents the largest organ of the body and is an active endocrine organ. There is cross talk between the endocrine and the immune system. Inflammatory cytokines are proteins produced during inflammation that activate the hypothalamic-pituitary-adrenal (HPA) axis. When the HPA axis continues to be activated, this leads to diseases that are triggered and maintained by chronic inflammation [6]. These diseases include but are not limited to type 2 diabetes, cardiovascular disease (CVD), colon cancer, breast cancer, dementia, and depression. These have been classified in literature by Pederson [6] as "diseasome of physical inactivity," leading to abdominal adiposity reflected in an accumulation of visceral fat mass. This accumulation is associated with systemic inflammation. Chronic inflammation plays a role in the pathogenesis of insulin resistance, atherosclerosis, neurodegeneration, and tumor growth. Exercise and movement have an anti-inflammatory effect by decreasing visceral fat mass and increasing LPL and other myokine expressions [6] (◘ Fig. 53.3).

Tumor necrosis factor alpha (TNFα) is an inflammatory cytokine that is stimulated with sympathetic nervous system stimulation and is a key player in the pathobiology of inflammatory disorders including rheumatoid arthritis (RA), irritable bowel disorder (IBS), and Crohn's disease. There is evidence to point toward TNFα playing a key role in metabolic syndrome. Those with type 2 diabetes have high protein expression of TNFα in skeletal muscle and plasma. In vitro studies by Pederson [6] demonstrate that TNFα has a direct inhibitory effect on insulin. Infusing TNFα in healthy humans creates insulin resistance in skeletal muscle. Starkie et al. [19] showed that TNFα levels were blunted after 3 hours

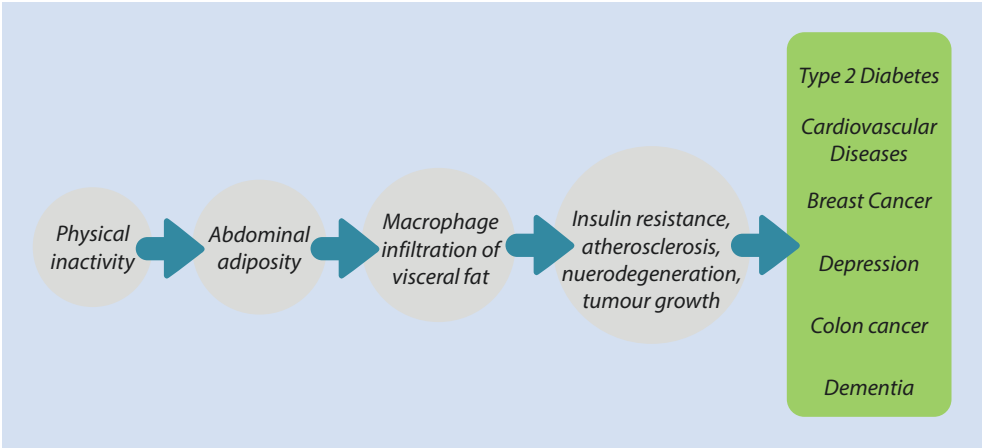

Fig. 53.3 Diseasome of inactivity. (Courtesy of Julie Buttell, PT, MPT, COMT)

of ergometer cycling. This indicates that exercise can reverse the TNF effects of insulin resistance.

If physical activity is crucial in controlling inflammation, one must ask what role mental state plays? Recent research is providing evidence that the mind and body work together to establish homeostasis. Moliere stated, "The mind has a great influence over the body, and maladies often have their origin there" [20]. Mental stress is a common thing in our lives, yet chronic unremitting stress is deleterious to our health.

Stress stimulates our sympathetic nervous system (SNS), which is responsible for the upregulation of the neuronal and hormonal response known as fight or flight. The stress response starts with the release of acetylcholine, activating the secretion of epinephrine from the adrenal gland. Blood vessels dilate in the skeletal muscle and constrict in the gastrointestinal organs. The adrenal glands produce cortisol, an anti-inflammatory response, decreasing our immune response and the body's ability to absorb calcium. Low-grade production of cortisol, due to constant stress, decreases immune function, playing a role in developing autoimmune disease, as well as disrupting the brain's gray and white matter connectivity [20]. This conductivity is vital for the four lobes of the brain to communicate. Decreases in communication lead to mental illness, memory loss, and behavioral disorders [20].

The vagus nerve is responsible for regulating the parasympathetic nervous system and controlling the body's immune response. It does this by activating the HPA axis, which gives information from the body to the brain in an afferent pathway and stimulates a response from the brain to the body in an efferent pathway through the cholinergic anti-inflammatory pathway (CAP) [20]. Immune receptors are located on the vagus nerve. When diseased cells proliferate, an increase in inflammatory cytokines stimulates our immune system to respond. Vagus nerve stimulation increases serotonin and norepinephrine in the presence of inflammatory cytokines and acts as an anti-inflammatory pathway to release corticosteroids by the adrenal glands. The efferent response inhibits inflammation by suppressing inflammatory cytokine production after the release of acetylcholine, which is a neurotransmitter that delivers messages between neural structures and helps with muscle contractions.

The vagus nerve plays a key role in the neuroendocrine-immune axis to maintain homeostasis, but is only activated when the SNS is turned off. Turning off the SNS is a difficult task, as it is stimulated by both high-grade stressors as well as low-grade stressors that require one to remain alert and focused. This prevents the transfer of information to the brain from the parasympathetic nervous system via the vagus nerve [20].

From this research, we know any activity to increase the parasympathetic nervous system will decrease stress and systemic inflammation while improving our immunity [20]. Slipping into the parasympathetic nervous system must be a mindful effort, as we are not frequently in stress-free situations. Meditation, mindfulness, and diaphragmatic breathing show promising research on diminishing our stress response, therefore decreasing risk for initiation and maintenance of the disease process. The diaphragm is innervated by the vagus nerve. When breathing diaphragmatically, air is taken into the low belly, letting the abdomen rise fully before the chest. The vagus nerve is stimulated and sends messages to the brain that the system is safe and relaxed. This allows the vagus nerve to have its anti-inflammatory effect through its afferents activating the HPA axis. Impaired HPA axis due to stress will decrease the communication between the brain and the vagus nerve, creating a risk for such human inflammatory diseases and disorders as rheumatoid arthritis, irritable bowel syndrome, multiple sclerosis, asthma, and dermatitis, and others [20].

53.5 Effects of Bed Rest Resulting in Chronic Dysfunction

Bed rest adds another dimension to this sequela. Some individuals are on bed rest for only a short period after surgery or injury, while others become bedfast for extended periods. The risk of developing osteoporosis and osteopenia is

increased in conditions with lack of mechanical challenge to the skeletal system, as seen with immobility. When there is not a sufficient amount of load or strain on the bone, the trabeculae lose its strength, and bone density is lost. The bone loss of osteoporosis reflects the disrupted balance of formation and resorption activities of remodeling, where removal of bone driven by osteoclasts exceeds the ability of osteoblasts to replace it. To protect or recover bone quantity and quality in osteoporotic patients, pharmaceutical agents and strategic exercise programs have been used [21].

Changes in spinal morphology and atrophy with bed rest are being researched in spaceflight. Belavy et al. [21] kept nine male subjects on bed rest with their heads downwardly tilted for 60 days. Axial magnetic resonance imaging of the lumbar spine showed increased disc volume, increased spinal length, change in lumbar spine curvature, and decrease of the cross-sectional area (CSA) of the multifidi and increased CSA of the psoas. This decrease was greatest at L4–L5 in the multifidus, one of the most frequent sites for spinal instability and fusion. Stabilizing the spine at this level is imperative for prevention of lumbar pain. Lumbar instability leads to decreased function of the transverse abdominis and gluteal muscles. These are postural muscles that are responsible for pelvic, hip, and spine stability. When weakness develops in these muscles, the psoas becomes overactive, pulling the lumbar spine into an extended unstable position. Five of the nine subjects reported low back pain during the study or upon ambulating after bed rest. Posterior disc height increased while multifidi CSA decreased. Having periods of inactivity due to bed rest causes changes including pain, postural asymmetries, balance dysfunction, muscle imbalances, and delayed anticipatory response due to decreased spinal stabilization.

Sarabon and Rosker [22] studied 16 healthy older males (59.6 years +/− 3.4) who were kept on bed rest for 14 days to determine trunk muscle stabilization. The subjects were instructed to raise their arms overhead as quickly as possible when a light was observed in their visual field, testing anticipatory responses. The researchers determined the subject's response to being pushed off balance and that was labeled a reflex response. To initiate the reflex response, pressure was placed at the subject's elbow randomly and quickly released. Reactive reflex responses in the trunk were measured with EMG, testing the abdominal obliques and trunk extensor muscle activity. All muscles demonstrated a delayed anticipatory and reflex response following bed rest that persisted for more than 14 days. This study suggests delayed reflexive responses in the elderly persist after 2 weeks of bed rest.

In another study of 19 elderly individuals (66 +/− 1 year) kept on bed rest for 10 days, Coker et al. [23] found body weight, muscle strength, speed of stair climbing, speed of sit to stand transfer, and walking speed significantly reduced. Findings also included decreased VO_2 max and lean muscle mass, as well as an increase in body fat. The authors theorized that the infiltration of lipids into skeletal muscle may play a role in precipitating or affecting the decline of strength and/or functional capacity.

In a study by Fardo et al. [24], 28 healthy female students were confined to a bed for 90 minutes and compared to people in a control group who were sitting for the same period of time. The two groups were compared for pain responses with electrical stimulation to determine which area of the brain was most affected. The horizontal bed rest group demonstrated an inhibition in the central prefrontal portion of the brain making them more sensitive to pain. This region is involved with cognitive, affective, and motor aspects of pain processing. Although this was not conducted with chronic pain patients, it may indicate individuals on bed rest have less inhibition for pain control.

Chronic low back pain, along with any ongoing pain or illness, has been demonstrated to show changes in diaphragmatic breathing. The diaphragm precedes any movement of the body by lowering and subsequently establishing abdominal pressure which helps stabilize the lumbar spine. The lower ribs must be stabilized by the abdominals and can only expand to the sides. Vostatek et al. [25] used magnetic resonance imaging to study the breathing patterns of 35 individuals, half of which had chronic low back pain. The group with chronic low back pain was found to have diaphragmatic changes including increased respiration rate, increased anterior expansion, decreased total excursion, expansion more horizontal than vertical, and a higher resting position of the diaphragm in the thorax. The group with pain suffered from insufficient abdominal strength which resulted in poorly stabilized lower ribs. Abdominal weakness is associated with decreases in proper muscle balance, spinal stabilization, pelvic floor, and respiratory control. Smith et al. [26] found disorders of urinary incontinence and respiration were stronger predictors of frequent back pain than physical activity and obesity. Furthermore, the researchers found patients with only low back pain are likely to develop urinary or respiratory dysfunctions within 2–3 years of onset of back pain.

Chronic neck pain has been associated with decreased pulmonary function. Dimitriadis et al. [27] compared 45 individuals with chronic neck pain with 45 matched controls. The authors found the pain group had significantly reduced vital capacity (the volume of air expressed from the lungs), forced vital capacity, expiratory reserve volume (the additional amount of air that has been left in the lungs after expiration), and maximum voluntary ventilation (the volume of gas that has been inhaled 15 seconds when a person breathes as quickly and deeply as possible). The reduction in lung volumes resembled restrictive pulmonary dysfunctions, more than obstructive. Muscle imbalances and spinal instability, also found in the pain group, included weak neck flexors/extensors and decreased range of motion. The diaphragm is an integral part of the core. It may be helpful to visualize the core as a cylindrical container with the top of the container being the vocal cords, the bottom being the pelvic floor, and the sides being the internal obliques, the quadratus lumborum, and the diaphragm. This cylindrical container provides pressure against external forces, providing stability for the trunk.

Along with physical and respiratory changes, mental changes often occur in individuals with chronic dysfunction. Social networks have a great influence on our physical health. Christakis and Fowler [28] in 2007 found a 171% increased likelihood of becoming obese if a friend became obese. It was only 41% more likely someone would become obese if a sibling became obese. This gives reason to think mindset in community, and physical activities within communities, are essential. A Harvard study showed body position can influence hormone levels. Assuming a powerful posture opening shoulders, with a straight spine, increased testosterone 20% and decreased cortisol levels 25% [29]. This gives feedback that physical activity does not need to be intense to be effective. Many options from chair yoga to Tai Chi can be effective for the chronically ill individual [30].

Genetic changes have been noted in individuals with physical inactivity. DNA sequencing does not change, but how the cells read the gene can be influenced by disease state, environment/lifestyle, and age of the individual, also known as epigenetics. Bed rest studies have shown us physical inactivity is one of the main contributing factors in metabolic disturbances. "Transcriptional analysis of human skeletal muscle after 9 days of bed rest revealed changes in the expression of more than 4500 genes, and the downregulation of a total of 54% of genes involved in the oxidative phosphorylation pathway" [16]. This supports the theory suggesting physical inactivity is one of the main factors in the start of many chronic diseases. When we are inactive, fat is no longer used as an energy source but stored around our organs. Visceral fat has been shown to initiate the onset of almost all inflammatory diseases [6].

The above evidence poses the question of the significance of myokine and LPL deficiency in the inactive population and the role for anti-inflammatory diets coupled with movement. The imperative for intervention, including passive range of motion, submaximal movement, and balance training among those on bed rest or who are physically inactive, can no longer be ignored.

53.6 Rehabilitation of Chronic Dysfunction

Returning to exercise after being bedfast, chronically ill, or a period of immobility should happen progressively to allow the body to adapt to a new routine. As described above, being bedridden can lead to deconditioning, negatively affecting health. For this reason, it is important to discuss appropriate exercise prescription to allow the chronically ill and bedridden patient to regain strength, range of motion, and stability required for daily tasks.

A referral to physical therapy can be of great benefit to those with chronic dysfunction. Manual therapy, including joint and soft tissue mobilization, can decrease pain, adhesions, and inflammation and increase mobility, allowing the patient to move into normal postures. The effects of sympathetic nervous system (SNS) overactivation must also be decreased, awakening the parasympathetic nervous system to allow the vagus nerve to give input to the brain regarding the bodies' immune state and stabilize the blood pressure. This can be addressed through diaphragmatic breathing, mindfulness training, relaxation, and physical exercise. Massage may be needed for myofascial issues including muscle and soft tissue holding. Acupuncture or dry-needling techniques may be beneficial in calming the nervous system [31]. Inflammation must be addressed by a nutritionist to improve diet and resolve gut issues. These are all provided in conjunction with physical therapy, and the result is facilitation of improved muscle balance, spinal stabilization, postural awareness, and functional movement.

Introducing diaphragmatic breathing and meditation benefits the individual with chronic dysfunction, creating metabolic and physical changes. Breathing and mindfulness training will allow the nervous system to calm, causing anti-inflammatory effects allowing for pain reduction and aiding in healing. Lung capacity, thoracic extension, resting posture, and muscle tone can all be improved by learning appropriate breathing patterns. There are many programs and apps available to assist in this training, such as Headspace™, Muse™, Calm™, and others.

Proper positioning, correcting muscle imbalances, and education in correct body mechanics contribute to decreasing stress. Shahidi et al. [31] studied 60 asymptomatic workers performing a computer task that became progressively more difficult and stressful. As stress increased, the workers developed an increase in their forward head posture with activation of the upper trapezius, resulting in pulling the shoulders upward. If this response occurs in pain-free workers, it is likely that those with chronic pain will have an exaggerated response.

Various types of vibration therapy have been used with patients with chronic dysfunctions. As it is known that bed rest and inactivity lead to osteoporosis, degenerative disc disease, and chronic pain, vibration therapy may have a role to play in mitigating the damage. To increase bone density, whole-body vibration therapy may be administered passively in supine, seated, and standing positions. In a study by Holguin et al. [32], healthy individuals were kept on bed rest for 90 days. Decreased disc swelling and a return of disc volume were seen in the group who underwent 10 minutes per day of whole-body vibration after 7 days of being taken off bed rest. Compared with the control group who did not receive vibration therapy, those receiving the therapy retained disc convexity throughout the lumbar spine and reduced the incidence of back pain by 46%. There has also been some potential for whole-body vibration to serve as a surrogate for exercise for those that are unable to participate in physical activity and as an adjunct to therapy. Evidence demonstrates multiple significant advantages using vibration therapy as an intervention [10].

Another type of vibration therapy can be used locally to address pain using a TENS unit. Lundberg et al. [33] enrolled 731 patients, 596 with chronic pain, where there was placement of an electrode or a vibrator near or at the area of pain. Treatment was localized to the antagonist muscle or a trigger

point near the painful area for 30 to 45 minutes, and pain was found to be reduced in 82% of the patients. Even patients with moderate to severe pain typically had at least 50% reduction in complaints. Vibration is thought to have a greater effect on the central nervous system to dampen pain.

Assessment and treatment of pain generators is most important to help calm the SNS and allow for appropriate relaxation during treatment. Limitations in soft tissue and joint mobility should be addressed. Active range of motion and passive range of motion are among the safest form of exercise that can be performed during bed rest and periods of low activity. Passive range of motion improves joint mobility, improves synovial fluid, and prevents joint contractures, allowing the individual to maintain range of motion until it can be performed actively. Active range of motion is used to help the individual gain control of their musculoskeletal system and progressively expose the body to gravity regaining muscle strength, flexibility, coordination, and agility. Benefits of returning to an active lifestyle can be experienced almost immediately when beginning an exercise program.

Submaximal isometric exercises are added in the early phases of the exercise prescription to ensure deconditioning does not worsen. Submaximal isometric exercises occur when one can contract a muscle without movement of the joint. These exercises help maintain neuromuscular function and strength with low intensities that will not disrupt newly formed collagen fibers. Strengthening exercises should be added to the program once flexibility has been achieved and isometric control is established. These exercises begin with only body weight and then progress to external loads, such as light weights. Muscle strengthening assists in reversing the negative effects of prolonged bed rest and chronic inactivity, preventing muscle atrophy and improving circulation.

Focus on even distribution of weight is essential, easing into simple movements as walking, squatting, and reaching. Proper movement control and utilization of correct movement patterns is also necessary. Progression moves into endurance tasks, allowing for return to activities of daily living. Balance training, motor control, and proprioception need to be addressed to restore efficient movement strategies, prevent injury, and allow appropriate energy expenditure during daily tasks. This can be achieved through closed chain exercises designed to enhance neuromuscular control and replicate common movements performed in activity of daily living. Visual and spatial awareness, balance reactions, and postural control need to be addressed so one can return to movement without risk of falling or reinjury. Attention to core and trunk stabilization exercises is imperative for improvement of posture and balance. One must focus on proper alignment to ensure the body can achieve proper motor patterning/control. These tasks listed above vary from patient to patient. Range of motion and strength gains may be seen in the first 4–6 weeks of rehabilitation, but neuromuscular control, balance training, and postural awareness may take much longer for the patient to master. Addressing all the above issues ranges from months to years of physical therapy.

When developing an exercise program for the bedridden or chronically ill, careful consideration needs to be taken to ensure the exercise prescription is appropriate. Inappropriate exercise can be detrimental to the healing process, creating unnecessary discomfort. Prior level of function, current state of physical/mental and metabolic status, balance, proprioception, and neuromuscular control need to be considered in development of the best exercise program for the individual.

Caution is also raised to guard against those who recommend over-training. Overall, exercise can help decrease the chance of developing heart disease, increase bone density, and improve immunity. Exercise is beneficial, but caution needs to be taken to not overdo. Heavy long-term exercise causes harm to the body and suppresses the immune system [14]. The innate immune system responds negatively to chronic stress of intensive exercise. Natural killer cell activity is enhanced, destroying abnormal cells and viruses in the body while neutrophil function (the immune response to bacteria) is suppressed. In athletes, however, investigators have had little success in linking long-term intense exercise with higher incidence of infection and illness.

Many components of the immune system exhibit change after prolonged heavy exertion. An altered immunity may last between 3 and 72 hours, giving viruses and bacteria an advantage increasing the risk of infection. Studies on the influence of moderate exercise training on cellular protection and immune function have shown that near-daily brisk walking reduces the number of sick days by half. Compared to the inactive population, no data suggests moderate exercise training is linked with improved immunity [14].

53.7 Conclusion

In this chapter, we have discussed the stages of normal tissue healing and what abnormal healing looks like and described the many changes that occur due to pain or inactivity. Many physiological and metabolic changes are associated with inactivity and bed rest. This chapter aims to help the reader understand the physiological changes that occur due to pain and inactivity, assisting in improving treatment strategies for individuals with chronic dysfunction. Further research needs to be conducted on effective treatment approaches and protocols for proper rehabilitation of the chronically ill patient. Education of the public should continue to focus on prevention of these chronic conditions.

Systems Biology
National Institutes of Health, Intramural Research
Systems Biology as Defined by NIH
► https://irp.nih.gov/catalyst/v19i6/systems-biology-as-defined-by-nih

Institute of Systems Biology: biomedical research organization (nonprofit)

ISB is a holistic approach that encompasses all metabolic systems and their networks to bring a usable understanding of the complexity of the biological systems of whole of living organisms, where they are perturbed, and a basis for developing interventions that restore structure and function. There is a peer collaboration among healthcare and technology disciplines. Integrative medicine, and functional medicine, has evolved on the foundation of systems biology. It is important for integrative and functional healthcare practitioners to have a robust appreciation of the concept of systems biology to build their paradigm of integrative and functional medicine (■ Figs. 54.1 and 54.2).

55.1 Initial Nutrition Assessment Process Background

The initial nutrition assessment is based on the Nutrition Care Process established by the Academy of Nutrition and Dietetics (the Academy) and is summarized as follows:

- Assessment
- Diagnosis
- Intervention
- Monitoring
- Evaluation (Fig. 55.1)

55.1.1 Chart Review and Preparation

The RDN reviews the paper and/or electronic medical record for information about the client's health history, nutrition history, anthropometrics, and any other information that could be helpful to begin to evaluate the person's nutritional status.

Papers or documents that can be helpful for nutrition consultations:

- Nutrition intake forms submitted prior to nutrition consultation.
- While reviewing the chart, you can fill in the "blank nutrition assessment and consultation summary form."
- Blank "progress note" to write notes during appointment (lined paper with the client's name, medical record number (MRN), and date of birth (DOB)).
- Charge sheet (varies by practice).
- Nutritional supplement list and company contact information packet (varies by practice).
- Updated list of supplements.

55.1.2 Before Appointment

Prior to the actual consultation/appointment, the patient service representative (PSR) will need to take care of technical information, paperwork, and other items:

- PSR: Confirm that patient has filled out all necessary forms and take photo (if approved and appropriate). If not, prepare forms that need to be completed and explain each one in detail, if necessary. Chart should be prepared ahead of time.
  - Notice of privacy practices (PSR)
  - HIPAA authorization (PSR)
  - Diet prescription or specific referral form (if needed)
  - Integrative nutrition intake form (self- or physician-referred)
  - Diet diary (1- to 3-day history)
  - Fats and oils questionnaire
  - Medical symptoms questionnaire
- Photograph (taken by PSR): Take a photograph of the client to be placed in the chart. This will be used for ease of recognition and better recall of client story and team approach to care.
- Dietitian (RDN): Introduce yourself, welcome, and ask how the person prefers to be addressed. Lead client to private, quiet consultation room. Invite the client to sit in designated chair in counseling area. If a family member or friend of the client wants to join the consultation and is 18 years or older, ask client for permission.
- When necessary, ask the client whether a dietetic intern can observe the appointment.

55.1.3 Nutrition Assessment Process

55.1.3.1 Background and Explanation of Assessment

- Explain to client, when necessary, the uniqueness of dietetics and integrative medicine by providing the handout "What is DIM?".
- Ask client to state his or her most important goals to achieve during the session. Be sure to address these goals during the session and in the visit summary.
- Briefly explain the nutrition assessment process, when necessary:
  - In-office assessments: Bioelectric impedance analysis (BIA), weight, waist circumference, nutrition physical exam, and others.
  - Review of nutrition intake forms, medical symptoms questionnaire (MSQ), fats and oils questionnaires, and any others.
  - Ask client to sign MSQ.
  - Review diet diary. If not completed, take a 24-hour dietary recall.
  - Develop intervention of a nutrition action plan and supplement plan.

55.1.3.2 In-Office Assessments and Measurements

In-office assessments (not all of these tests are completed at every visit on every client):

- Nutrition physical exam
- Anthropometrics: height, weight, and waist circumference
- Bioelectric impedance analysis (BIA): measurements taken on a massage or acupuncture table or other surface client can easily and comfortably lay supine
- 02 Sat (respiratory issues)
- Handgrip strength measurement
- Blood pressure and pulse
- Frame size assessment

Other assessments/measurements:

- Other circumferences (pediatric, head; sports, bicep; muscle injury, atrophy of specific muscle(s); amputation)

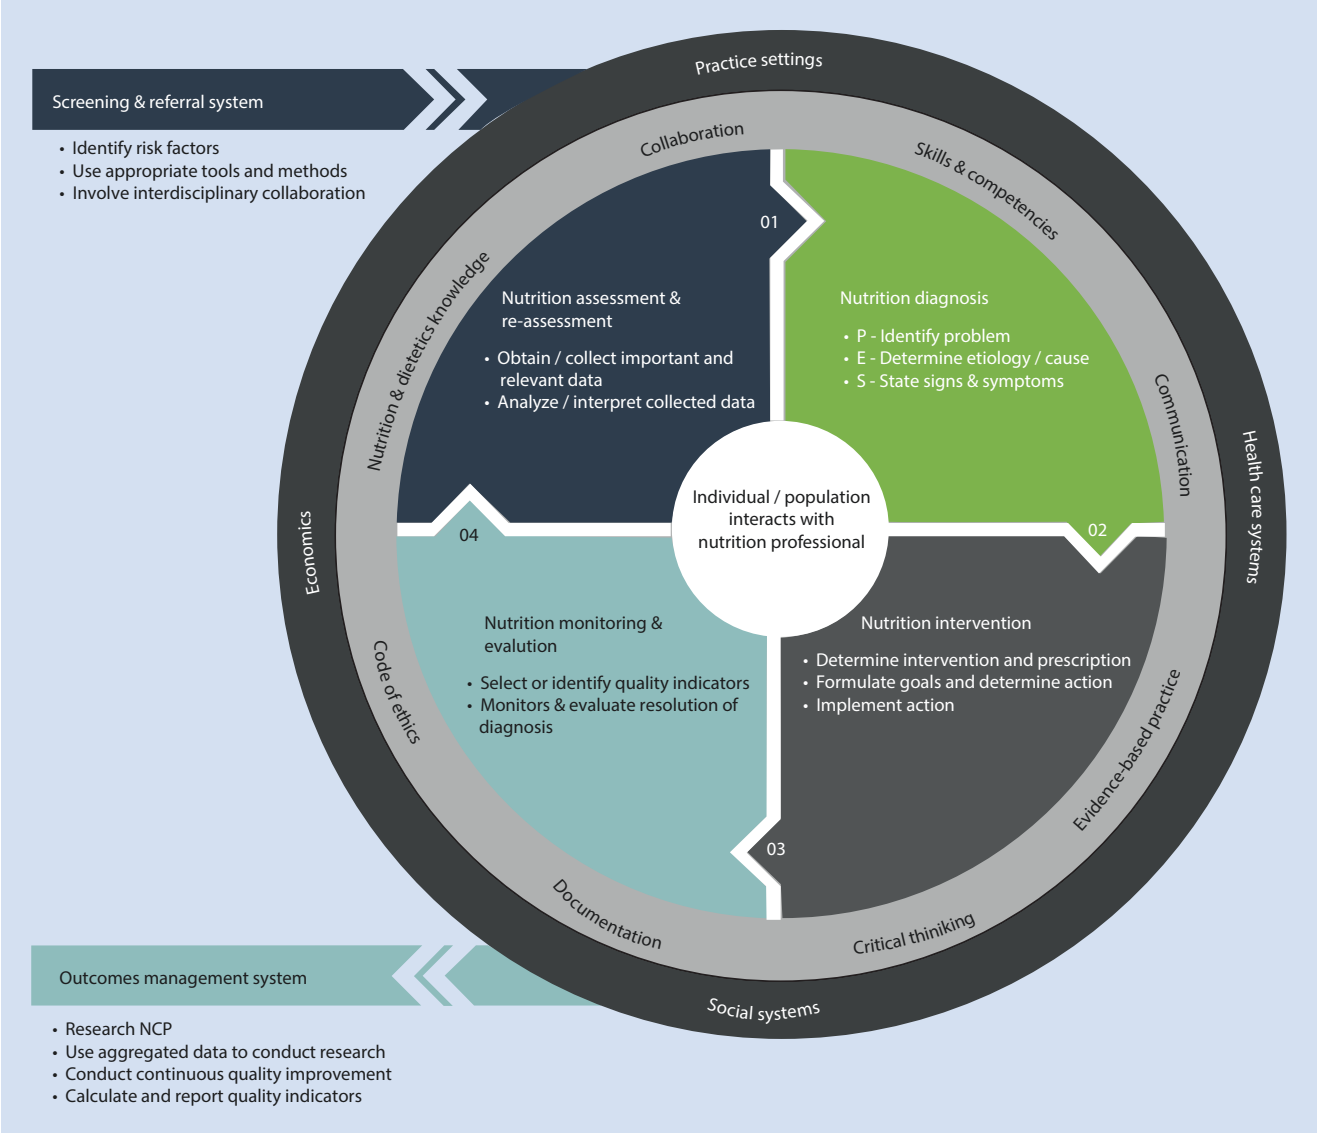

Fig. 55.1 The Nutrition Care Process highlights the importance of systematically combining elements of assessment, diagnosis, intervention, monitoring, and evaluation (ADIME) in the long-term management of patients. (Reprinted from Swan et al. [13]. With permission from Elsevier.)

- Zinc tally
- Iodine patch test
- Urinary pH
- Urinary ascorbic acid

55.1.3.3 Review Forms with Client

- Nutrition intake forms (initial comprehensive or brief follow-up form)
  - Fill in blanks and ask questions in areas needing clarification or expansion.
  - Ask additional questions, if necessary.
- Diet diary
- Review important findings in lab work/note labs needing to be monitored/retested and timeline.
- Review BIA results and other measurements.

55.1.3.4 Develop Priorities and Create Nutrition Action Plan

- Review most important nutrition/lifestyle changes to accomplish goals within anticipated time and client adherence to plan.
- Review supplement recommendations for understanding, tolerance, and manageability.
- Discuss important lifestyle changes (exercise, sleep, stress management, food preparation, procurement).
- Discuss whether further laboratory testing is recommended.
- Set measurable goals for next appointment.
- Write and provide a copy to the client of the nutrition action plan for the client to have record and reference to his/her nutritional goals and actions.

55.1.3.5 Review Other Recommendations

- If recommended, explain any further nutritional laboratory testing recommended by you, the physician, or advanced practice registered nurse (APRN).
- Schedule follow-up, "touch base," and phone call within a week for 10–15 minutes to answer questions and monitor progress of nutrition action plan.
- Plan time for follow-up visit: 1–6 months, depending on the complexity of the case and nutrition action plan.

55.1.3.6 Documentation and Follow-Up

- After appointment, organize the chart, notes and laboratory results.
- Ensure action items are followed-up and completed (email articles, "to-dos," recipes, laboratory requisition, testing kits, etc.).
- Document (write, type, dictate) the nutrition note and finalize by signing and submitting to the referring doctor for review and/or signature.
- Write the nutrition and supplement plan, if necessary.
- What should be done prior to the next visit (labs, diet diary, etc.)?
- Document treatment goal(s) and plan for client.
- Based on nutrition assessment, develop nutrition diagnostic statements and intervention (plan) by following the Nutrition Care Process (NCP) form for Nutrition Diagnostic Statements, PES:
  - Problem
  - Etiology
  - Signs/symptoms (◘ Figs. 55.2, 55.3, and 55.4)

55.1.4 Chronic Disease Pathophysiology

55.1.4.1 Nutrient Insufficiencies

1. IDU/MAPDOM
2. Nutritional triage theory
3. Long latency nutritional insufficiencies

55.1.4.2 Inflammation/Immune Dysregulation

1. Nutritional influences on inflammation: eicosanoids and bioflavonoids
2. Nutritional influences on immune regulation: nutrient control and cytokine metabolism

55.1.4.3 Biochemical Individuality

1. Signs and symptoms
2. Phenotype
3. Family history
4. Genomics/genotype/methylation
5. Environmental history

55.1.4.4 Lifestyle

1. Activity
2. Sleep
3. Community (beliefs/self-care)

55.1.4.5 Energy Dysfunction

1. Mitochondrial ATP production (glycolysis, gluconeogenesis, ketosis)
2. Dietary intake and output
3. Body composition

55.1.4.6 Toxic Load

1. Metabolic influences of toxic substances (heavy toxic metals, petrochemicals, etc.)
2. Metabolic influences of toxic stress factors (lack of sleep, emotional, etc.)
3. Toxic load = total toxic influence on an individual's metabolism
4. Toxic epigenetic influence on gene expression

55.1.4.7 Sleep and Stress

1. Sleep quality reflects state of circadian rhythm affecting all systems positive or negative.
2. Stress perturbs immune and hormonal and circadian rhythm and impacts nutrient status.

55.2 Glossary

Bioflavonoid A plant pigment responsible for the colors found in fruits and vegetables that has antioxidant properties beneficial to humans. Bioflavonoids include flavonols (quercetin), favanones (hesperetin), isoflavones (genistein), and anthocyanidin (cyanidin) [1].

Body composition An individual's body percentage of fat, bone, muscle, and intra/extracellular hydration. Chronic disease expression of altered body fat distribution is an important consideration in body composition and usually measured as waist circumference, waist-to-hip ratio, and waist-to-height ratio.

Cytokine metabolism Cytokines are four families of mostly lymphoid cells: interleukins (ILs), tumor necrosis factors (TNFs), interferons (IFNs), colony stimulating factors (CSFs). Cytokines are produced in response to immunological challenges from nutritional deficiency, infection,

Complaints/Concerns

What do you hope to achieve in your visit?

If you had a magic wand and could erase three problems, what would they be?
(list your three main health concerns)

1												
2												
3												

Fig. 55.2 Nutrition new patient intake form

If you had a magic wand and could erase three problems, what would they be?
(list your three main nutrition concerns)

1												
2												
3												

When was the last time you felt well?												

Did something trigger your change in health?

55

The biggest challenge(s) to reaching my nutrition goals is/are?

In the past, I have tried the following techniques, diets, behaviors, etc. to reach my nutrition goals…

What makes you feel better?												
What makes you feel worse?												

What is the lowest body weight that you have been comfortably able to maintain for at least 2 years in your adult life, since around age 30?												

Please note any past or current injuries:

Fig. 55.2 (continued)

Readiness Assessment

Rate on a scale of 5 (very willing) to 1 (not willing)
In order to improve your health, how willing are you to:

Significantly modify your diet	☐ 5 ☐ 4 ☐ 3 ☐ 2 ☐ 1
Take several nutritional supplements each day	☐ 5 ☐ 4 ☐ 3 ☐ 2 ☐ 1
Keep a record of everything you eat each day	☐ 5 ☐ 4 ☐ 3 ☐ 2 ☐ 1
Modify your lifestyle (e.g., work demands, sleep habits, exercise)	☐ 5 ☐ 4 ☐ 3 ☐ 2 ☐ 1
Practice a relaxation technique	☐ 5 ☐ 4 ☐ 3 ☐ 2 ☐ 1
Engage in regular exercise/physical activity	☐ 5 ☐ 4 ☐ 3 ☐ 2 ☐ 1
Have periodic lab tests to assess your progress	☐ 5 ☐ 4 ☐ 3 ☐ 2 ☐ 1

How much ongoing support and contact (e.g., telephone, e-mail) from the nutritionist would be helpful to you as you implement your personal health program?

Allergy Information

Please list food allergies	
Please list non-food allergies	
What type of allergic symptoms do you experience?	
Notes:	

Fig. 55.2 (continued)

Medical History

Name:	Reason:
Name:	Reason:
Name:	Reason:
Name:	Reason:
Name:	Reason:
Name:	Reason:
Name:	Reason:

Have you had prolonged or regular use of Tylenol? ☐ Y ☐ N

Have you had prolonged or regular use of acid -blocking drugs (Tagamet, Zantac, Prilosec, etc.)? ☐ Y ☐ N

Frequent antibiotics >3 times per year? ☐ Y ☐ N Long term antibiotics? ☐ Y ☐ N

Fig. 55.2 (continued)

Environmental Information

Do you have known adverse food reactions or sensitivities? ☐ Y ☐ N	If yes, please describe symptoms.
Are you exposed regularly to any of the following? *(check all that apply)*	What is your occupation?
☐ Ciga rette smoke ☐ Auto exhaust/fumes ☐ Dry-cleaned clothes ☐ Nail polish/hair dyes ☐ Heavy metals ☐ Teflon Cookware ☐ Aluminum Cookware ☐ Perfumes ☐ Paint fumes ☐ Mold ☐ Pesticides ☐ Fertilizers ☐ Pet dander ☐ Chemicals	Please note any regular exposure to harmful chemicals/substances. Please not any past exposure to harmful chemicals/substances.
Do you use any recreational drugs? If so, please note.	

Notes:

Lifestyle Information

Do you engage in moderate cardiovascular physical activity at least 3 days a week, for a minimum of 20 minutes duration? (brisk walking, jogging, hiking, cardio exercise classes, cycling, stair-climbing, etc.)

☐ Y ☐ N

Activity	Type/Intensity (low-moderate-high)	# Days/Week	Duration (minutes)
Stretching/Yoga			
Cardio/Aerobics			
Strength Training			
Sports or Leisure			

Rate your level of motivation for including exercise in your life? ☐ Low ☐ Med ☐ High

Note any problems that limit your physical activity.

Fig. 55.2 (continued)

Lifestyle Information (continued)

Do you smoke? ☐ Y ☐ N	How many years?
Packs per day?	2nd hand smoke exposure? ☐ Y ☐ N
Excess stress in your life? ☐ Y ☐ N	Easily handle stress? ☐ Y ☐ N
Daily Stressors: *Rate on a scale of 1 (low) to 10 (high)* ☐ Work____ ☐ Family____ ☐ Social____ ☐ Finances____ ☐ Health____ ☐ Other:____	
Do you feel your life has meaning and purpose? ☐ Y ☐ N ☐ unsure	Do you believe stress is presently reducing the quality of your life? ☐ Y ☐ N
Average number of hours you sleep per night during the week?	Average number of hours you sleep per night on weekends?
Trouble falling asleep? ☐ Y ☐ N	Rested upon waking? ☐ Y ☐ N
Do you wake up during the night? ☐ Y ☐ N If yes, how many times?	
Note the approximate times you generally wake during the night.	
How would you rate the overall quality of your sleep? *low quality* 1 2 3 4 5 *high quality*	

Family History

Surgeries/Hospitalizations

Please list any surgeries or hospitalizations (include dates and your ages if known).

Dental History
Do you have any silver/mercury amalgam fillings? ☐ Y ☐ N If **Y**, how many?
Do you have any ☐ Gold fillings ☐ Root canals ☐ Implants ☐ Bridges ☐ Crowns
Do you have any ☐ Tooth pain ☐ Bleeding gums ☐ Gingivitis ☐ Chewing problems
Do you visit a dentist regularly (twice per year)? ☐ Y ☐ N
Have you ever had an infection in your jawbone? ☐ Y ☐ N
TMJ : ☐ grinding teeth ☐ jaw clicking ☐ braces? If yes, what age ____ ☐ surgery ☐ jaw pain
Teeth: ☐ extraction? How many? _____ ☐ Which teeth are missing? (# or name)_____

Ingestion: Nutrition History

Have you ever had a nutrition consultation? ☐ Y ☐ N

Have you made any changes in your eating habits because of your health? ☐ Y ☐ N

Please describe.

Do you currently follow a special diet or nutritional program? ☐ Y ☐ N

Check all that apply.

☐ Low fat	☐ Low Carb	☐ High protein	☐ Low sodium
☐ No Gluten	☐ Vegetarian	☐ Vegan	☐ Diabetic
☐ No Dairy	☐ No Wheat	☐ Weight Loss	☐ Other _____

How often do you weigh yourself?

Fig. 55.2 (continued)

Have you had any recent history of weight loss or weight gain? If so, please describe.

How many meals per day do you eat?	How many snacks?
Do you avoid any particular foods? *If yes, describe.*	
If you could only eat a few foods a week, what would they be?	
How many meals do you eat out per week?	☐ 0–1 ☐ 1–3 ☐ 3–5 ☐ more than 5 per week

Check all the factors that apply to your current lifestyle and eating habits:

- ☐ Fast eater
- ☐ Erratic eating patterns
- ☐ Eating too much
- ☐ Late night eating
- ☐ Dislike healthy food
- ☐ Time constraints
- ☐ Travel frequently
- ☐ Do not plan meals or menus
- ☐ Rely on convenience items
- ☐ Family member have different tastes
- ☐ Love to Eat
- ☐ Eat because I have to
- ☐ Have a negative relationship to food
- ☐ Struggle with eating issues
- ☐ Emotional eater (stress, bored, etc.)
- ☐ Confused about food/nutrition
- ☐ Frequently eat fast foods
- ☐ Poor snack choices

Current Eating Habits

Mark the meals you eat regularly: ☐ Breakfast ☐ Lunch ☐ Dinner ☐ Snacks

Where do you obtain your food from: ☐ home prepared from whole foods ____% ☐ organic ___%
☐ home prepared convenience food ____% ☐ eat out ____%

Mark how many times you eat or drink the following items per week:

___ Soda (regular)	___ Fast food	___ Dried fruit	___ Crackers
___ Soda (diet)	___ Candy	___ Canned fruit	___ Pasta
___ Alcohol	___ Ice cream	___ Fresh Fruit	___ Brown rice
___ Hot tea	___ Pudding	___ Jelly/jam	___ White rice

Fig. 55.2 (continued)

___ Cold tea
___ Coffee (regular)
___ Coffee (decaf.)
___ Sugar in coffee
___ Coffee drinks
___ Sweetened drinks
___ Sparkling water
___ Purified water
___ Tap water
___ Fruit juice
___ Lemonade
___ Milk (cow)
___ Milk (goat)
___ Soy Milk
___ Rice Milk
___ Nut Milk
___ Herbal teas

___ Refined sugars
___ Tuna fish
___ Swordfish
___ Sushi/sashimi
___ Salmon/other fish
___ Lunch meats
___ Bacon
___ Hot dogs
___ Whole eggs
___ Red meat
___ Poultry
___ Tofu
___ Tempeh/Miso

Sweeteners:

___ Equal/Nutrasweet (Aspartame)
___ Splenda (sucralose)
___ Saccharin
___ Stevia/Xylitol

___ Sweets (cookies)
___ Green Salads
___ Raw veggies
What kind?

___ Cooked veggies
What kind?

___ Potatoes
___ Yams/Sweet Potatoes
___ Popcorn
___ Cereals
___ Oatmeal
___ Bagels/pretzels
___ White bread
___ Sprouted Br.
___ Wheat Bread

___ Corn tortillas
___ Flour tortillas
___ Potato Chips
___ Tortilla Chips
___ Pizza
___ Yogurt (plain)
___ Yogurt (sweet)
___ Prepared meals (Lean cuisine, etc.)
___ M icrowave meals/soups
___ Restaurant meals (healthy)
___ Restaurant meals (unhealthy)
___ Airplane meals
___ Legumes (beans, lentils)

Notes:

Fig. 55.2 (continued)

Ingestion: Nutrition History (continued)

What are the top three dietary changes do you think would make the most difference in your overall health?	**1.** **2.** **3.**
How committed are you to making dietary changes in order to improve your health?	*not committed* **1 2 3 4 5** *very committed*

Please list all nutritional supplements you currently take daily. Please include brand names and amounts as well as any herbs/botanical products.

Do you drink alcohol? ☐ Y ☐ N If yes, how many drinks per week?

Do you drink coffee or other caffeinated beverages? ☐ Y ☐ N If yes, # daily?

Do you use artificial sweeteners? ☐ Y ☐ N If yes, which ones?

Digestion:

Do you feel like belching or are you bloated after eating? ☐ Y ☐ N

Do you have (or had) any eating disorders? ☐ Y ☐ N If yes, please describe.

Bowel Movements: How often? _____ Color? _____ Consistency? _____

Your Birth: ☐ Natural/vaginal ☐ C-Section

Were you breastfed as an infant (if known)? ☐ Y ☐ N

Please note anything additional about your nutrition/eating habits.

Fig. 55.2 (continued)

Fats and Oils

Please indicate how many times PER WEEK you eat the following fats/oils.

OMEGA 9 *(stabilizer)* ~50% of daily fat calories Oleic Fatty Acid	___ Almond Oil ___ Almonds/Cashews ___ Almond butter ___ Avocados ___ Peanuts ___ Peanut butter (natural/soft)	___ Olives ___ Olive Oil ___ Sesame Seeds/Tahini ___ Hummus (tahini oil) ___ Macadamia Nuts ___ Pine Nuts
OMEGA 6 *(controllers)* *Essential Fatty Acid Family* *~30% of daily fat calories* **LA** ☐ GLA ☐ DGLA ☐ AA	___ Eggs (whole), organic (AA) ___ Meats (commercial) (AA) ___ Meats (grass-fed, org) (AA) ___ Brazil nuts (raw) ___ Pecan (raw) ___ Hazelnuts/Filberts (raw) ___ Hemp Seeds	___ Evening Primrose (GLA) ___ Black Currant Oil (GLA) ___ Borage Oil (GLA) ___ Hemp Oil ___ Grapeseed Oil ___ Sunflower Seeds (raw) ___ Pumpkin seeds (raw)
OMEGA 3 *(fluidity/communicators)* *Essential Fatty Acid Family* *~10% of daily fat calories* ALA ☐ EPA ☐ DHA	___ Fish Oil capsule: ↑DHA ___ Fish Oil capsule: ↑EPA ___ Fish (salmon/fin-fish) ___ Fish (shellfish) ___ Flax seeds/meal	___ Flax Oil ___ UDO's DHA Oil ___ Algae ___ Greens Powder w/algae ___ Chia seeds
BENEFICIAL SATURATED *(structure)* *~10% of daily fat calories* Short Chain/Medium-chain Triglycerides	___ Coconut Oil ___ Butter, organic ___ Ghee (clarified butter) ___ Dairy, raw & organic	___ Meats, grass-fed ___ Wild game ___ Poultry, organic ___ Eggs, whole organic
DAMAGED FATS/OILS (promoting stress to cells & tissues) *Should be <5% (try to avoid)* Trans Fats Acrylamides Odd-Chain Fatty Acids VLCFA/damaged	___ Margarine ___ Reg. vegetable oils (corn, sunflower, canola) ___ Mayonnaise (Commercial) ___ Hydrogenated Oil (as an ingredient) ___ "Imitation" cheeses ___ Tempura	___ Doughnuts (fried) ___ Deep-fried foods ___ Chips fried in oil ___ Reg. Salad dressing ___ Peanut Butter (JIF, etc) ___ Roasted nuts/seeds ___ Non-dairy products

Fig. 55.2 (continued)

Nutrition Physical Exam

Review the following and check, circle, and make notes as you proceed through the nutrition assessment.

General Appearance: ☐ Age (looks older/younger?) ☐ Body type (apple/pear?) ☐ Central Adiposity ☐ Fatness (excessive/diminished) ☐ Neat? ☐ Sick? ☐ Tremor/Tic ☐ Vitality/energy	**Face/Neck:** ☐ Eyes (clear, red, spots, discharge, dry, tearing?) ☐ Eyes (bulging, swollen) ☐ Eyelid (drooping over eye) ☐ Eyelid/inside (pallor,very red) ☐ Wrinkles (excessive) ☐ Skin color/pigmentation ☐ Cheeks rosacea/redness ☐ Neck/armpit/legs (dark skin) acanthosis nigricans (AN) ☐ Skin (acne, freckles) ☐ Eyebrows (hairless ends?) ☐ Ears (crease in lobe) ☐ Nasal function (stuffy, clear) ☐ Thyroid (goiter?)	**Skin:** ☐ Easy bruising ☐ Rashes/hives ☐ Bumps on back of arms? ☐ Excessive Tan/Pale color? ☐ Dry/Flaky/Oily? ☐ Scars ☐ Tatoos ☐ Warts/ abnormal spots ☐ Piticulae (deep red spots) ☐ Front thighs (pustules) dermatitis herpetiforme
Handshake: ☐ Temperature (hot, cold, moist) ☐ Strength/Tremor		**Nails:** ☐ Spots, ridges, pale nail beds, white lines ☐ Strong curve? ☐ Fungus (fingernails, toes?)
Head/Hair/Scalp: ☐ Head shape ☐ Hair (thin/thick/color/dyes) ☐ Hair loss (head/body) ☐ Flaky scalp? ☐ Scalp: sores/scabs	**Mouth:** ☐ Lips (cracking, shape) ☐ Lips (angular cracks) ☐ Tongue (fissures, decreased taste, smooth?) ☐ Breath odor (halitosis, acetone, garlic, musty, ETOH) ☐ Bleeding gums	**Structure:** ☐ Neck/posture ☐ Gait ☐ Muscles/tone ☐ Joints/connective tissue ☐ Physical disability
Hydration: ☐ Skin, tongue ☐ BIA: ICW/ECW/TBW ☐ Ankle/wrist signs of edema/dehydration - "pitting" ☐ Constipation/diarrhea		

Notes:

Nutrition Assessment Summary Form
Reason for Nutrition Appointment or follow-up, "Chief Complaint" or relevant Medical Diagnoses

Any Foods Withdrawn

Age	Wt	Ht	Waist Circ:	Phase <	% IBW
Nutrition Physical Exam, Dental History (I, D, U)					

Subjective (Including Past Medical History (PMH) and History of Present Illness (HPI)):

Goal(s) of Appointment:

MSQ Summary (may use top ~3 categories)	Medications/Supplements
Digestion (BM frequency/form, symptoms) (D)	Labs: Abnormal or Meaningful "Normal" Values
Diet (I, D, U)	Lifestyle: Stress, Environmental Exposure, Physical Activity (I, D, U)
Assessment of Nutrition Status // Progress and Monitoring/Evaluation of previous plan	
Plan // Goals	

I: Ingestion D: Digestion U: Utilization

Fig. 55.3 Nutrition assessment summary form

genotype, toxic influences, stress, and/or physical injury. Chronic inflammatory cytokine production contributes to all chronic disease.

Eicosanoid Arachidonic acid (AA) and eicosapentaenoic acid (EPA) serve as precursors for the synthesis of eicosanoids (prostaglandins, prostacyclins, leukotrienes, and thromboxanes) which have an anti-inflammatory effect.

Energy dysfunction Mitochondrial energy metabolism, dietary intake and output, effect on body composition, physical activity, and influence of stress on blood glucose/insulin/hormonal energy relationships.

Epigenetics Environmental influences that control gene activity within a cell without changing the gene structure [2]. Each gene has the capability of about 40,000 different expressions depending on the environmental messaging. Epigenetic effects can be passed on from generation to generation. The discovery of epigenetics has revealed a nongenetic mode of inheritance that influences our health. The most vulnerable periods in the lifespan for epigenetic changes are in utero/pregnancy, early childhood, teenage years, menopause (female), and andropause (male).

Gluconeogenesis During low-carbohydrate intake or starvation, protein is used as de novo synthesis of glucose [3]. Gluconeogenesis is about 60% efficient in ATP production.

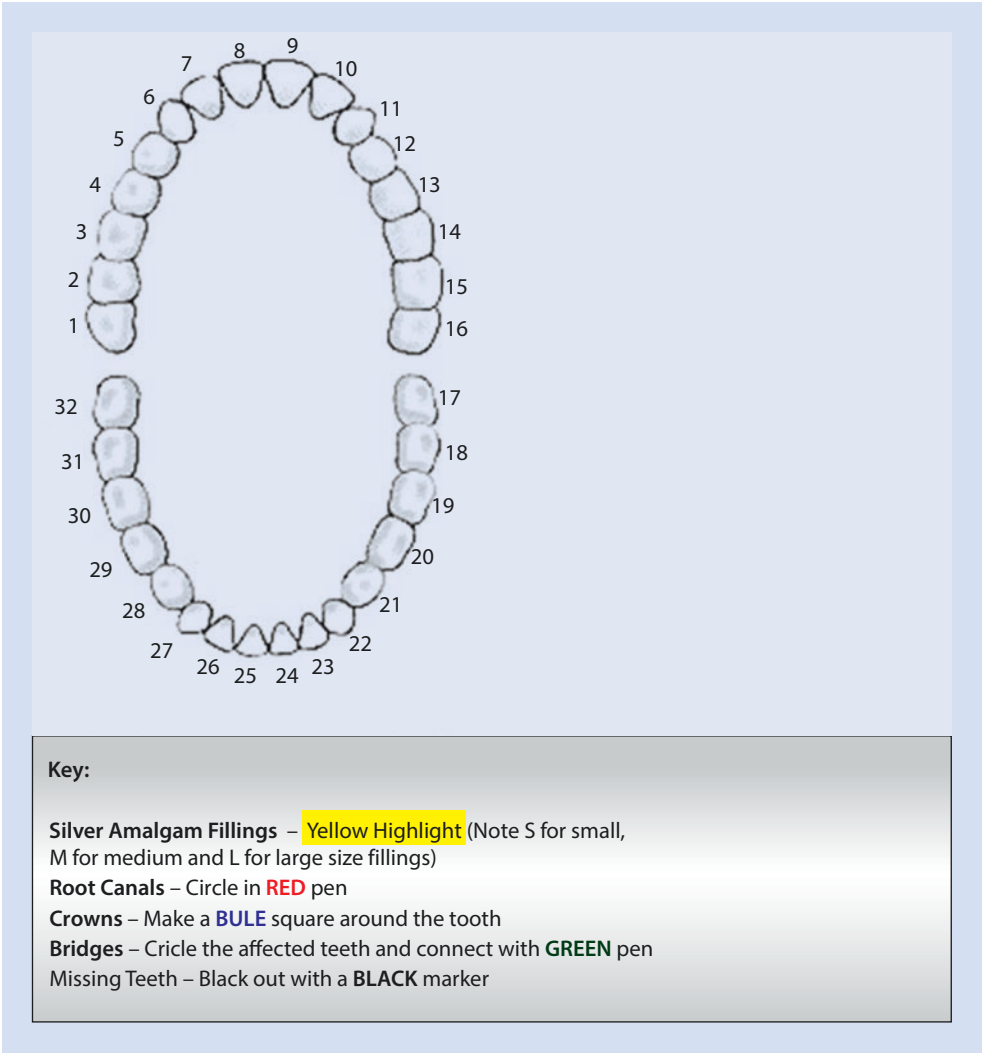

Fig. 55.4 Dental health impacts the entire physiologic function from neurologic to gastrointestinal and multiple organ systems. It is a critical part of the nutritional physical examination

Glycolysis Anaerobic pathway to release glucose without the presence of oxygen; lactic acid is the end product [4]. Glycolysis is about 30% efficient in ATP production.

I-D-U Dietetic and integrative medicine nutritional assessment heuristic of an individual's nutrition status including intake, digestion and utilization of nutrients.

Ketosis To maintain metabolic homeostasis, ketone metabolism is the most energetically efficient metabolic fuel to synthesize glucose using fatty acids and ketone bodies under periods of prolonged food restriction or low-carb/high-fat dietary regimen.

Lack of sleep Underlying deregulation of neurotransmitters and hormones that help flip the on-off switch between waking and sleep. Lack of sleep quality and duration disturbs the 24-hour circadian rhythm and management of wake-time energy. Lack of sleep associations are allergies, central adiposity, diabetes, hypertension, heart disease, and other physical ailments [5].

Lifestyle and community Most chronic disease often has a social basis as well as a biological basis. An individual's social network can influence their health and alter gene expression [6]. An individual is more likely to be healthy if they are a part of a community that supports a healthy diet, lifestyle, and emotional environment.

Long latency nutritional insufficiencies The presumption has been that if the intake of the nutrient is sufficient to prevent the expression of the index disease (i.e., iodine and goiter, vitamin D and rickets, etc.), then the nutrient intake is sufficient for the entire organism. But a nutrient deficiency could have long-term consequences and contribute to chronic disease, either by a similar mechanism to that inducing the index disease or by an entirely different mechanism [7].

MAPDOM Within the "U" of the I-D-U assessment heuristic, the MAPDOM acronym represents the six most important nutritional categories determining an individual's health. MAPDOM stands for: minerals, antioxidants, pro-

teins, D-fat-soluble vitamins (D, E, A, K), oils/fats, and methylation nutrition.

Methylation Denotes the addition of a methyl group to a substrate for the substation of an atom or group by a methyl group (-CH3). Can be involved in modification of heavy metals, regulation of gene expression, and regulation of protein function and RNA metabolism [8]. Primary nutrients involved as cofactors in methylation metabolism are B6, B12, folate, B2, zinc, and magnesium.

Nutritional triage theory When the availability of a micronutrient is inadequate, metabolic resources will ensure that functions needed for short-term survival are protected at the expense of functions whose lack of a micronutrient only has long-term consequences [9].

Petrochemicals Derived from petroleum or natural gas (ethane, propane, butane, and other hydrocarbons), petrochemicals are used to manufacture artificial products including plastic, medicine, medical devices, cosmetics, furniture, cars, and computers [10]. Humans can ingest phytochemicals or it can be absorbed through the skin. When they accumulate in tissues and organs, they are responsible for brain, nerve, and liver damage, birth defects, cancer, asthma, hormonal disorders, and allergies.

Toxic heavy metals Metals and metal compounds that have a negative effect on human health by building up in biological system [11]. They include arsenic, beryllium, cadmium, hexavalent chromium, lead, and mercury. Other toxic metals may include essential metals if imbalanced (zinc and copper), medicinal metals (platinum and bismuth), metals in emerging technology (indium and uranium), toxic metalloids (arsenic and antimony) and certain nonmetallic elements if imbalanced (selenium and iodine) [12] (◘ Fig. 55.5).

55.3 Gastrointestinal Assessment (◘ Fig. 55.6, ◘ Table 55.1)

55.3.1 Testing for Low Stomach Acidity (Hypochlorhydria)

A normal stomach acid level creates a pH of 1.5–2.5. As we age, the parietal cells in the stomach lining produce less hydrochloric acid (HCl) or "stomach acid." In fact, half of people over the age of 60 have low stomach acid. Low stomach acid can also be caused by long-term use of acid-blocking medications (i.e., Pepcid®, Prilosec®, etc.), which increases stomach pH to 3.5 or higher. This change in pH inhibits pepsin, which is necessary for protein digestion. Interestingly, symptoms of low acidity often mimic those of high acidity.

Stomach acid is necessary for absorption of minerals (magnesium, calcium, iron, zinc, and copper) and vitamin B12. Also, stomach acid provides our first defense against food poisoning, *H. pylori*, and parasitic and other infections. Without adequate acid, we leave ourselves open to decreased immune resistance. Overgrowth of bacteria in the intestinal tract occurs in 20 percent of people aged 60 to 80 and in 40 percent of people over 80.

The following may cause hypochlorhydria: pernicious anemia, chronic *H. pylori* infection, long-term use of proton pump inhibitors (like Prilosec®), autoimmune gastritis, and mucolipidosis type IV.

55.3.2 Common Symptoms of Hypochlorhydria

Bloating, belching, burning, or flatulence immediately after meals	Indigestion, diarrhea, or constipation
A sense of fullness after eating	Nausea after taking supplements
Dilated blood vessels in cheeks/nose	Itching around the rectum
Acne	Undigested food in stool
Iron deficiency	Chronic candida infections
Chronic intestinal parasites or abnormal flora	

55.3.3 Diseases Associated with Hypochlorhydria

Addison's disease	Diabetes	Hypothyroidism
Asthma	Eczema	Lupus erythematosus
Celiac disease	Gallbladder disease	Myasthenia gravis
Chronic autoimmune disorders	Graves disease	Osteoporosis
Chronic hives	Hepatitis	Pernicious anemia
Dermatitis herpetiformis (herpes)	Hyperthyroidism	

55.3.4 Self-Testing and Treatment for Low HCL/Hypochlorhydria

1. Begin by taking one 350–750 mg capsule of betaine HCL with a protein-containing meal. A normal response in a healthy person would be discomfort – basically heartburn. If you do not feel a burning sensation, begin taking two capsules with each protein-containing meal. Meals should last a minimum of 20 minutes and a maximum of 60 minutes. Remember to chew every bite well (your stomach does not have teeth).
2. If there are no reactions after 2 days, increase the number of capsules with each meal to three.

Anthropometrics: Height ____ Weight ___ BMI ___ Body Fat % ____ BP _____/_____ Pulse ____
Waist Circum _____ Waist Circum/Height Ratio: _____

Assessment	History/Physical	Labs/Procedures	Nutrition Diagnosis	Nutrition Intervention
Intake - food, liquids, organic vs. non-, food preparation, toxin intake, processing, packaging, air/skin intake (toxin)				
Food Nutrients Meal Timing & Mastication Toxin Intake Fluids				
Digestion - Adeq HCL, digestive enzymes, bioavailability, meds, emotional stress, toxins, genetics or acquired deficits				
Protein/Carb Digestion Digestion of Fat Enzyme deficiency Endotoxins / Pathogens Microbiome GI Structure				
Utilization - MAPDOM -Intestinal competence, food allergies, malabsorption, meds, toxins ,microbial overgrowth				
Cellular & Molecular metabolism Hydration/fluid status Nutrient absorption				
MAPDOM - Nutrient Requirements -affected by Disease states, stress, environment, age, drugs, genetic differences				
Mineral Status Fiber BM frequency, consistency				
Antioxidants Water Soluble Vitamin C / Phytonutrients				
Protein Status Wound healing Connective tissue Glucose transport Immune status				
D / Vitamin D, A, K Contraindications Vitamin E				
Oils/Lipid/Fatty Acids EFA/Omega-9/ Beneficial Saturated Fats Inflammation status				
Methylation - Clinical symptoms - genomics or Fam Hx - biomarkers - r/o Mood Disorder/Cancer				
Sum total of previous factors influence assessment -Nutritional Status				

Fig. 55.5 Nutrition status assessment I-D-U worksheet

Subjective	Objective	GI tract
Medical symptoms questionnaire GI symptoms: constipation, diarrhea, stomach pain, etc. Other themes in systems: headaches, sinuses/nasal, frequent illness, emotions... **Diet history** Themes of diet (repetitive intake of foods + symptoms) Food symptoms Genomic risk **Patient report of food sensitivities** **Nutrition-focused physical** Nails, hair, skin (rashes) Abdominal exam: RUQ, LUQ, RLQ, LLQ Oral cavity exam **Water balance (BIA, edema)**	**Conventional labs** Small bowel biopsy IgE testing: anaphylaxis IgG: primarily systemic symptoms IgA: primarily GI symptoms Micronutrients: suspected malabsorption, general screening (Fe, B12, Vitamin D) Hydrogen breath Mannitol/lactulose **Genetic testing** **functional labs** CDSA Neurotransmitters: emotional indication, insomnia Organic acids Stomach acid test	**Mouth** Saliva Enzymes (amylase, lipase) Mastication quality/ time Dental health **Esophagus** Eosinophilic esophagitis Swallow difficulties GERD or sensation of discomfort **Stomach** pH (too high/low) **Biliary - Bile acids** **pancreas** Elastase, amylase, etc. **Small intestine** Flora (beneficial, imbalanced, dysbiosis) Surgeries/disease (IBD/IBS) **Large intestine** Short-chain fatty acids Surgeries/disease (IBD/IBS) β-glucuronidase Inflammation (lactoferrin, calprotectin)

Fig. 55.6 Gastrointestinal assessment. GI assessment is a fundamental component of integrative and nutritional nutrition therapy and should be evaluated at every visit. Documentation at each visit is critical to assess progress

3. Continue increasing the number of capsules every 2 days, using up to eight capsules with each meal if necessary. These dosages may seem large, but a normally functioning stomach manufactures considerably more. You'll know you've taken too much if you experience tingling, heartburn, diarrhea, or any type of discomfort including a feeling of unease, digestive discomfort, neck ache, backache, headache, or any new odd symptoms. If you experience tingling, burning, or any symptom that is uncomfortable, you can neutralize the acid with 1 teaspoon of baking soda in water or milk.
4. When you reach a state of tingling, burning, or any other type of discomfort, cut back by one capsule per meal. If the discomfort continues, discontinue the HCL and consult with your healthcare professional.
5. Once you have established a dose (not to exceed eight capsules without consulting with your healthcare provider), continue this dose.
6. With smaller meals, you may require less HCL, so you may reduce the amount of capsules taken.
7. Individuals with very moderate HCL deficiency generally show rapid improvement in symptoms and have early signs of intolerance to the acid. This typically indicates a return to normal acid secretion.
8. Individuals with low HCL/pepsin typically do not experience such quick improvement, so to maximize the absorption and benefits of the nutrients you take, it is important to be consistent and continue your HCL supplementation.

Precautions: Administration of HCL/pepsin is contraindicated in peptic ulcer disease. HCL can irritate sensitive tissue and can be corrosive to teeth; therefore, capsules should not be emptied into food or dissolved in beverages.

When you have adequate HCL, you will have good absorption of all your nutrients and can then watch the rapid regeneration of health in every brain/body system.

Table 55.1 Fats and oils survey

Fats and oils survey	Name	Date
Please indicate how many times per week you eat the following fats/oils		
Omega-9 (*stabilizer*) ~50% of daily fat calories Oleic fatty acid	___Almond oil ___Almonds/cashews ___Almond butter ___Avocados ___Peanuts ___Peanut butter (natural/soft)	___Olives ___Olive oil ___Sesame seeds/tahini ___Hummus (tahini oil) ___Macadamia nuts ___Pine nuts

Nutritional Diagnosis Resources

Leigh Wagner, Diana Noland, and Jeanne A. Drisko

56.1 Abbreviations – 1044

© Springer Nature Switzerland AG 2020
D. Noland et al. (eds.), *Integrative and Functional Medical Nutrition Therapy*,
https://doi.org/10.1007/978-3-030-30730-1_56

Nutritional diagnosis (ND) as a terminology beyond ICD CM codes related to malnutrition that emerged in 2000 as defined by the Medicare Medical Nutrition Therapy (MNT) legislation, in coordination with the American Dietetic Association (Academy of Nutrition and Dietetics).

ND assists the nutrition practitioner in defining nutrition-related metabolic injuries to guide therapy, intervention, and counseling for the purpose of disease management. MNT involves in-depth individualized nutrition assessment and a duration and frequency of care using the Nutrition Care Process to manage diseases as outlined by Medicare law.

56.1 Abbreviations

CPT codes: Current Procedural Terminology codesprocedure codes that describe the healthcare professional services

ICD: International Classification of Disease

MNT Codes 97802, 97803, and 97804 (CPT codes that RNDs use).

Because codes change over time and across insurance programs, it is important with the current codes related to nutrition professionals are up to date:

Medicare MNT

- ► cms.gov/medicare/coding/icd10/2017-icd-10-cm-and-gems.html
- ► eatrightpro.org/payment/coding-and-billing/diagnosis-and-procedure-codes/diagnosis-codes-for-medicare-mnt

Malnutrition

57.1 How to Help Your Friends and Family Support Your Lifestyle Changes When You Follow a Specialized Diet (Table 57.1)

Table 57.1 Specialized diets for GI healing: Allowed foods and forbidden foods *(italics = none)*

	Comprehensive elimination diet	Gluten-free/casein-free	Specific carbohydrate diet	Gut and psychology syndrome diet	Anti-fungal diet	FODMAP diet	Restoration diet
Protein	ALL unprocessed meats: chicken, turkey, duck, goose, quail, ostrich, fish, shellfish, lamb, venison, rabbit, eggs. Wild game	ALL unprocessed meats	ALL unprocessed meats: beef, pork, chicken, turkey, duck, goose, quail, ostrich, fish, shellfish, lamb, venison, rabbit, eggs. Processed meats that do not have any SCD forbidden ingredients	Eggs, fresh (if tolerated) Fresh meats (not preserved), fish, shellfish Broths with every meal Canned fish in oil or water only	ALL unprocessed meats: beef, pork, chicken, turkey, duck, goose, quail, ostrich, fish, shellfish, lamb, venison, rabbit, eggs. Tofu, tempeh, texturized vegetable protein	All unprocessed meats Eggs	All unprocessed meats in small amounts: pureed, well-cooked, stews, soups
Dairy products and dairy alternatives	NONE Dairy alternatives are allowed: coconut, hemp, rice	NONE Dairy alternatives are allowed: nut, coconut, hemp, rice, soy	All natural cheeses ***except for ricotta, mozzarella, cottage cheese, cream cheese, feta, processed cheeses and spreads.*** Homemade yogurt cultured 24 hours	All natural cheeses Yogurt – homemade	Eggs, plain yogurt (cow, sheep, goat) with live cultures, organic soy milk, soy cheese, coconut milk, unaged goat cheese	Lactose-free dairy products: milk, cottage cheese, rice milk, almond milk, hemp milk	Goat milk or sheep milk kefir. Dairy alternatives as coconut kefir
Fats and oils	Sunflower, olive, flax, ghee, coconut, avocado, nut oils	ALL	Avocados, olive oil, coconut oil, corn oil, avocado oil, etc.	Butter, ghee, coconut, avocado oil, olive oil	ALL	ALL	Ghee, coconut, olive, Sam Queen's restorative ghee
Nuts and seeds	Coconut, pine nuts, chia seeds, flaxseeds, almonds, Brazil nuts, walnuts, chestnuts, filberts, pecans, nut flours, and meals	ALL that are non-processed with dairy or gluten	Almonds, Brazil nuts, walnuts, chestnuts, filberts, pecans, nut flours and meals	Almonds, avocado, Brazil nuts, coconut, filberts, walnuts, chestnuts, pecans, nut flours and meals, peanuts, nut butters	ALL raw. Can roast at home or cook them	***Nuts and seeds in moderation Nut butters in moderation,*** Psyllium	***Nut butters in tiny amounts***

Table 57.1 (continued)

	Comprehensive elimination diet	Gluten-free/casein-free	Specific carbohydrate diet	Gut and psychology syndrome diet	Anti-fungal diet	FODMAP diet	Restoration diet
Non-starchy vegetables	ALL	ALL	Most: fresh, frozen, raw or cooked. Asparagus, broccoli, cauliflower, artichokes, beets, Brussels sprouts, cabbage carrots, celery, cucumbers, eggplant, zucchini, summer squash, rhubarb, peppers, garlic, lettuce, spinach, mushrooms (unless candidiasis), onions, turnips, watercress. NO canned vegetables	Most: fresh, mostly cooked, some raw	ALL	Alfalfa, avocado, bamboo shoots, bean shoot, beets, bok choy, broccoli, chili peppers, carrots, celery, chive, corn, cucumber, eggplant, fennel, kohlrabi, lettuce, olive, parsnip, mushroom, snow peas, spinach, squash, water chestnut, watercress	Well-cooked
Starchy vegetables	ALL except corn	ALL	***NONE: potatoes, yams***	Beets, winter squash ***NONE: potatoes, yams***	***NONE: Exclude corn, yams, potatoes***	peas, potato, sweet potato, taro, turnip, pumpkin,	Well-cooked
Legumes	ALL	ALL	Dried navy beans, lentils, peas, split peas, unroasted cashews, peanuts in shell, natural peanut butter, lima beans, string beans	***Lima beans, peas (dried split, fresh green) These are consumed in later stages of the diet only, best sprouted***	Small amounts, not more than 1 cup cooked per day	Sweet peas, peanuts, peanut butter	Dahl
Fruits	ALL	ALL	ALL. Juices with no additives	ALL, fresh and dried	***Restricted: only whole/fresh or frozen in protein smoothie***	RESTRICTED QUANTITY:1/2 cup serving/no more often than every 2 hours Berries, citrus fruits, cantaloupe, banana, jackfruit, kiwi, grapes, passion fruit, pineapple, rhubarb, guava, pawpaw, lychee	Cooked, smoothies
Grains	Quinoa, millet, amaranth, teff[a], oat[a], tapioca, rice, sorghum	Quinoa, millet, amaranth, teff[a], oat[a], tapioca, rice, sorghum	***NONE***	***NONE***	***NONE***	Barley, oats, quinoa millet, teff[a], oat[a], tapioca, rice, sorghum, seitan, amaranth, buckwheat, arrowroot, sago, oat bran, barley bran NO: WHEAT/RYE	Rice congee

(continued)

Table 57.1 (continued)

	Comprehensive elimination diet	Gluten-free/casein-free	Specific carbohydrate diet	Gut and psychology syndrome diet	Anti-fungal diet	FODMAP diet	Restoration diet
Herbs and spices	All pure spices, fresh or dried	All pure spices, fresh or dried	All pure spices, fresh or dried	All pure spices, fresh or dried	Fresh only	All pure spices, fresh or dried ***No onion*** ***Minor amts of garlic tolerated***	Not at first, then add: turmeric, ginger, cumin, coriander, and other spices
Beverages	Water, broths. Uncaffeinated herbal teas, seltzer, mineral water Diluted juices, vegetable juices	ALL without dairy or gluten	Water, tea, weak, freshly made water Broths	Water, tea, weak, freshly made water Broths	Water, herbal tea	Tea, herbal teas, herbal infusions, hot water, coconut water Coffee: <2 cups daily Chicory/roasted	Broths Water Herbal teas Seltzer, mineral water, diluted juices, diluted vegetable juices
Sweeteners	Use sparingly: brown rice syrup, agave nectar, honey, stevia, fruit sweetener, blackstrap molasses	ALL	Honey if tolerated Saccharine	Honey	Stevia	Maple syrup, rice syrup, Treacle, golden syrup, glucose syrup, NutraSweet, sucralose, aspartame, stevia, saccharine	Use sparingly
Miscellaneous	Broths Medical foods (non-dairy, soy, or gluten-containing) Fermented and cultured foods Vinegar (not white vinegar)	Broths Medical foods (non-dairy, soy, or gluten-containing) Fermented and cultured foods Vinegar	Broths Gelatin Pickles (without additives)	Soups Stews Cellulose in supplements Gin, scotch occasionally Pickles (without additives) Tea, weak, freshly made Vinegar Wine (dry)	Lemon and lime and vitamin C crystals as replacements for vinegar Herbal tea ***Tequila and mead in small amounts***	Jam, marmalade, vegemite, marmite Alcohol: clear refined spirits such as gin and vodka in moderation	Medical Foods Broths Herbal Infusions Coconut kefir Coconut water

57.1.1 Explain What You Are Doing and Why

- As you begin your nutrition and lifestyle changes, you may receive questions or even criticism from family and friends. Sometimes all that is needed to gain their support is to have an honest talk and explain *why* you're making these changes.
- Ask for support. Be positive about your desire to change, and let your friends/family know that encouraging words help you a lot.
- Tell them the positives you are experiencing. "I am avoiding _____ because it makes me feel better, I have more energy, my digestion is better, and I no longer struggle with difficult symptoms."
- If friends and family are interested, provide them with resources that you've gotten from your healthcare team to help your friends and family understand more. They may want to join you in your health quest!

57.1.2 Nutrition Approaches to Wellness Is "The Road Less Traveled"

- By choosing to approach your health and wellness with food and nutrition, you are using "food as medicine" and not a pill to control your symptoms. Be realistic and know that this takes time. These changes will not happen overnight, so be patient and work closely with your nutritionist to continue to steadily heal and achieve your best health and self!

57.1.3 Make Light of It

- If you feel there is unwanted attention on you, make light of the situation. If someone asks, "Why are you not eating _____?", casually respond with "Oh, I'm making some nutrition changes for my health." Then ask a question about them.
- Tell your friends and family that you have a boot camp/dictator nutritionist who demands you make these changes, and you have no other choice. *She's/he's scary!* ☺ We're always happy to be the scapegoat.

57.1.4 Be Confident

- These health changes are ultimately for *YOU*! Friends and family may give you hard time or pressure you to stray from your plan. Regardless, you are the one who will see and feel benefits, so it's important to remind yourself that you're doing it for you! If necessary, talk to them about it. They may not even realize what they are doing.

57.1.5 Plan Ahead: Social Setting and Restaurants

- For social events: bring a dish you know you can eat, eat before you go, or pack a snack to take with you.
- Make suggestions for a restaurant that you trust will have selections for you.
- Gain the support of servers by conveying that you want to *partner* with them to develop your meal as opposed to *telling* them what you need. Ask their opinion. Be positive and cooperative to make it an enjoyable experience for everyone. (If you're unsure whether they take your request seriously, tell them you have a food allergy, which could result in a medical emergency if exposed to a particular food.)
- At restaurants, it doesn't hurt to smile at your server and say, "I promise I'll tip, can I get your help modifying my meal to fit my current health needs?".

57.1.6 My Loved Ones Don't Want to Eat What I Need to Eat

- Explain to them that these changes are about using food to heal your body. Compromise by making meals that they can substitute in items they prefer versus casseroles or mixed dishes.
- If you must, make special meals for you and freeze the rest for future meals while others eat their meal of choice.
- Over time, your friends/family may begin to notice the positive impact of a healthy diet by seeing the physical, mental, and emotional changes *in you* and be more open to trying new foods.

57.2 How to Embrace Your Decision to Follow a Specialized Diet

- **I can't do this. It's too hard** ***"The dangerous thing about excuses is that if we recite them enough times, we actually come to believe they are true"***
- Accepting responsibility for your life is a must. Once you take the responsibility, real change is within your reach. Ask yourself this question: Is it harder to make these changes and feel well or to not make changes and continue to struggle with my symptoms?
- Tip: Begin each day with positive self-talk. Post your favorite inspirational or motivational quotes in the house, pray, practice deep breathing, listen to calming music, exercise, or enjoy the company of others.

- **I can't see a difference** ***"You don't have to see the whole staircase, just take the first step"***
  - You are a work in progress, which means you get there a little at a time and not all at once. Your symptoms didn't develop in a week and will probably not go away in a week.
  - Tip: Consider journaling your symptoms or experiences so you have a self-reported history to reflect back on. You may be improving more than you realize.

- **I can't change my lifestyle** ***"If you want something different, you have to do something different"***
  - Slowly but surely, you'll learn the little things you can do to make these changes easier. Over time, you'll realize what use to seem like a huge inconvenience is now a routine part of your day.
  - Tip: Identify your less helpful habits. Instead of focusing on breaking them, focus on replacing them with new positive habits.

57

- **I can't cook** ***"Keep calm and cook on"***
  - Mistakes are an important part of life. Keep experimenting and you will slowly begin to learn the ways of the kitchen. We provide many recipes and resources that are very basic and can get you started.
  - Tip: Stick with what you are comfortable with and try a new recipe once a week.
  - Take advantage of cooking classes and YouTube videos on "how-to" basics in the kitchen.

- **I can't do this with my work/school schedule** ***"You are confined only by the walls you build yourself"***
  - You will likely be confronted with barriers at some point. Not every day will go according to plan and that's okay. Strive to make the best decision when faced with challenges and use our resources/handouts to provide strategies for various situations.
  - Tip: Let leftovers be your best friend. Cook extra portions at the evening meals or on the weekend to use for the week.

- **I can't see the point of this anymore** ***"Believe you can and you're halfway there"***
  - You're in the driver seat! We strive to help you in any way we can, but you are the one who makes the final decision. Discover the reason *why* you want to make these changes and focus on that why instead of focusing on the challenges.
  - Tip: Find your drive. Find your inspiration. Find your why.

- **I can't afford it** ***"Don't judge each day by the harvest you reap, but by the seeds you plant"***
  - Remind yourself that this is about working toward wellness. If you think healthy is expensive, you haven't priced illness lately.
  - Tip: Use the coupons at the front of the store, shop for what is in season, and plan ahead to avoid spoilage.

Motivational Interviewing

Leigh Wagner, Diana Noland, and Jeanne A. Drisko

58.1 The Practitioner (Healthcare Provider) – 1053

58.2 Observing the Client – 1053

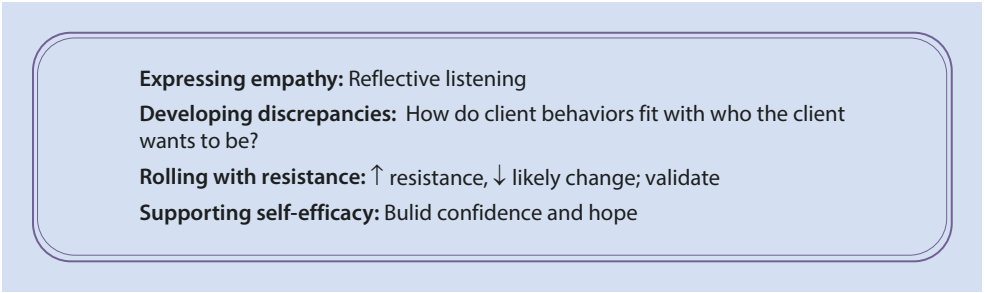
© Springer Nature Switzerland AG 2020
D. Noland et al. (eds.), *Integrative and Functional Medical Nutrition Therapy*,
https://doi.org/10.1007/978-3-030-30730-1_58

Motivational interviewing (MI) is a collaborative person-centered form of guiding to elicit and strengthen a person's motivation for change. It is a counseling technique that is client-centered and goal-oriented. Integrative and functional medicine nutrition practitioners and other practitioners use MI mainly in the clinical setting when working with behavior change one-on-one with clients. The following document summarizes some of the key principles of MI. When observing clinical nutrition patients, look for MI in action, and questions below will help identify whether the practitioner is using MI (Fig. 58.1).

Working with clients with chronic diseases means often practitioners are working toward behavior change. In MI, *ambivalence* is a foundational challenge. In MI, ambivalence refers to both the desire to change and the desire to maintain the status quo (Fig. 58.2).

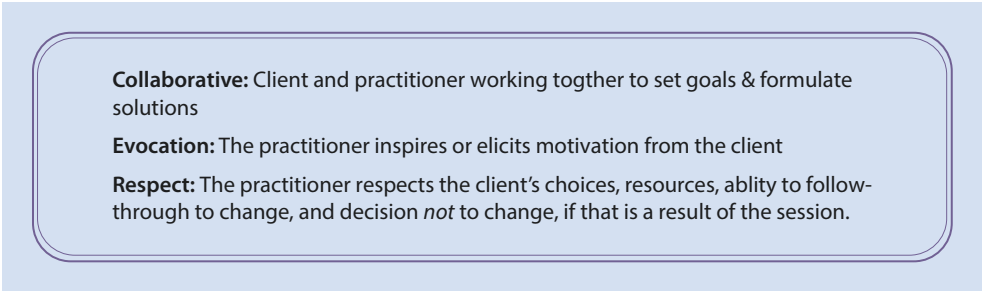
Refer below for reflections as a practitioner when using MI with patients. Start by asking these questions (Fig. 58.3):

1. Who is making the argument for change? Patient? Practitioner? Parent? Child? Spouse? Other?
2. Is the encounter patient-centered?
3. Is the encounter goal-directed?



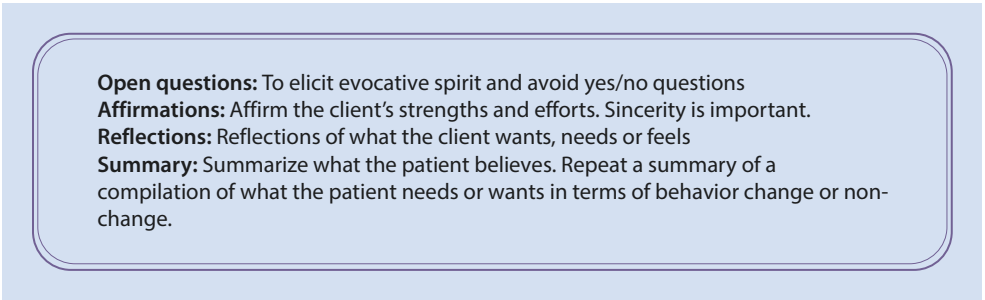
Expressing empathy: Reflective listening
Developing discrepancies: How do client behaviors fit with who the client wants to be?
Rolling with resistance: ↑ resistance, ↓ likely change; validate
Supporting self-efficacy: Bulid confidence and hope

Fig. 58.1 Four principles of motivational interviewing



Collaborative: Client and practitioner working togther to set goals & formulate solutions
Evocation: The practitioner inspires or elicits motivation from the client
Respect: The practitioner respects the client's choices, resources, ablity to follow-through to change, and decision *not* to change, if that is a result of the session.

Fig. 58.2 Motivational interviewing spirit



Open questions: To elicit evocative spirit and avoid yes/no questions
Affirmations: Affirm the client's strengths and efforts. Sincerity is important.
Reflections: Reflections of what the client wants, needs or feels
Summary: Summarize what the patient believes. Repeat a summary of a compilation of what the patient needs or wants in terms of behavior change or non-change.

Fig. 58.3 Skills of motivational interviewing

58.1 The Practitioner (Healthcare Provider)

Does the practitioner:
- Use open questions?
- Practice reflective listening?
- Show the "righting reflex?"
- Fall into the "expert trap?"

58.2 Observing the Client

Does the patient demonstrate ambivalence (the desire to change with the desire to remain the same)?

Do you notice the client using "change talk?"

Change talk:

1. *Desire for change*: What are the patient's desires, preferences, and wishes for change?
2. *Ability to change*: If the patient were to change, what strategies would he or she use to achieve change? How would the patient change?
3. *Reasons for change*: Most predictive of an actual change made by patient/client, e.g., get in shape, reduce risk of disease, for kids, etc.
4. *Need for change*: Visceral/emotional reasons for change. Values-based.

Do you notice the client using:

1. "Commitment language?"
   - Client's statements of commitment to actual change
2. "Sustain talk?"
   - Clients' own arguments or reasons against change or desire for status quo, inability for change

Authorization for the Release of Information

60.1 Diet Diary Instructions

The information you record in your food diary will help you and your health care provider identify patterns in your diet that may correlate to your health condition. This information can help them to design an eating program to meet your special needs (Fig. 60.1).

These instructions will help you get the most out of your food diary. Generally, food diaries are meant to be used for a whole week, but studies have shown that keeping track of

Name :					
Date/Time	Location/ Activity	Food or Beverage Consumed	Amount (cup, etc)	Mood	Symptoms

Was this a typical day for you? Yes No If no, why not:

Reviewed by _____ Date/Time _____

Fig. 60.1 Diet diary

what you eat for even 1 day can help you make changes in your diet.

60.1.1 Date and Time

Write the date and time of day you ate the food.

60.1.2 Food or Beverage Consumed

In this column, write down the type of food you ate or drank. Be as specific as you can. Don't forget to write down "extras," such as butter, oils, salad dressing, mayonnaise, sour cream, sugar, and ketchup. Please include brand names when possible or indicate if an item was homemade.

60.1.3 How Much

In this space indicate the amount of the particular food item you ate. Give your best estimate of the size (2″ x 1″ x 1″), the volume (1/2 cup), the weight (2 ounces), and/or the number of items (12) of that type of food.

60.1.4 Where

Write what room or part of the house you were in when you ate. If you ate in a restaurant, fast-food chain, your desk, or your car, write that location down.

60.1.5 Activity While Eating

In this column, list any activities you were doing while you were eating (e.g., working on the computer, driving, watching TV, sitting at the dinner table).

60.1.6 Mood

How were you feeling while you were eating (e.g., sad, happy, rushed, stressed, bored)?

60.1.7 Symptoms

In this column, make a note of any symptoms (good or bad) you experience throughout the day to help tune into how certain foods make you feel. *Include* bowel/urine habits such as formed stool, loose stool, hard stool, scant urination, or frequent urination; feelings of discomfort such as gas, bloating, heartburn, headaches, brain fog, low energy, or sinus congestion; and feelings of wellness such as increased energy, mental clarity, and/or relief of previous symptoms. Try to correlate the entries as closely as possible with the times listed to the left on the diet diary form.

60.1.7.1 Hints

- Do not change your eating habits while you are keeping your food diary unless your doctor or dietitian has given you specific instructions to do so.
- Tell the truth. Your doctor or dietitian can help only if you record what you really eat.
- Record what you eat on all days your doctor or dietitian recommends.
- Be sure to bring the completed forms back with you to your next appointment.

60.2 Basic Rules to Remember

60.2.1 Write Everything Down

Keep your form with you all day, and do your best to write down everything you eat or drink. A piece of candy, a handful of pretzels, a can of soda pop, or a small donut may not seem like much at the time, but over a week these foods may add up!

60.2.2 Do It Now

Don't depend on your memory at the end of the day. Record your eating as you go.

60.2.3 Be Specific

Make sure you include "extras," such as gravy on your meat or cheese on your vegetables. Do not generalize. For example, record French fries as French fries, not as potatoes.

60.2.4 Estimate Amounts

If you had a piece of cake, estimate the size (2″ × 1″ × 2″) or the weight (3 ounces). If you had a vegetable, record how much you ate (1/4 cup). When eating meat, remember that a 3-ounce cooked portion is about the size of a deck of cards.

If you have any questions, contact your doctor or dietitian (Fig. 60.2).

60.3 Gluten-Free Dairy-Free Guide

I have recommended that you avoid gluten and/or dairy to determine whether one or the other may be affecting your health. Withdrawing these foods is often recommended to:

1. Alleviate any potential stress or inflammation in your body
2. Determine which foods/food groups may be affecting your health

By withdrawing gluten and/or dairy, you may alleviate stress on your whole body and immune system. This dietary plan

Date	Time	Food or Drink: What kind	How much	Where	Activity	Mood	Symptoms
1/3/08	8am	Quaker instant oatmeal made with water	1 cup	Car	Driving to work	Rushed/anxious	Loose bowel at 7am

Fig. 60.2 Sample food diary entry

will help minimize symptoms, promote vitamin and mineral absorption, and generally calm down your immune system and overall decrease inflammation.

Did you know that an estimated 70% of your immune system is associated with your digestive tract? When we consistently consume foods that we are unable to process, our immune system is constantly on high alert. This stress makes our body vulnerable to other illnesses or diseases: depression, anxiety, diabetes, cancer, cardiovascular disease, and others.

With that said, it is important to remain 100% committed to this plan. Keep in mind that you have been eating these foods for 10, 20, 30, and more years. It takes a lot of time (months and *years*) for your body to recover from these offending foods. Since it takes time, patience, and commitment, I suggest you set aside a 5–6-week period that gives you the freedom to prepare or plan meals and/or menus. Depending on the time you have available and your comfort in the kitchen, you may want to prepare meals each night of the week or cook large batches on weekends to eat throughout the week.

Common foods that all clients are asked to eliminate and/or minimize during the trial are caffeine (for certain individuals, 2 cups of green tea or organic coffee daily may be beneficial), alcohol, and added sugars. Plus, the two proteins that are difficult for many bodies to process are gluten and casein. Gluten is a protein formed when water mixes with certain grains (wheat, rye, barley, etc.) and their flours. Casein is a major protein in dairy foods.

For the next _____ **weeks/months**, you will remove gluten and casein as well from your diet. Consuming these "offending foods" can be associated with symptoms including:

- Joint/muscle pain, aches, or twitching
- Fatigue/low energy
- Digestive upset: bloating, gas, diarrhea, constipation, reflux, abdominal pain, etc.
- Headaches/migraines (may be brief or prolonged)
- Sore throat, stuffy nose, runny nose, itchy nose or eyes
- Skin rash or redness
- Lower back pain
- Anemia or low iron levels
- Vitamin/mineral imbalances
- Brain "fog," lack of focus and/or concentration
- Sleepiness, insomnia, fatigue, apathy
- Mood disturbances: irritability, depression, anxiety
- Excitability (feeling hyper or "buzzed")
- Inflammation of any kind

Symptoms associated with the food "reintroduction" or "challenge" period may not be the same symptoms experienced before the food withdrawal trial. For example, before the diet, a person's symptom may be chronic sinus pain. Once the food is reintroduced/challenged, their main symptom may be abdominal pain or diarrhea. This does not mean that the food group being challenged was not causing the sinus pain. It means the body and immune system react differently when the offending agent is removed and then reintroduced.

60.3.1 General Guidelines: What Can I Eat and Drink?

Food withdrawal recommendations are based on an individual assessment which evaluates specific symptoms, lab values, and health recommendations. Food withdrawal and specific nutrition recommendations are necessary to allow the GI tract to heal while providing optimal levels of nutrients to support metabolism, reduce inflammation, and promote healing. The types and amounts of carbohydrates, protein, and fats recommended for each individual will vary based on the individual's GI tract ability to digest and absorb nutrients. For impaired GI tracts, elemental forms of food may be used (simple sugars, amino acids, oils), while a more functional GI tract will allow consumption of whole foods

(fruits, vegetables, meats). Instead of focusing on those foods you *can't* eat, we will focus on those you *can enjoy*! The following is a summary of whole foods, supplemental support, and beverages that you will enjoy during your trial:

60.3.2 Cleansing Beverages

- *Water, mineral water, and green and herbal tea:* Keep a *glass* or *stainless steel* water bottle or other container to keep you supplied with water and clean liquids throughout the day. Water helps deliver nutrients to your cells, and subsequently water helps remove waste and toxins from the body. In other words, drinking water and green or herbal teas helps you take out the body's trash!
- *Organic coffee*: If you tolerate coffee and caffeine, 1–2 cups daily (8 ounces).

60.3.3 Healthy Carbohydrates

- *Guidelines:* Organic, when possible (dirty dozen/clean 15), varied colors, and types.
- *Avoid/minimize:* High-fructose corn syrup, processed/packaged foods, simple sugars, and drinks.
- *Low-starch vegetables:* Should make up 50% of your plate at each meal.
- *Starchy vegetables and fruits:* Sweet potatoes, potatoes, corn, fresh or frozen (not canned) fruit.
- *Beans/legumes:* All dried beans/green/waxed beans.
- Soy may or may not be recommended or tolerated by all people. Thus, ask your dietitian or physician whether or not soy should be consumed.
- Peanuts should be organic.
- *Whole grains:* Quinoa, rice, amaranth, millet, Teff, buckwheat, and others.
- *Nut, seed milks:* Almond, hazelnut, coconut, soy (if tolerated), oat (if tolerated), rice, or other nondairy milks.
- *Supplemental carbohydrates/fiber:* Ground flaxseed, psyllium, modified citrus pectin, oat bran.

60.3.4 Clean Protein

- *Guidelines:* Organic meats, BPA-free canned beans, raw nuts and seeds.
- *Avoid:* High-temperature cooking or grilling, charred meats, improperly stored meats, processed meats, roasted nuts, processed nut butters.
- *Poultry, meat, seafood:* Free-range/organic (if possible) poultry, wild game (bison/buffalo, deer/venison, lamb, etc.), wild Alaskan salmon, protein powders.
- *Eggs:* Pasture-raised, omega-3, and organic eggs are preferable choices.
- *Beans/legumes, lentils:* Plant-based protein.
- *Nuts and seeds:* Plant-based protein.
- *Supplemental protein:* Whey protein powder, amino acid complex, other protein powders.

60.3.5 Balanced Fats and Oils

- *Guidelines:* Organic meats, cold pressed oils, temperature-resistant cooking oils, organic butters.
- *Avoid:* Damaged fats and oils, trans fats (packaged foods), processed butters, fast food.
- *Nuts and seeds:* All peanuts should be organic. Pistachios may or may not be recommended.
- *Fats and oils:* Olive oil, avocado, organic pasture butter, coconut oil. See Fats and Oils Handout, which lists options: Healthy *Omega 9, 6, 3, and beneficial saturated fats*.
- *Supplemental fats and oils:* On an individual basis, MCT oil, fish oil, evening primrose, borage oil, black currant oil.

60.3.6 Preparation

Week 1

1. *Clean the cupboards:* When possible, clear your cupboards and refrigerator of foods that are not "approved" on your particular withdrawal trial. Read labels, and look for added sugars, high-fructose corn syrup, and any of the "red flag" words we discussed.
2. *Shop for foods and stock your pantry:* Make sure that your refrigerator and cupboards are prepared with "approved" items so that you're always able to make a safe choice.
3. *Supplements:* Order any supplements or protein powders recommended by your doctor or dietitian.
4. *Caffeine and your genes:* Individuals with SNP's CYP1A1, CYP1A2, and CYP1B1 should avoid caffeine or consume no caffeine after noon.
5. *Wean off caffeine, if necessary:*
   - Begin on a weekend so you're able to take naps, as needed.
   - For the first 3 days, cut down to 1/2 normal amount of coffee, soda, black tea, or other caffeinated beverages.
   - For the next 4 days, drink 1 cup caffeinated green tea steeped in boiling water for 5 minutes.
   - You may consider taking 1000–2000 mg buffered vitamin C powder (Emergen-C is one brand that would be ok, even though it has added sugar, it would still help you adjust to decreased caffeine intake).
   - Drink a minimum of 6–8 glasses filtered water daily.
6. *Diet diary:* You will need to keep a diet diary for the 3 days prior to reintroduction or "challenge" period and throughout the reintroduction process. This process is time-consuming, but it is very important. You want to make your efforts worth it by noting any symptom changes. This helps determine next steps for continued healing (Tables 60.1 and 60.2).

Table 60.1 Diet snapshot

Yes: These items are gluten—/dairy-free			
Naturally gluten- and dairy-free foods			
Vegetables and fruits			
Beans (lentils, navy, kidney, black beans, garbanzo beans/chickpeas, etc.)			
Nuts/seeds (almonds, walnuts, pecans, cashews, sunflower seeds, etc.)			
Meat, poultry, seafood, eggs			
Gluten-free grains and gluten alternatives (not recommended if grain-free)			
Amaranth	GF oats (may not be	Rice (brown, wild, white)	Tapioca
Arrowroot	recommended for	Rice bran	Teff
Buckwheat	celiac disease)	Sago	
Flax	Millet	Sorghum	
Flours made from nuts,	Organic, non-GMO corn	Soy	
beans, and seeds	Quinoa		
Dairy-free alternatives			
Almond milk[a]	Coconut milk yogurt	Hazelnut milk[a]	Rice milk
Cocoa butter	Daiya (tapioca-based	Hemp seed milk[a]	*So Delicious* brand
Coconut butter and oil	cheese shreds)	100% fruit sorbet	Yogurts, desserts
Coconut milk[a]	Ghee (if guaranteed	Imagine brand soups	Milks
Coconut milk creamer	casein-free)	Oat milk[a]	
For those who avoid dairy, kosher "pareve" products are considered milk-free under kosher dietary law; however, they may contain a very small amount of milk protein. Individuals who have a dairy allergy will want to look closer at the ingredients list for confirmation of safety before consuming the product			
Make sure to read labels. If there is insufficient information on the label to make an informed decision, avoid the food. You can also call food companies to gather manufacturing information			
[a]Preferably unsweetened version			

Condiments: Any condiments made from apple cider vinegar are safe; Heinz and Organicville brand condiments are gluten-free.

Deli meats: Applegate Farms, Boar's Head, and Hormel Naturals are gluten-free.

Cosmetics (shampoos and others): Desert Essence and Burt's Bees are gluten-free

Medications: Celiac Central website (► celiaccentral.org/resources)

- ► http://www.glutenfreedrugs.com/
- Ingredients in medications that may indicate gluten: Wheat, modified starch (source not specified), pregelatinized starch (source not specified), pregelatinized modified starch (source not specified), dextrates (source not specified), dextrimaltose (when barley malt is used), caramel coloring (when barley malt is used), dextrin (source not specified, but usually by corn or potato)

60.3.7 Breakfast Ideas

- *Eggs and greens:* Two omega-3 or organic eggs with 2 cups sautéed greens with onions in vegetable or chicken broth. Drizzle with olive oil after sautéed. Add poached or sliced hard-boiled egg over the greens and season with sea salt, pepper, or other spices as desired.
- *Warm apple cinnamon quinoa:* 1/2 cup cooked quinoa with diced apples, 1/2 teaspoon cinnamon, and 1/4 cup almonds/walnuts or drizzle of natural peanut butter or almond butter.
- *Nutty cereal:* 1 1/2 cups gluten-free cereal with 1 cup unsweetened soy milk or other unsweetened milk alternative, 1/4 cup nuts or 2 tablespoons nut butter (peanut, almond, etc.), 1 tablespoon ground flaxseed.
- *Protein smoothie:* 1 cup unsweetened milk alternative with 1 serving hemp seed protein, RAW protein, or egg protein powder (Jay Robb brand is a staple at Whole

Table 60.2 Possible gluten-containing food items

Caution: These items contain gluten or dairy and must be avoided			
Gluten-containing food items		**Dairy- or casein-containing food items**	
Barley	Matzo flour/meal	Butter	Recaldent®
Barley malt/extract	Pastas (wheat-based)	Cheeses (most, except	Rennet casein
Bran	Panko	some soy brands)	Sherbet

Candy	starch	Lunch meats	
Deli/luncheon meats	Over-the-counter meds	Margarine	
Herbal supplements	Prescription meds	Nisin	
Imitation bacon	Surim	Nougat	
Imitation seafood	Vitamin and mineral	Sausage	
Lotions, body care	supplements	Semisweet chocolate	

Foods), 1 cup frozen or fresh berries, 1 cup fresh spinach or other green or 2–3 stems from leafy greens, 1 tablespoon olive oil or Balance 3-6-9 oil or flaxseed oil (depending on those recommended by your healthcare practitioner); however, you can always default to olive oil, 1/4 avocado, or 1 tablespoon ground flax or flaxseed oil.

- *Breakfast roll-up:* 3.5 ounces leftover fish or chicken wrapped in a gluten-free rice or Teff tortilla filled with 2 tablespoons guacamole and 3 tablespoons salsa. Enjoy with 1 cup fresh fruit such as cubed cantaloupe.
- *Rice cakes or crackers with hummus and a side of chicken sausage or nut butter:* Two rice cakes topped with hummus and 3 ounces leftover meat or gluten-free turkey or chicken sausage (1 link Applegate Farms chicken sausage) or spread with 2 tablespoons almond or organic peanut butter. Serve with a whole grapefruit or 1 cup fresh berries or mixed fruit.

60.3.8 Lunch/Dinner Ideas

- *Hummus and veggies with gluten-free crackers:* 1/4 cup hummus (chickpeas/garbanzo bean garlic dip) or baba ghanouj (same as hummus only with eggplant instead of chickpeas). Dip the fresh vegetables and/or gluten-free crackers. Choose a variety of brightly colored and flavored vegetables: bell peppers, carrots, celery, snap peas, mini-sweet peppers, cucumber, broccoli, cauliflower, zucchini, etc.
- *Lentil tacos with mixed greens:* Sauté onions and garlic and add cooked lentils. Season with Mexican seasoning, lime juice, and a pinch of salt, and serve with a brown rice tortilla or corn tortilla (make sure the corn tortilla is 100% gluten-free – no added wheat).
- *Gluten-free pasta with veggie-boosted sauce and side salad:* Sauté 1/2 to one whole onion (chopped), 1/4 cup zucchini, 2 cloves garlic with 1–2 tablespoons olive oil, a pinch of salt, and Italian seasoning with 3 ounces of chicken. Add 1/2 cup Classico brand (or other brand with no sugar added) marinara sauce and 1/4 cup white, black, or garbanzo beans. Serve over 3/4 cup brown rice, gluten-free pasta. Serve with a side salad.
- *Salmon salad four ways:* Mix canned wild Alaskan salmon (e.g., Bear & Wolf or Kirkland brands from Costco) or chunk light tuna in water mixed with 1–2 tablespoons light mayonnaise or vegenaise, 2 teaspoons lemon or lime juice, 1/4 cup diced grapes or apples, and 1 tablespoon walnuts; season with pepper to taste.
  - Serve over a bed of greens and mixed vegetables.
  - Dip or top gluten-free crackers.
  - Dip with vegetables: carrots, broccoli, cucumber, etc.
- *Salad with herbs:* 2 cups mixed salad greens (romaine, leaf lettuce, spinach, cabbage) and herbs: (basil, cilantro, parsley, mint), top with your favorite chopped vegetables (tomatoes, onions, bell peppers, asparagus, shredded beets, sprouts, broccoli, cauliflower). Add 1/4 cup quinoa or brown rice and 1/2 beans, and sprinkle with raw nuts and 1 tablespoon dried fruit (raisins, cranberries, diced figs, etc.). Dress with a citrus or balsamic vinaigrette or vinegar and extra virgin olive oil. Optional: Top with 2–3 ounces leftover chicken, canned or fresh cooked salmon, or canned chunk-light tuna in water.

60.3.9 Lunch/Dinner Ideas

- Turkey spinach meatloaf with mashed cauliflower
- Gluten- and dairy-free fajita/burrito bowls
- Asian chicken salad
- Italian Tuscan vegetable soup
- Grilled citrus trout crunchy Mediterranean slaw
- Whole roast chicken with sweet apple walnut kale
- Black bean cakes with mango salsa
- Quinoa cabbage soup
- Curry chicken breast with tomato and coconut milk served over brown rice or quinoa
- Chicken salad wraps/roll-ups
- Quick lemon and garlic quinoa salad and spiced collard greens
- Spaghetti squash
- Quick sautéed chicken with sautéed vegetables with cashews
- Ginger peanut or almond chicken with sweet potatoes and snap peas
- Fish tacos with citrus slaw
- Salmon salad
- Quick turkey pasta sauce
- Cumin-crusted salmon and cauliflower rice

60.3.10 Snacks

- Hummus and veggies or gluten-free crackers/chips (Beanitos – bean chips)
- Trail mix
- Hard-boiled eggs
- Apple or pear with almonds/nut butter
- Cinnamon mixed nuts
- Roasted chickpeas
- Quick and easy kale chips
- Chocolate avocado pudding
- Whipped sweet potatoes (Table 60.3)

Table 60.3 Gluten- and dairy-free shopping list

Vegetables				
Artichoke	Carrots	Kohlrabi	Pumpkin	Swiss chard
Asparagus	Cauliflower	Leeks	Radishes	Tomatoes
Avocado	Celery	Mushrooms	Romaine lettuce	Turnips
Beets/beet greens	Collard greens	Mustard greens	Rutabaga	Winter squash
Bell peppers	Cucumber	Okra	Salad greens	Yams
Bok choy	Eggplant	Olives	Snap peas	Yellow squash
Broccoli	Fennel	Onions	Snow peas	Zucchini
Brussels sprouts	Green beans	Parsnips	Spinach	
Cabbage	Kale	Potatoes	Sweet potatoes	
Herbs and spices				
Fresh or dried herbs and spices				
Italian (blends of basil, oregano, marjoram, parsley, thyme, sage, and rosemary)				
Fruits				
Apples	Currants	Lemons	Peaches	Raspberries
Apricots	Dates	Limes	Pears	Strawberries
Bananas	Dried fruits	Mango	Pineapple	Tangerines
Blackberries	Figs	Melons	Plums	Watermelon
Blueberries	Grapes	Nectarines	Pluots	
Cherries	Grapefruit	Oranges	Pomegranate	
Cranberries	Kiwi	Papaya	Prunes	
Dairy alternatives				
Unsweetened almond milk, coconut milk, hemp seed milk, hazelnut milk, etc.				
Daiya tapioca-based cheese shreds				
Meat, fish, poultry, protein				
Fresh or frozen poultry (turkey, chicken, etc.)				
Wild game (deer (venison), elk, duck, buffalo, etc.)				
Grass-fed beef				
Wild Alaskan salmon or other wild Pacific seafood				
Eggs (preferably pasture raised, organic)				
Clean deli meats: Boar's head, Applegate farms deli meats				
Beverages				
Water		Vegetable juice, up to 8–16 oz. daily		
Green, white, and herbal teas (chamomile, peppermint, ginger, tulsi)		Mineral water (still or sparkling) Organic coffee 1–2 cups daily (8 oz. cups)		
Coconut water				
Fats and oils				
Nuts, nut butters, and nut flours (e.g., almond butter, cashew butter, pumpkin butter)				
Organic peanuts and peanut butters				
Extra virgin olive oil				

Table 60.3 (continued)

Vegetables	
Unrefined coconut oil	
Organic, pasture butter Grapeseed oil, flaxseed oil, etc.	
Frozen foods	
Variety of frozen vegetables, fruits (preferably organic)	
Snacks	
Terra brand vegetable chips (sweet potato, taro, yuca, batata, parsnip, and ruby taro)	
Baby carrots, celery sticks or other veggies	
Hummus made with olive oil	
Rice crackers	
Mary's gone crackers brand gluten-free crackers	
Fresh fruit	
Nuts and trail mixes (without yogurt/chocolate-covered pieces)	
Cereals, grains, and beans/legumes	
Amaranth	Brown or white rice
Beans/legumes: Lentils, peanuts, soybeans, black, navy, garbanzo (aka chickpeas), black-eyed peas, great northern, kidney, etc.	Cream of rice Brown rice tortillas Rice crackers
Buckwheat	Rice cakes
Quinoa	La tortilla brand Teff tortillas
Quinoa flakes	Corn
100% buckwheat soba noodles	Corn tortillas
Buckwheat kasha	Polenta
Cream of buckwheat	Millet
Wild rice (not the same as rice)	Tapioca
Enjoy life brand cereals (nutty flax and Rice cereals, GF granolas)	Sorghum Flaxseed
Condiments	
Condiments made with apple cider vinegar	
Vinegars, oils

60.4.3 Book Resources

- These books are full of great ideas and menus. However, the information related to health conditions may or may not be appropriate for all patients as we individualize a plan specific to each patient.
- Take caution when using cured meats or meats with nitrates/nitrites. Opt for organic grass-fed meat if possible.
- Be sure to note other ingredients you may not currently eat (i.e., dairy, soy, grains, eggs, etc.)
- *Well Fed* by Melissa Joulwan
- *Wheat Belly* by William Davis
- *Eating on the Wild Side* by Jo Robinson
- *Practical Paleo* by Diane Sanfilippo
- *Nom Nom Paleo* by Michelle Tam and Henry Fong

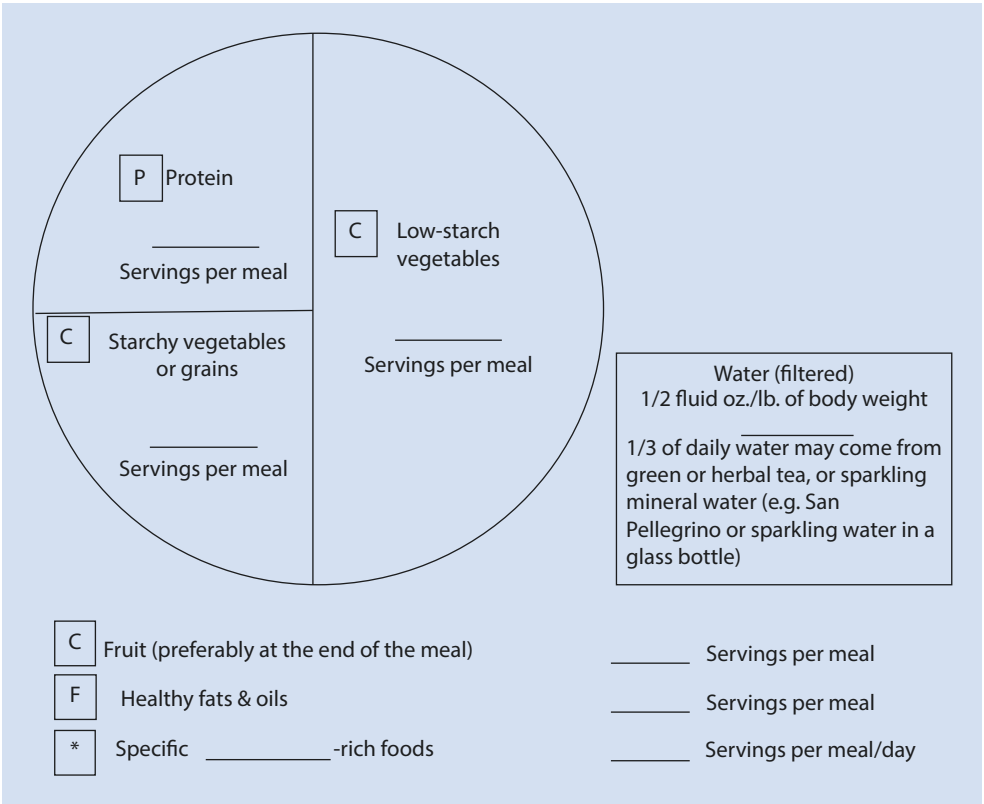
- *The Gluten Connection* by Shari Lieberman

60.4.4 The Plate: Meal Guide

This meal guide will help you build a meal. The ultimate goal is for you to meet your nutritional and health needs with real, *whole* foods. If your body is accustomed to eating more convenience, processed, or packaged foods, with time, your body will begin to crave these whole foods your body *needs to live*. Eventually, you will be able to listen to your body's cravings and signals of hunger or fullness to decide when and how much to eat.

Please refer to handouts below for P (protein), C (carbohydrate), and F (fats and oils). If you need to avoid dairy foods (casein), please eat two servings daily of the calcium-rich dairy-free foods (see ◘ Fig. 60.3).

60



P Protein
_____
Servings per meal
C Low-starch vegetables
_____
Servings per meal
C Starchy vegetables or grains
_____
Servings per meal
Water (filtered)
1/2 fluid oz./lb. of body weight
_____
1/3 of daily water may come from green or herbal tea, or sparkling mineral water (e.g. San Pellegrino or sparkling water in a glass bottle)
C Fruit (preferably at the end of the meal)
_____ Servings per meal
F Healthy fats & oils
_____ Servings per meal
* Specific _____-rich foods
_____ Servings per meal/day

◘ **Fig. 60.3** The Plate guide is the first page of a 4 page guide to helps patients build a healthy and balanced meal that includes protein, complex carbohydrates and healthy fats and oils. There is an astrisk section to include any specific nutrient-dense foods that the patient should try to include in their regular diet. This can be personalized for each patient by filling in the blanks for their specific needs

60.5 Protein Guide

60.5.1 Why Are Proteins Important? (Table 60.4)

Table 60.4 Protein guide

Proteins make up healthy cell membranes	Proteins are a major part of muscle tissue	
Proteins provide energy	Proteins supply essential amino acids our body cannot make	
Proteins support immune defense	Some hormones/chemical messengers are proteins	
Bile salts contain proteins needed for nutrient absorption and detoxification	Enzymes are proteins required proper metabolism	
****include protein with every meal and start your meals with two bites of protein****		
Plant-based protein	**Example**	**#Servings**
Grains and beans Canned, dry, frozen Organic when possible Look for BPA-free cans	GF grains: Quinoa, rice, amaranth, Teff, buckwheat, millet Legumes/beans: Kidney, black, lima, navy, pinto, white, lentils, green peas, black-eyed peas, split peas, etc. Soy beans and soy products: Soy beans, tofu, tempeh, soy milk Vegetable protein powders	
Seeds and seed butters Raw, unsalted, preferable sealed, and refrigerated	Seeds: Pumpkin seeds, sesame seeds, sunflower seeds, chia seeds, flaxseeds Seed butters: Sesame tahini	
Nuts and nut butters Raw, unsalted, preferable sealed, and refrigerated	Nuts: Almonds, cashews, hazelnuts, peanuts, pecans, pistachios, walnuts, macadamia nuts Nut butters: Peanut, almond, and cashew butters Excluding peanut butter, nuts are not a primary protein source	

Table 60.4 (continued)

Clean animal protein	**Example**	**#Servings**
Lean red meat Organic, free range/grass-fed	Beef: Medallions, filet mignon, steaks – Flank, skirt, top round Pork: Tenderloin Lamb and game meats: Lamb shoulder and shoulder steak, bison	
Poultry Lean, organic, free range	Lean cuts include the breast and dark meat Chicken, duck, goose, Turkey	
Fish/seafood Fresh, cold water	Wild-caught, northern Pacific fish and seafood Sardines and anchovies Scallops, mussels, oysters	
Egg white Organic, free-range Omega-3-rich eggs	Chicken eggs, duck eggs purchase locally where possible	
Organic dairy Grass-fed, GMO-, pesticide-, hormone-, and antibiotic-free	Milk, cheese, yogurt, cream, butter, cottage cheese, cream cheese, sour cream, ice cream Purchase locally where possible	
Type of protein	**Serving size estimate**	**Protein grams**
Grains	1/2 cup	6 grams
Beans and lentils	3/4 —1 cup	7 grams
Whole egg/egg white	2 each	12 grams/ 8 grams
Meat, poultry, seafood	3–6 ounces	7 grams/ ounce
Seeds/peanut butter	3/4 cup/2 tbsp.	8 grams
Protein powders	Variable	10–15 grams per ~2 tablespoons

60.6 Carbohydrate Guide

60.6.1 Why Are Carbohydrates Important?

- Complex carbohydrates (carbs) are the body's primary energy source and preferred source for the brain and nervous system.
- Complex carbs provide essential vitamins and minerals needed for good health.
- Complex carbs contain many phytonutrients ("Phyto" = plant, nutrients) known to help our bodies remove toxins, fight infection, and prevent disease.
- Complex carbs provide fiber and bulk to our diet, promoting satiety and healthy digestion.
- Complex carbs help remove toxins, slow absorption, and promote colon health.
- Choose mostly complex carbs: Low-starchy vegetables (raw, fermented, steamed, sautéed, boiled, pureed) (Table 60.5).

Table 60.5 Carbohydrate guide

Carbohydrate category	Example	#Servings
Low-starchy vegetables		
Organic, fresh, local – When possible Fresh, raw, cooked, frozen (when cooking add oil/fats just before serving)	Artichoke, asparagus, baby corn, bamboo shoots, bean sprouts, beets, broccoli, Brussels sprouts, cabbage, carrot, cauliflower, celery[a], cucumber, greens[a] (collard, kale, mustard, turnip, kohlrabi, lettuce[a]), leeks, mushrooms, okra, onions, pea pods, rhubarb, radish, rutabaga, sauerkraut, spinach[a], summer and spaghetti squash, sugar snap peas, Swiss chard, turnips, water chestnuts Nightshades: Tomatoes, sweet and hot peppers[a], eggplant, tomatillos, pepinos, pimentos, paprika, cayenne peppers	
Starchy vegetables		
Organic, fresh, local – When possible Fresh, raw, cooked, frozen These can fill 1/4 of your plate	Beans/lentils: Garbanzo beans, kidney beans, black beans, lentils, lima beans, navy beans, pinto beans, white beans Peas: Black-eyed peas, green peas, split peas, chickpeas, parsnips, plantains, sweet potatoes, taro, yams, pumpkin, squash Nightshades: Potatoes[a]	
Starchy grains		
Organic, non-GMO These can fill 1/4 of your plate	Rice: Wild, brown, long grain, basmati, arborio Quinoa, amaranth, Teff, buckwheat, millet, corn, oats **Avoid, if gluten-free:** Wheat, barley, rye, spelt	
Fruit		
Organic, fresh, local Eat with meals Fresh, dried, frozen	Grapefruit, apples[a], apricots, blueberries[a], pears, plums, strawberries[a], oranges, nectarines[a], peaches[a], pineapple, grapes[a], bananas, kiwi, papaya, figs, raisins, cantaloupe, watermelon	
Carbs and sweeteners to avoid	High-fructose corn syrup Artificial sweeteners: Splenda, equal, sweet'N low (sucralose, aspartame, saccharin, acesulfame, etc.) Avoid processed, packaged carbohydrates Limit 100% fruit juices to 3–4 ounces and only with meals Avoid sugar-sweetened drinks	
Type of carbohydrate		**Serving size estimate**
Low-starchy vegetables, spaghetti squash		1 cup or 2 cups lettuces
Starchy vegetables and grains		1/2 cup or 1 small potato
Fruit (apple, orange, melon, berries)		1 small or 1/2 cup

[a]Organic when possible

60.7 Fat/Oil Guide

60.7.1 Why Are Fats and Oils Important? (Table 60.6)

Table 60.6 Fats and oils guide

Fats provide energy	Fats make up a large portion of our brain and nervous system	
Fats build healthy cell membranes	Dietary fats supply essential fatty acids our body cannot make	
Fats make hormones	Fats make bile salts for nutrient absorption and detoxification	
Fats help absorb fat soluble vitamins	Fats insulate, protect, and cushion our organs	
Fat or oil category	**Example**	**#Servings**
Omega-9s Oleic fatty acids *Stabilizers* ~50% daily fat calories	Raw nuts and seeds: Almonds, cashews, peanuts, sesame seeds Walnuts, macadamia nuts, pine nuts Peanut butter (natural, oil on top), almond butter Tahini (sesame seed butter), olives Almond oil, olive oil, avocado, hummus	
Omega-6s Linoleic acid *Controllers* ~30% daily fat calories	Eggs (whole, organic) Meats (commercial, grass-fed) Raw nuts and seeds: Brazil nuts, pecans, hazelnuts, filberts, walnuts, hemp seeds, sunflower seeds, pumpkin seeds Oils: Evening primrose, black currant, borage, hemp, grapeseed	
Omega-3s Alpha-linolenic acid *Fluidity/ communicators* ~10% daily fat calories	Fish oil (high DHA or EPA), 3-6-9 balanced or DHA oils Fish (salmon/fin-fish), fish (shellfish) Flaxseeds (ground/meal), chia seeds Flax oil Algae	
Beneficial saturated fats SCT and MCT *Structure* ~10% daily fat calories	Butter (organic, pasture), ghee (clarified butter – Indian cuisine) Dairy (preferably organic, raw) Meats (preferably grass-fed) wild game, poultry (preferably organic) Coconut oil and butter, MCT oil (medium-chain triglyceride) Eggs (whole, organic)	
Fats to avoid Trans fats and damaged LCFA *Stressors* <5% daily fat calories	Most packaged foods and fast foods Margarine, vegetable oils (corn, sunflower, canola), mayonnaise (commercial), hydrogenated oil (as an ingredient), "imitation" cheeses tempura, doughnuts (fried), deep-fried foods, chips, regular salad dressing, peanut butter (Jif, Skippy, etc.), roasted nuts/seeds, dairy substitutes (not including almond, coconut milk, etc.) Avoid acrylamides formed with high-temperature cooking – browning during grilling, baking, frying, or deep-frying will produce acrylamide	Zero (less than 5%)
Type of fat or oil		**Serving size estimate**
Hummus		1/3 cup
Nuts, seeds, ground flaxseeds, olives		1/4 cup
Nut butters (peanut butter, almond butter, cashew, coconut butter, etc.)		2 tablespoons
Oils (olive oil, almond oil, avocado oil, etc.)		1 tablespoon
Butter or ghee (clarified butter – Indian cuisine)		1 teaspoon
Eggs		2 each
Fatty ocean fish, meat, poultry		3–4 ounces
Avocado		1/2 avocado

Supplementary Information

Glossary

AMI Any mental illness – a mental, behavioral, or emotional disorder (excluding developmental and substance use disorders)

Behavioral health nutrition An umbrella term incorporating conditions with altered, mental, and intellectual states that may be influenced by nutrients or nutritional status.

BDNF gene The BDNF gene provides instructions for making a protein found in the brain and spinal cord called brain-derived neurotrophic factor. This protein promotes the survival of nerve cells (neurons) by playing a role in the growth, maturation (differentiation), and maintenance of these cells. In the brain, the BDNF protein is active at the connections between nerve cells (synapses), where cell-to-cell communication occurs. The synapses can change and adapt over time in response to experience, a characteristic called synaptic plasticity. The BDNF protein helps regulate synaptic plasticity, which is important for learning and memory. The BDNF protein is found in regions of the brain that control eating, drinking, and body weight; the protein likely contributes to the management of these functions [1].

Bioflavonoid A plant pigment responsible for the colors found in fruits and vegetables that has antioxidant properties beneficial to humans. Bioflavonoids include flavonols (quercetin), favanones (hesperetin), isoflavones (genistein), and anthocyanidin (cyanidin) [2].

Body composition An individual's body percentage of fat, bone, muscle, and intra/extracellular hydration. Chronic disease expression of altered body fat distribution is an important consideration in body composition and usually measured as waist circumference, waist-to-hip ratio, and waist-to-height ratio.

Chromatin The matter of chromosomes, includes DNA and all the factors physically associated with it: small chemical groups covalently attached to DNA (e.g., methyl groups), bound histone and nonhistone proteins, and associated RNA molecules [3].

Chromosomes Chromosomes are thread-like molecules that carry hereditary information for everything from height to eye color. They are made of protein and one molecule of DNA, which contains an organism's genetic instructions, passed down from parents [4].

CNS Central nervous system

Cytokine metabolism Cytokines are four families of mostly lymphoid cells: interleukins (ILs), tumor necrosis factors (TNFs), interferons (IFNs), colony stimulating factors (CSFs). Cytokines are produced in response to immunological challenges from nutritional deficiency, infection, genotype, toxic influences, stress, and/or physical injury. Chronic inflammatory cytokine production contributes to all chronic disease.

DHA Docosahexaenoic acid – 20 C; N-3 fatty acid; plays a role in membrane structure. DHA is present in large amounts in neuron membrane phospholipids, a structural component of the human brain, cerebral cortex, skin, sperm, testicles, and retina.

Eicosanoid Arachidonic acid (AA) and eicosapentaenoic acid (EPA) serve as precursors for the synthesis of eicosanoids (prostaglandins, prostacyclins, leukotrienes, and thromboxanes) which have an anti-inflammatory effect.

Energy dysfunction Mitochondrial energy metabolism, dietary intake and output, effect on body composition, physical activity, and influence of stress on blood glucose/insulin/hormonal energy relationships.

EPA Eicosapentaenoic acid – 22 C; N-3 fatty acid; plays a role in membrane function; Can be synthesized from alpha linolenic acid (ALA), although not efficiently (<5%)

Epigenetics Epigenetics is the study of heritable changes in gene expression (active versus inactive genes) that does not involve changes to the underlying DNA sequence – a change in phenotype without a change in genotype – which, in turn, affects how cells read the genes. Epigenetics affects how genes are read by cells and subsequently how they produce proteins [5]. Epigenetics is the reason why a skin cell looks different from a brain cell or a muscle cell. All three cells contain the same DNA, but their genes are expressed differently (turned "on" or "off"), which creates the different cell types [4].

Environmental influences that control gene activity within a cell without changing the gene structure [6]. Each gene has the capability of about 40,000 different expressions depending on the environmental messaging. Epigenetic effects can be passed on from generation to generation. The discovery of epigenetics has revealed a nongenetic mode of inheritance that influences our health. The most vulnerable periods in the lifespan for epigenetic changes are in utero/pregnancy, early childhood, teenage years, menopause (female), and andropause (male).

Epigenetics control genes Certain circumstances in life can cause genes to be silenced or expressed over time. In other words, they can be turned off (becoming dormant) or turned on (becoming active) [5]. The control of gene expression is the result of the *epigenetic marks* on the genetic material of that cell and termed the epigenetic signature of that cell type. The genome does not change; it is the expression that changes [7].

Epigenetic inheritance Occurs when phenotypic variations that do not stem from variations in DNA base sequences are transmitted to subsequent generations of cells or organisms [3]. The transmittance of information from one generation of an organism to the next (e.g., parent-child transmittance) that affects the traits of offspring without alteration of the primary structure of DNA (i.e., the sequence of nucleotides) [8].

Epigenome The total of all the epigenetic markings in a cell type [7]. The *epigenome* is a multitude of chemical compounds that can tell the *genome* what to do [9]. The epigenome consists of chemical compounds that modify, or mark, the genome in a way that tells it what to do, where to do it, and when to do it. Different cells have different epigenetic marks. These epigenetic marks, which are not part of the DNA itself, can be passed on from cell to cell as cells divide and from one generation to the next [9].

Eugenics The study of or belief in the possibility of improving the qualities of the human species or a human population, especially by such means as discouraging reproduction by persons having genetic defects or presumed to have inheritable undesirable traits (negative eugenics) or encouraging reproduction by persons presumed to have inheritable desirable traits (positive eugenics) [10].

GALT Gut-associated lymphatic tissue. Bacterial colonization of the gut is essential for proper development of the GALT. Polysaccharides produced by bacteria activate T-cell-dependent immune response, specifically CD4 T cells, B cells, immunoglobulins, balance of TH1, TH2, TH17 cells, etc.

Germline The cellular lineage of a sexually reproducing organism from which eggs and sperm are derived; the genetic material contained in this cellular lineage which can be passed to the next generation [11].

Gluconeogenesis During low-carbohydrate intake or starvation, protein is used as de novo synthesis of glucose [12]. Gluconeogenesis is about 60% efficient in ATP production.

Glycolysis Anaerobic pathway to release glucose without the presence of oxygen; lactic acid is the end product [13]. Glycolysis is about 30% efficient in ATP production.

Gut-immune system It is comprised of GALT, MALT, TLR, microbes, PANTH cells, and organs of the digestive system which can be triggered by environmental factors such as stress, drugs, infection, LPS, etc.

Histones Proteins that DNA wraps around. (Without histones, DNA would be too long to fit inside cells.) If histones squeeze DNA tightly, the DNA cannot be "read" by the cell. Modifications that relax the histones can make the DNA accessible to proteins that "read" genes [4].

HUFA Highly unsaturated fatty acids – include N-3 and N-6 fatty acids, EPA and DHA

I-D-U Dietetic and integrative medicine nutritional assessment heuristic of an individual's nutrition status including intake, digestion and utilization of nutrients.

Ketosis To maintain metabolic homeostasis, ketone metabolism is the most energetically efficient metabolic fuel to synthesize glucose using fatty acids and ketone bodies under periods of prolonged food restriction or low-carb/high-fat dietary regimen.

Lack of sleep Underlying deregulation of neurotransmitters and hormones that help flip the on-off switch between waking and sleep. Lack of sleep quality and duration disturbs the 24-hour circadian rhythm and management of wake-time energy. Lack of sleep associations are allergies, central adiposity, diabetes, hypertension, heart disease, and other physical ailments [14].

Lifestyle and community Most chronic disease often has a social basis as well as a biological basis. An individual's social network can influence their health and alter gene expression [15]. An individual is more likely to be healthy if they are a part of a community that supports a healthy diet, lifestyle, and emotional environment.

Lifestyle medicine An approach to decreasing disease risk and illness burden by utilizing lifestyle interventions. The practice of medicine that extends beyond primary prevention, to modifying existing risk factors that cause disease, and rehabilitation from the disease and prevention of recurrence [16].

Long latency nutritional insufficiencies The presumption has been that if the intake of the nutrient is sufficient to prevent the expression of the index disease (i.e., iodine and goiter, vitamin D and rickets, etc.), then the nutrient intake is sufficient for the entire organism. But a nutrient deficiency could have long-term consequences and contribute to chronic disease, either by a similar mechanism to that inducing the index disease or by an entirely different mechanism [17].

MALT The mucosal-associated lymphoid tissue in the mucosal lining of the digestive lumen.

MAPDOM Within the "U" of the I-D-U assessment heuristic, the MAPDOM acronym represents the six most important nutritional categories determining an individual's health. MAPDOM stands for: minerals, antioxidants, proteins, D-fat-soluble vitamins (D, E, A, K), oils/fats, and methylation nutrition.

Methylation The addition of a methyl (CH_3) group from S-adenosylmethionine to a cytosine nucleotide or lysine or arginine residue [5]. The addition of a methyl group, or a "chemical cap," to part of the DNA molecule, which prevents certain genes from being expressed [4].

DNA hypomethylation refers to the loss of the methyl group in the 5-methyl cytosine nucleotide. Methylation is a natural modification of DNA and mainly affects the cytosine base (C) when it is followed by a guanosine (G) in mammals (methylation) [19].

Hypermethylation is an increase in the epigenetic methylation of cytosine and adenosine residues in DNA [20].

Methylation Denotes the addition of a methyl group to a substrate for the substation of an atom or group by a methyl group (-CH3). Can be involved in modification of heavy metals, regulation of gene expression, and regulation of protein function and RNA metabolism [18]. Primary nutrients involved as cofactors in methylation metabolism are B6, B12, folate, B2, zinc, and magnesium.

MET minute A metabolic equivalent of a task. It is a physiological measure expressing the energy cost of physical activities. One MET is the energy equivalent expended by an individual while seated at rest. The MET equivalent is the energy expended compared to rest, so MET values indicate the intensity. An activity with a MET value of 5 means five times the energy is being expended than would be at rest. MET minutes is the time engaged in an activity with consideration to the number of METs [21].

Microbiome The collection of microbes in our digestive system which includes bacteria, fungi, viruses, and parasites.

Nutraceutical *Derived* from *nutrition* and *pharmaceutical*, broadly a food or part of a food that provides medical or health benefits, including disease treatment and prevention.

Nutraceuticals range from specific nutrients to dietary supplements, herbal products, and processed foods and include beta-carotene, fish oil, garlic, green tea, oat bran, olive oil, and various herbs. Sometimes called functional foods. Also, "standardized pharmaceutical-grade nutrients, known as nutraceuticals"

Nutritional triage theory When the availability of a micronutrient is inadequate, metabolic resources will ensure that functions needed for short-term survival are protected at the expense of functions whose lack of a micronutrient only has long-term consequences [22].

Petrochemicals Derived from petroleum or natural gas (ethane, propane, butane, and other hydrocarbons), petrochemicals are used to manufacture artificial products including plastic, medicine, medical devices, cosmetics, furniture, cars, and computers [23]. Humans can ingest phytochemicals or it can be absorbed through the skin. When they accumulate in tissues and organs, they are responsible for brain, nerve, and liver damage, birth defects, cancer, asthma, hormonal disorders, and allergies.

Plasticity The adaptability of an organism to changes in its environment or differences between its various habitats [24].

Prebiotic A substrate that is selectively utilized by host microorganisms conferring a health benefit.

Probiotic A live microorganism that, when administered in adequate amounts, confers a health benefit on the host.

Secretory IgA Protective antibody which comprises 80% of the gut antibodies and is primarily in the gut lumen. It is the earliest of the antibodies to respond to an immune trigger.

SMI *Serious mental illness* – is defined as a mental disorder with serious functional impairment which substantially interferes with or limits one or more major life activities.

Suboptimal The negative effects of levels of consumption that lie above the minimum, but under the optimal level of consumption for these vitamins.

Telomeres Caps at the end of each strand of DNA that protect chromosomes, like the plastic tips at the end of shoelaces. Telomeres determine how cells age. Without the caps, telomeres become frayed until they can no longer do their job, DNA strands become damaged, and cells can't do their job [25].

TLR Toll-like receptor.

Toxic heavy metals Metals and metal compounds that have a negative effect on human health by building up in biological system [26]. They include arsenic, beryllium, cadmium, hexavalent chromium, lead, and mercury. Other toxic metals may include essential metals if imbalanced (zinc and copper), medicinal metals (platinum and bismuth), metals in emerging technology (indium and uranium), toxic metalloids (arsenic and antimony) and certain nonmetallic elements if imbalanced (selenium and iodine) [27].

Transgenerational epigenetic inheritance is the transmittance of information (epigenetic marks such as DNA methylation, histone modifications) from one generation of an organism to the next (e.g., parent-child transmittance) that affects the traits of offspring without alteration of the primary structure of DNA (i.e., the sequence of nucleotides) [28].
